An example of how the hemispherical projection is used in rock block stability analysis is given by the case of a rock slope containing a wedge of rock that is delineated by two fracture surfaces, as shown in Figure 13. This figure also shows how the stability of this wedge is a function of the friction angle of the fractures and three angles that relate to the geometry of the fractures. These latter three angles can be measured directly and quickly from the hemispherical projection. Further simplification of this analysis is possible by ignoring the stabilizing effect of the wedge factor, i.e., the quotient $\sin\beta/\sin 1/2\xi$. This leads to kinematic analyses, in which only the feasibility of instability, given the interaction between the fracture and excavation geometry, is considered.

Kinematic analyses test for whether the geometry of the fractures and the excavation surface are capable of defining blocks that can be released into

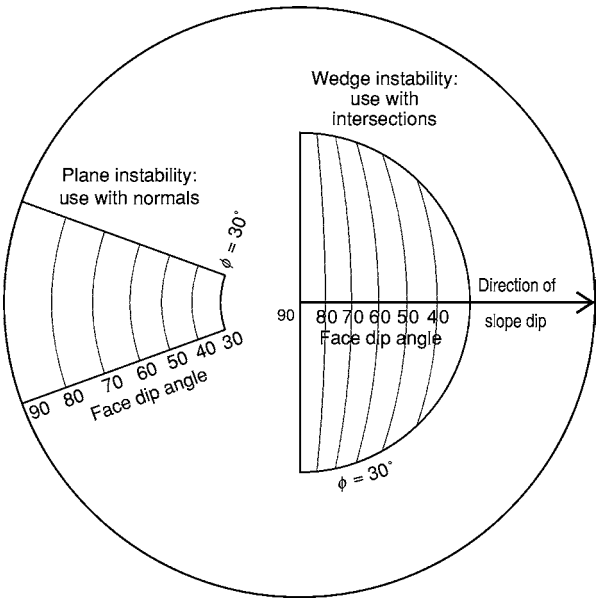

Figure 14 Example of kinematic assessment overlay for rock slope instability due to plane and wedge sliding.

the excavation, and therefore may be unstable. Again, for no external forces and fractures possessing only frictional strength, the kinematic criteria relate to orientations only, with the result that, once more, the hemispherical projection can be used rapidly to assess stability. Figure 14 shows an overlay that can be used for assessing instability due to plane and wedge sliding in a rock mass for which the friction angle is 30°. To use this overlay, the fracture data (both poles and great circles) are plotted on a sheet of tracing paper and placed on a hemispherical projection net, with a second sheet of tracing paper on which the assessment overlay is drawn placed over the top. The overlay is then rotated to identify those slope orientations that give rise to either poles or intersections falling within the unstable zones. Because the overlay also shows various slope angles, it can quickly be used to select a slope angle that avoids the kinematic conditions leading to instability.

A similar analysis can be undertaken for underground excavations. Figure 15 shows three hemispherical projections illustrating the unstable kinematic conditions that apply to a tetrahedral block formed by three fractures and the horizontal roof to a tunnel or cavern. These blocks are identified on the projection as areas bounded by three great circles. If the vertical direction (i.e., the centre of the projection) lies within the projection of the block, this indicates that the block is able to fall. In the case of sliding instability, the direction of sliding is the steepest of either a line of maximum dip or the intersection of two planes. For blocks that are identified as being

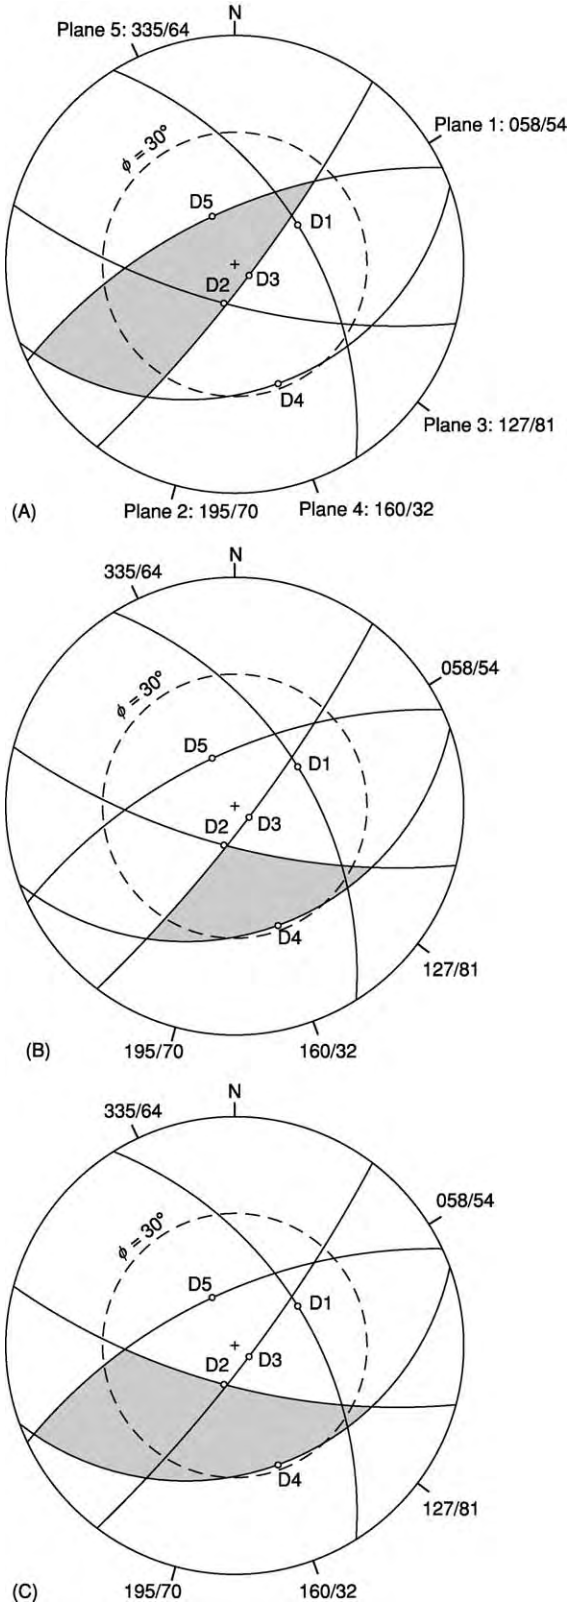

Figure 15 Identification of falling, sliding, and stable blocks in the roof of an underground excavation. (A) Block 345 falls verti cally. (B) Block 234 slides on the intersection of planes 2 and 3. (C) Block 245 slides on the line of maximum dip of plane 2.

unstable, a further rigorous equilibrium analysis can be undertaken in order to determine their size and hence support requirements. These analyses can be time consuming and prone to error if undertaken by hand, and so are usually performed by computer programs.

Another form of kinematic analysis that is widely used is the so-called ϕ_j theory. This uses the principle that, if shearing along a fracture is to be avoided, the direction of action of the major principal stress acting on the fracture must lie within an angle ϕ_j, the friction angle, of the normal to the fracture. Now, close to an underground excavation the major principal stress is tangential to the boundary. This means that a geometric analysis can be used to identify those zones on the boundary where the orientation of the major principal stress is such as to induce shearing. This is illustrated in Figure 16, for the case of a rock mass that contains one dominant set of fractures, and hence can be assumed to be transversely isotropic.

Techniques for the analysis of foundations on fractured rock are not as straightforward as for slopes or underground excavations. However, with most engineering structures it is possible to use foundations that are sufficiently large as to impose stresses that are small enough to prevent instability from occurring. If it can be assumed that the rock beneath the foundation is continuous, then the induced stresses may be determined using analytical solutions developed from the theory of elasticity. This approach is widely used in soil mechanics, wherein the assumption of a continuum is often valid, but it is seldom used in rock mechanics for the reason that most near-surface rock masses are fractured. However, the concept of 'bulbs of pressure', or contours of major principal stress, from these analyses is useful in rock mechanics. As the ϕ_j theory shows, as the direction of action of the major principal stress is constrained by the presence of a fracture, the shape of the resulting stress contours is controlled by the fracture geometry. Figure 17 shows a simplified solution for the radial stress that is applicable to the case of rocks that contain one dominant set of fractures, and so can be assumed to be transversely isotropic. The contours of major principal stress are influenced strongly by the fracture geometry, showing that foundations on rock can induce high stresses in zones far removed from the foundation.

Engineering in Continuous Rock

For underground excavations in continuous rock, or in locations where the *in situ* stresses are sufficiently high as to allow a fractured rock to act as if it were continuous, it is the stress induced around the excavation that leads to instability. Simple analytical solutions for the induced stresses are available for only a restricted set of excavation geometries, namely, circular and elliptical openings that are in a state of plane strain. This last constraint requires the excavations to be long, of constant cross-section, and with

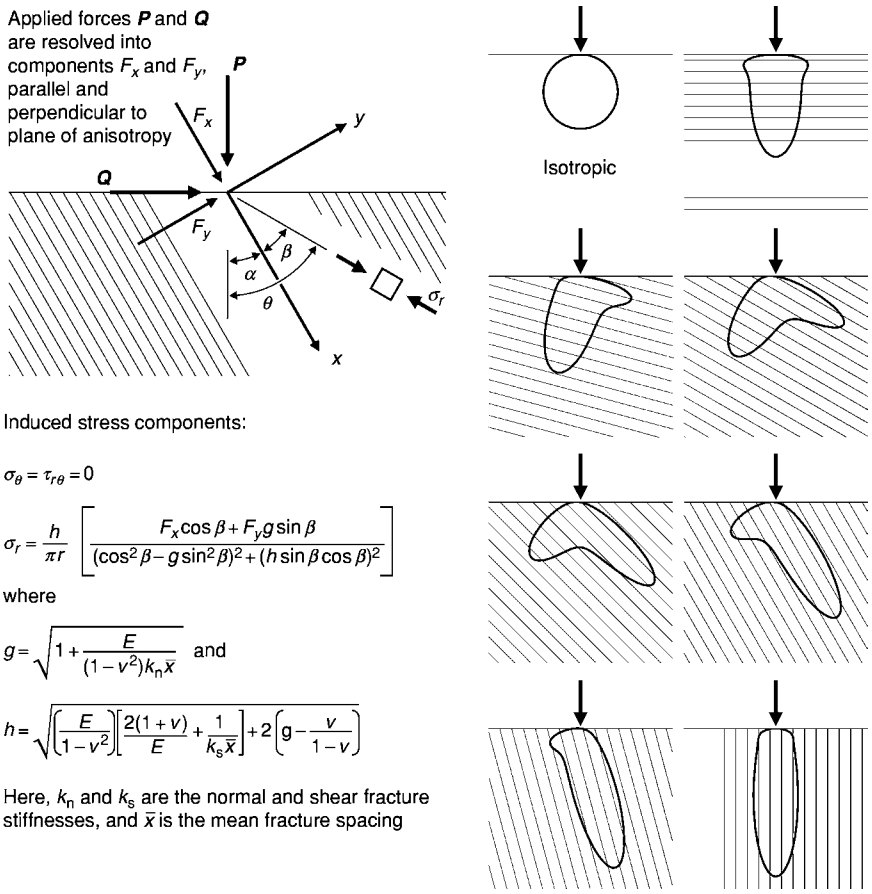

Figure 17 Simplified relations for contours of constant radial stress for a foundation in stratified material resembling a transversely isotropic rock.

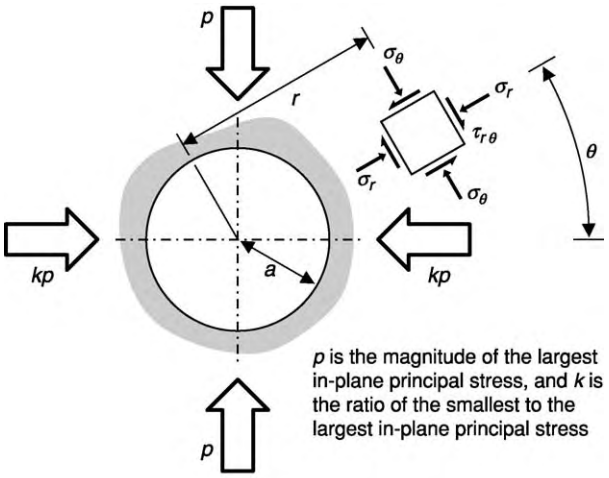
their axial direction parallel to one of the *in situ* principal stresses. Despite these severe restrictions on geometry, the fact that engineers are commonly required rapidly to assess the stability of underground excavations means that these solutions are used extensively.

Figure 18 shows a cross-section through a circular opening and presents the well-known Kirsch equations for the induced-stress components. These equations are used for many applications involving the analysis of stress around tunnels, wellbores, and mine shafts. As an example, Figure 18 also shows simplified relations for the specific case of the maximum and minimum values of tangential stress induced at the boundary of an excavation, and how these components vary as the *in situ* stress ratio varies. The figure shows how the maximum and minimum stresses are induced under uniaxial conditions, represented by $k = 0$, and that for isotropic conditions, represented by $k = 1$, the induced stress is constant around the boundary.

For the cases of stress induced around an elliptical excavation, a particularly elegant solution is available for the tangential stress induced at the boundary. This is shown in Figure 19. Also, for the particular case of an elliptical opening with a horizontal major axis, the extreme boundary stresses, which are induced in the side walls, roof, and floor, are also given. These final two equations can be equated, and doing so shows that the tangential stress is constant around the boundary in the case of an elliptical opening that has an aspect ratio equal to the *in situ* stress ratio. This elegant result is a valuable design guide for engineers wishing to minimize the range of stresses induced around the boundary of an excavation.

Numerical Analysis

With all of the fundamental analyses that are routinely used in rock mechanics and rock engineering, various simplifying assumptions are required in order to make the problem tractable. These simplified procedures are perfectly acceptable for the majority of applications, but for applications requiring an accurate understanding of the behaviour of a structure, more complex analyses are necessary. These are performed using computer programs that implement sophisticated numerical techniques. The techniques most often used in rock mechanics are finite element, boundary element, and finite difference methods for continua, and various discrete element methods



$$\sigma_r = \frac{p}{2}\left[(1+k)\left(1-\frac{a^2}{r^2}\right)-(1-k)\left(1-4\frac{a^2}{r^2}+3\frac{a^4}{r^4}\right)\cos 2\theta\right]$$

$$\sigma_\theta = \frac{p}{2}\left[(1+k)\left(1+\frac{a^2}{r^2}\right)+(1-k)\left(1+3\frac{a^4}{r^4}\right)\cos 2\theta\right]$$

$$\tau_{r\theta} = \frac{p}{2}\left[(1-k)\left(1+2\frac{a^2}{r^2}-3\frac{a^4}{r^4}\right)\sin 2\theta\right]$$

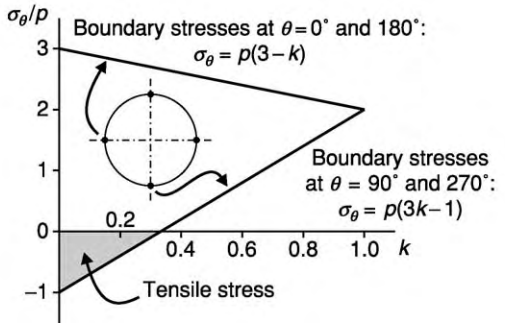


Figure 18 The Kirsch solution for stresses around a circular opening in isotropic continuous rock, under conditions of plane strain.

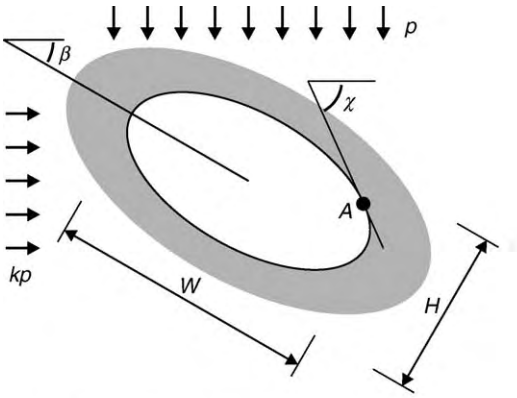


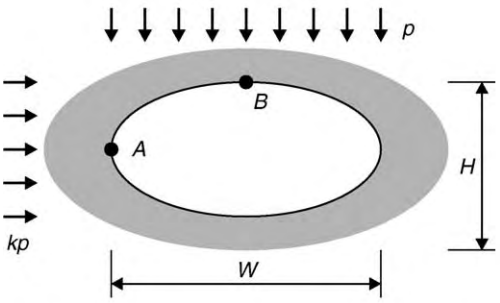
Boundary stress at point A:

$$\sigma_\theta = \frac{p}{2q}\left\{(1+k)\left[(1+q^2)+(1-q^2)\cos 2(\chi-\beta)\right]\right.$$

$$\left.-(1-k)\left[(1+q^2)\cos 2\chi+(1-q^2)\cos 2\beta\right]\right\}$$

where $q = W/H$,

p is the magnitude of the largest in-plane principal stress, and k is the ratio of the smallest to the largest in-plane principal stress



Extreme boundary stresses:

$$\sigma_A = p(1-k+2q)$$

$$\sigma_B = p\left(k-1+\frac{2k}{q}\right)$$

Figure 19 Simplified relations for the tangential stress at the boundary of an elliptical opening in isotropic continuous rock, under conditions of plane strain.

for discontinua. The background theory to these methods is complex, and their use is not straightforward. However, they are able to produce models and simulations of great accuracy and detail, and as researchers continue to implement new developments, the results obtained using them become ever more realistic. There is no doubt that the use of such procedures will become more widespread in the future.

ROCKS AND THEIR CLASSIFICATION

R C Selley, Imperial College London, London, UK

Introduction: What on Earth is a Rock?

To a geologist the term 'rock' is applied to all the solid materials of the Earth, whether they are hard enough to hit with a hammer or soft unconsolidated gravel, sand, or mud. The nomenclature and classification of rocks is a prerequisite to understanding them. One of several definitions of science is that it is organized knowledge. It is the organization and classification of knowledge that provides insight into processes and adds predictive value. The Periodic Table of the Elements illustrates these points admirably. Classification is an integral part of geology in all its forms. It extends from palaeontology, where the classification of fossils according to the binomial nomenclature of Linnaeus is a prerequisite to demonstrating evolution and understanding palaeoecology, to mineralogy, where minerals are grouped into like families according to their chemistry and crystallography.

The object of this chapter is to review the fundamental classification of rocks as a foundation for discussing igneous, sedimentary, and metamorphic rock nomenclature and classification (*see* **Sedimentary Rocks:** Mineralogy and Classification, **Metamorphic Rocks:** Classification, Nomenclature and Formation).

Rocks are traditionally grouped into three main classes, according to their genesis. These will now be defined and described. All generalizations are dangerous, however, including this one. Thus, a detailed examination of the classification (*see* **Igneous Processes**) of rocks soon reveals discrepancies and inconsistencies (*see* **Metamorphic Rocks:** Classification, Nomenclature and Formation). It may, therefore, be helpful to examine these subsequently.

A Classification of Rocks

Rocks are of three genetic types: igneous (formed from cooling magma), sedimentary (formed by the breakdown of pre-existing rock), and metamorphic (formed by the action of heat and pressure on pre-existing rock) (Figure 1 and Table 1).

Igneous Rocks

Magma is molten material from deep beneath the surface of the Earth. Through a variety of processes discussed elsewhere in this encyclopaedia, magma may move up through the crust towards the surface. It may cool very slowly beneath the surface to form coarsely crystalline rocks. These include silica-rich rocks, such as granite (*see* **Igneous Rocks:** Granite), and ferromagnesian-rich rocks, such as gabbro. If the magma reaches the surface, it erupts in volcanoes (*see* **Volcanoes**), and the melt cools quickly to form microcrystalline or even glassy rocks. Depending on their chemistry and texture, volcanic rocks may be classified as silica-rich rhyolite or ferromagnesian-rich basalt.

Thus, owing to their mode of formation, igneous rocks tend to be structureless when viewed at outcrop or in a hand specimen. Under the microscope they are seen to consist of a random arrangement of interlocking crystals of a range of different minerals, which formed when the melt crystallized. Porosity is generally absent.

Sedimentary Rocks

Sedimentary rocks are formed from the detritus of pre-existing rocks, which may be igneous, metamorphic, or sedimentary. The way in which rock is

Table 1 The three main classes of rock, their origins, and examples

Class of rock	*Origin*	*Examples*
Sedimentary	Deposition of particles of pre existing rocks	Gravel, sand, and mudstone
	Chemical replacement and precipitation	Limestone dolomite and salt
Metamorphic	Heated by igneous intrusions	Hornfels
	Heated and subjected to high pressure by deep burial	Slate, schist, and gneiss
Igneous	Volcanic eruptions	Basalt, andesite, and rhyolite
	Deep cooling of magma	Granite, diorite, and gabbro

weathered, eroded, transported, and deposited is discussed in detail elsewhere (*see* **Weathering, Sedimentary Processes:** Erosional Sedimentary Structures, **Sedimentary Environments:** Depositional Systems and Facies). Sediments possess a wide range of particle sizes, ranging from boulders to clay, and of chemical compositions, including silica, lime, and ferromagnesian volcanic detritus. These parameters of particle size and composition are used to classify sedimentary rocks (*see* **Sedimentary Rocks:** Mineralogy and Classification). Sedimentary rocks commonly exhibit two properties that may be used to differentiate them from igneous and metamorphic rocks. Where they crop out at the surface of the Earth, sedimentary rocks generally show stratification. The strata indicate successive episodes of deposition. Layering is usually absent from igneous rocks, as discussed above, but is found in some metamorphic rocks, as discussed below. When examined under the microscope, sedimentary rocks are generally seen to consist of particles. Void space (porosity) is commonly present between the constituent grains. If there are interconnected pores, these give the rock permeability. Permeability allows fluids to migrate through the rock and enables rock and soil to drain. Fossils are found only in sedimentary rocks, some of which are, indeed, made up of nothing else.

Sedimentary rocks include sands, including terrigenous silica-rich sandstone, and carbonates, termed limestone. Sediments composed of rounded pebbles are termed conglomerates, while those composed of angular clasts (fragments) are termed breccias.

Metamorphic Rocks

Metamorphic rocks are so termed from the Greek *meta-*, meaning altered, and *morphos-*, meaning shape. The word is applied to rocks, of whatever previous origin, that have been changed as a result of being exposed to high temperature, high pressure, or both. Two types of metamorphism are recognized, regional metamorphism, and thermal or contact metamorphism. When magma moves up through the crust it creates a metamorphic aureole in the adjacent cover rocks. This is termed contact or thermal metamorphism. By contrast, rocks that are subjected to high temperatures and pressures during deep burial are said to have undergone regional metamorphism.

Common thermally metamorphosed rocks include hornfels and quartzite. Regionally metamorphosed rocks include schist and gneiss.

Thermally metamorphosed rocks are often crystalline and devoid of porosity. They may be massive or layered, according to the character of the original rock. Regionally metamorphosed rocks are also commonly crystalline and devoid of porosity. They are, however, often banded. The banding seldom resembles the regular stratification of sediments, but often takes the form of curvaceous foliation and cleavage (*see* **Regional Metamorphism**).

Rock Classification: A Simple Summary

Igneous and metamorphic rocks are both normally composed of a mosaic of interlocking crystals that formed at high temperatures and pressures; they thus usually lack porosity and permeability. In the petroleum industry igneous and metamorphic rocks are generally grouped together under the term 'basement', indicating that it is pointless to continue drilling deeper into such tight rocks. Igneous rocks are generally massive and structureless, while metamorphic rocks are often banded.

Sediments, on the other hand, are deposited with space between the constituent particles. Thus, most sedimentary rocks, by their very nature, tend to be porous and permeable. Sediments are deposited episodically and thus characteristically exhibit stratification. They are also the only one of the three main classes of rock to contain fossils. Igneous, metamorphic, and sedimentary rocks may therefore be differentiated from one another using macroscopic structure and microscopic texture as shown in Figure 2.

Complications and Anomalies

When the tripartite classification of rocks was introduced at the beginning of this article it was pointed out that, like all classifications, it has complications

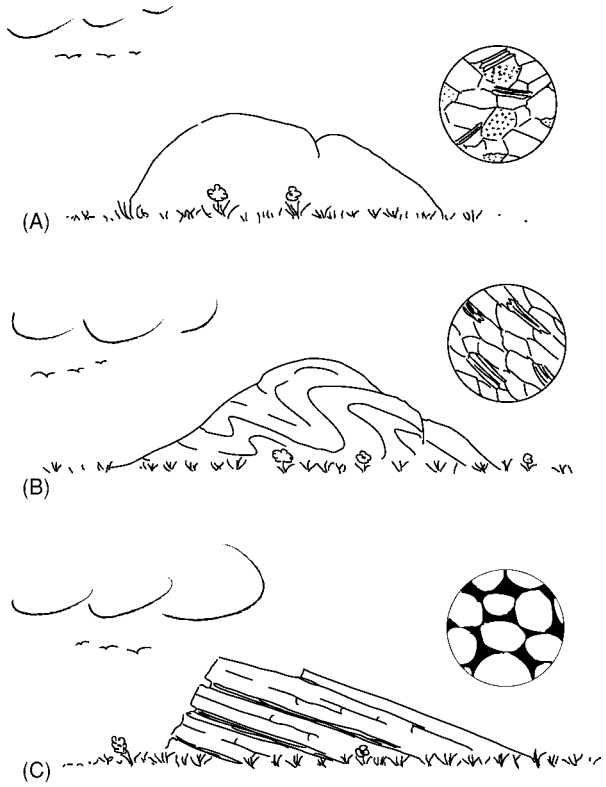

Figure 2 A rough guide to how igneous, metamorphic, and sedimentary rocks may be differentiated from one another by macroscopic structure (left) and microscopic texture (right). As discussed in the text, however, there are exceptions to these simple guidelines. (A) Igneous rocks are generally structureless in the field, with a random mosaic of crystals when viewed in thin section under the microscope. (B) Metamorphic rocks are gener ally banded (often curvaceous) in the field, with a linear arrange ment of crystals when viewed in thin section under the microscope. (C) Sedimentary rocks are generally stratified in the field and exhibit rounded grains with intergranular pores when viewed in thin section under the microscope.

and anomalies. These will now be examined for igneous, metamorphic, and sedimentary rocks in turn.

Igneous Rock Anomalies

When describing igneous rocks it was stated that they form from cooling magma and are generally composed of a mosaic of interlocking randomly arranged crystals. Thus, in hand specimen, and at outcrop, igneous rocks present a massive appearance. They generally lack the foliation of metamorphic rocks and the stratification of sediments. Now for the exceptions, which occur in both volcanic lavas and major intrusions.

Lava is extruded from a volcano episodically, on time-scales ranging from thousands of years to minutes. Major sequences of lava flows give rise to a very typical landform, with plateaus of lava bounded by cliffs in which successive lava flows can be discerned, separated from one another by weathered soil horizons that formed between individual flow events. Superficially this gives rise to landscapes analogous to those created by stratified sedimentary rocks. Plateau basalts are widespread around the world, from the Deccan Traps of India to the Tertiary volcanic province of the Scottish Hebridean islands. When examined closely, lavas commonly exhibit flow-banding on a variety of scales. This includes the 'ropy' structure of some basalt flows, the so-called 'pahoehoe' lavas of Hawaii, and a diverse range of structures that are morphologically similar to the post-depositional structures of sedimentary rocks (*see* **Sedimentary Processes:** Post-Depositional Sedimentary Structures). For example the Devonian rhyolites of the Glen Coe cauldron subsidence in Scotland exhibit excellent examples of slumps, slides, load-casts, and flame structures.

It was also noted earlier that igneous rocks generally lack porosity. Some gassy lavas, however, consolidate with contained bubbles of gas, giving rise to what are termed vesicular lavas. Vesicular lavas thus exhibit porosity, but, unless the bubbles are abundant and interconnected, there is no significant permeability.

Deep-seated igneous intrusions also sometimes show features indicative of sedimentation. These are most commonly found in ultrabasic ferromagnesian-rich intrusives, such as the gabbroic Skaergaard complex of Greenland and the Bushveld intrusion of South Africa. These intrusions show a gravity segregation of minerals, with the densest, such as chromite and iron ores, at the base, overlain by ferromagnesian minerals, and then feldspars above. It is clear that the minerals have crystallized out of a melt, and have settled under gravity. There is more. This gravity separation may occur not only on an intrusion-wide scale, but also on a scale of metres or centimetres, resulting in size-graded 'beds' analogous to those deposited by sediment gravity flows. The evidence suggests that convection currents within the magma chamber permit successive episodes of deposition from density flows. Inclined bedding analogous to that produced by traction currents in running water is also known (*see* **Unidirectional Aqueous Flow**).

Sedimentary Rock Anomalies

Sedimentary rocks are defined as those that are composed of fragments of pre-existing rocks, of a wide range of particle sizes, that are deposited under ice or water or in the atmosphere. They are thus commonly stratified and contain fossils, and usually exhibit porosity between the constituent sediment grains. This definition is adequate for gravels, sands, and muds and for the conglomerates, sandstones, and shales that are their lithified equivalents. There is,

however, a large group of sedimentary rocks where these characters are largely absent. These are the chemical sediments. The chemical sediments are a diverse group that includes limestones, dolomites, ironstones, evaporites, chert, hydrocarbons (peat, lignite, and coal), and phosphate (*see* **Sedimentary Rocks:** Chert; Dolomites; Evaporites; Ironstones; Limestones; Phosphates). Limestones are frequently composed of clasts and exhibit sedimentary structures analogous to those of sandstones. The other chemical rocks, however, owe their peculiar properties very largely to post-depositional chemical changes during diagenesis (*see* **Diagenesis, Overview**). In the extreme case of the so-called evaporites, it is now recognized that they should be more properly termed 'replacementites' since their original chemical composition has been completely changed, though primary sedimentary features may be discerned as ghostly relics. Indeed it could be argued that the evaporites/replacementites are really metamorphic rocks.

Stratification is sometimes absent in sedimentary rocks. Massive structureless sediments include 'loess' (wind-blown silt) and grain-flow and mass-flow deposits such as debrites and olistostromes.

Metamorphic Rock Anomalies

The previous paragraph on anomalous sedimentary rocks provides a useful introduction to problems of metamorphic-rock classification. Just as the boundary between chemical sediments and metamorphic rocks is gradational, so too is the boundary between detrital sediments and metamorphic rocks. During burial gravel lithifies to form conglomerate, sand forms sandstone, and mud forms shale. With increasing burial temperature and pressure, porosity is destroyed, and texture and mineralogy are modified. There is therefore a gradation between highly cemented sedimentary rocks and low-grade metamorphic rocks. Similar gradations occur when superficial igneous rocks undergo deep burial, with concomitant mineralogical and textural changes as they metamorphose. Historically nowhere has this problem been more acute than in the controversial theories about the origin of granite. Granites were believed to have formed from the slow cooling of magma that had intruded shallower rocks. It was pointed out, however, that, when considering the vast granite masses at the eroded roots of mountains, there was a space problem. This was resolved when it was realized that wholesale replacement of pre-existing rock had taken place. Intrusive granites were found only at shallow depths, having moved upwards from deep parent batholiths.

Rocks and their Classification: Conclusion

Rocks are of three genetic types: igneous, formed from cooling magma; sedimentary, formed mainly by the breakdown of pre-existing rock; and metamorphic, formed by the action of heat and pressure on pre-existing rock. Igneous and metamorphic rocks are both normally composed of a mosaic of interlocking crystals that formed at high temperatures and pressures; they thus usually lack porosity and permeability. In the petroleum industry igneous and metamorphic rocks are generally grouped together under the term 'basement', indicating that it is pointless to continue drilling deeper into such tight rocks. Igneous rocks are generally massive and structureless, while metamorphic rocks are often banded.

Sediments, on the other hand, are deposited with space between the constituent particles. Thus, sedimentary rocks, by their very nature, tend to be porous and permeable. Sediments are deposited episodically, and thus characteristically exhibit stratification. They are also the only one of the three main classes of rock to contain fossils.

All classifications have their illogicalities and inconsistencies. Thus sedimentary rocks grade with increasing burial into metamorphic rocks, and metamorphic rocks ultimately melt to form magma, which cools to form igneous rocks, which are weathered, eroded, transported, and redeposited as sediments.

RUSSIA

A S Yakubchuk, The Natural History Museum, London, UK
A M Nikishin, Lomonosov Moscow State University, Moscow, Russia

Introduction

The Russian Federation is the world's largest country, spread across 10 time zones from west to east and from the Arctic to Subtropical climates from north to south. Her territory is mostly plains in the lowlands of Eastern Europe and western Siberia and highlands in eastern Siberia. The country's mountain ranges are the Urals, Verkhoyansk, Koryak, Sikhote-Alin, Altai, Sayan, and Caucasus.

Geological exploration of this vast area started in the sixteenth century, when Russia began its advance to the east. However, it became systematic only in the eighteenth century when Russia invited European scientists and many Russian people received education in Europe, many in mining centres. This stimulated development of base metal and silver deposits in the Urals, Altai, and Transbaikalia provinces. Gold and platinum were discovered only in the late eighteenth to early nineteenth century in the Urals. This boosted exploration, and many prospectors moved to Siberia and the Russian Far East, where they found many rich gold placers before the Golden Rushes of the nineteenth century in the West.

These discoveries required systematisation, and the Russian government established the Geological Committee in 1882. After the 1917 Revolutions, these works expanded across the Soviet Union, and its first geological map at a scale of 1:5 000 000 was compiled by 1937. In the 1940–1970s, regional tectonic maps were compiled and many world-class deposits of Ni, Au, diamonds, and oil were discovered. During this period, Russian geology evolved in isolation, but under the significant influence of the German geological school. As a result, the fixistic approach dominated in geology and many local names were proposed for orogenic events, such as Baikalides, Salairides, etc. As a result, Russia has its own system of Proterozoic subdivisions, such as Riphean (1600–680 Ma), that incorporates the Middle and Upper Proterozoic in the International Scale, and Vendian (650–540 Ma), roughly corresponding to the Eocambrian. Phanerozoic subdivisions generally correspond to the International Scale.

After the introduction of plate tectonics, Russian geologists remained mostly non-mobilistic in their thinking. Its regional geology was revised in line with plate tectonic theory only in the 1980s, which was also a period of active study of the Russian shelves and participation of many geologists in international projects. During these years, Russian geological knowledge advanced significantly, with superdeep drilling in the Kola Peninsula, Urals, Central Asia, and western Siberia.

After the breakup of the Soviet Union in 1991, there has been a significant reduction of geological work. However, interesting compilations were produced, as well as detailed petrological studies. The country is now an area of international exploration activity.

General Geology

Russian territory consists of Precambrian cratons and Neoproterozoic to Cenozoic orogenic collages, overlapped by the Mesozoic-Cenozoic sedimentary basins (Figure 1). The East European and Siberian cratons are the oldest structures in continental Russia. On the Arctic shelf, west of the Gakkel Ridge in the Arctic Ocean, there are the Svalbard and Kara blocks. The Hyperborean Craton is prominent in the Arctic shelf east of the Gakkel Ridge and north of Chukotka. The cratons are bordered by the Neoproterozoic orogens of the Baikalides and Timanides, which probably continue on to the Arctic shelf. Between these cratons is the Palaeozoic orogenic collage of the Altaids, mostly hidden under the West Siberian Mesozoic-Cenozoic sedimentary basin. The Altaids extend to Transbaikalia (Figure 2). To the south of the Siberian Craton is the Mongolide orogenic collage. Between the Siberian and Hyperborean cratons and along the Far East coast are the Mesozoic-Cenozoic Circum-Pacific orogens. The Alpine orogenic belt borders the East European Craton in the south.

East European Craton

The East European Craton consists of shields, basement rises, and sedimentary basins. The Baltic Shield outcrops in the Kola Peninsula and Karelia. In the south, the crystalline basement occurs in the so-called Voronezh Rise. There are several sedimentary basins – Baltic, Moscow, Mezen, Volga-Ural, Pachelma, Ulianovsk-Saratov, Peri-Caspian – and the Peri-Urals foredeep.

The craton formed prior to 1.6 Ga (Figure 3). In the Baltic Shield, there are the Karelia, Central

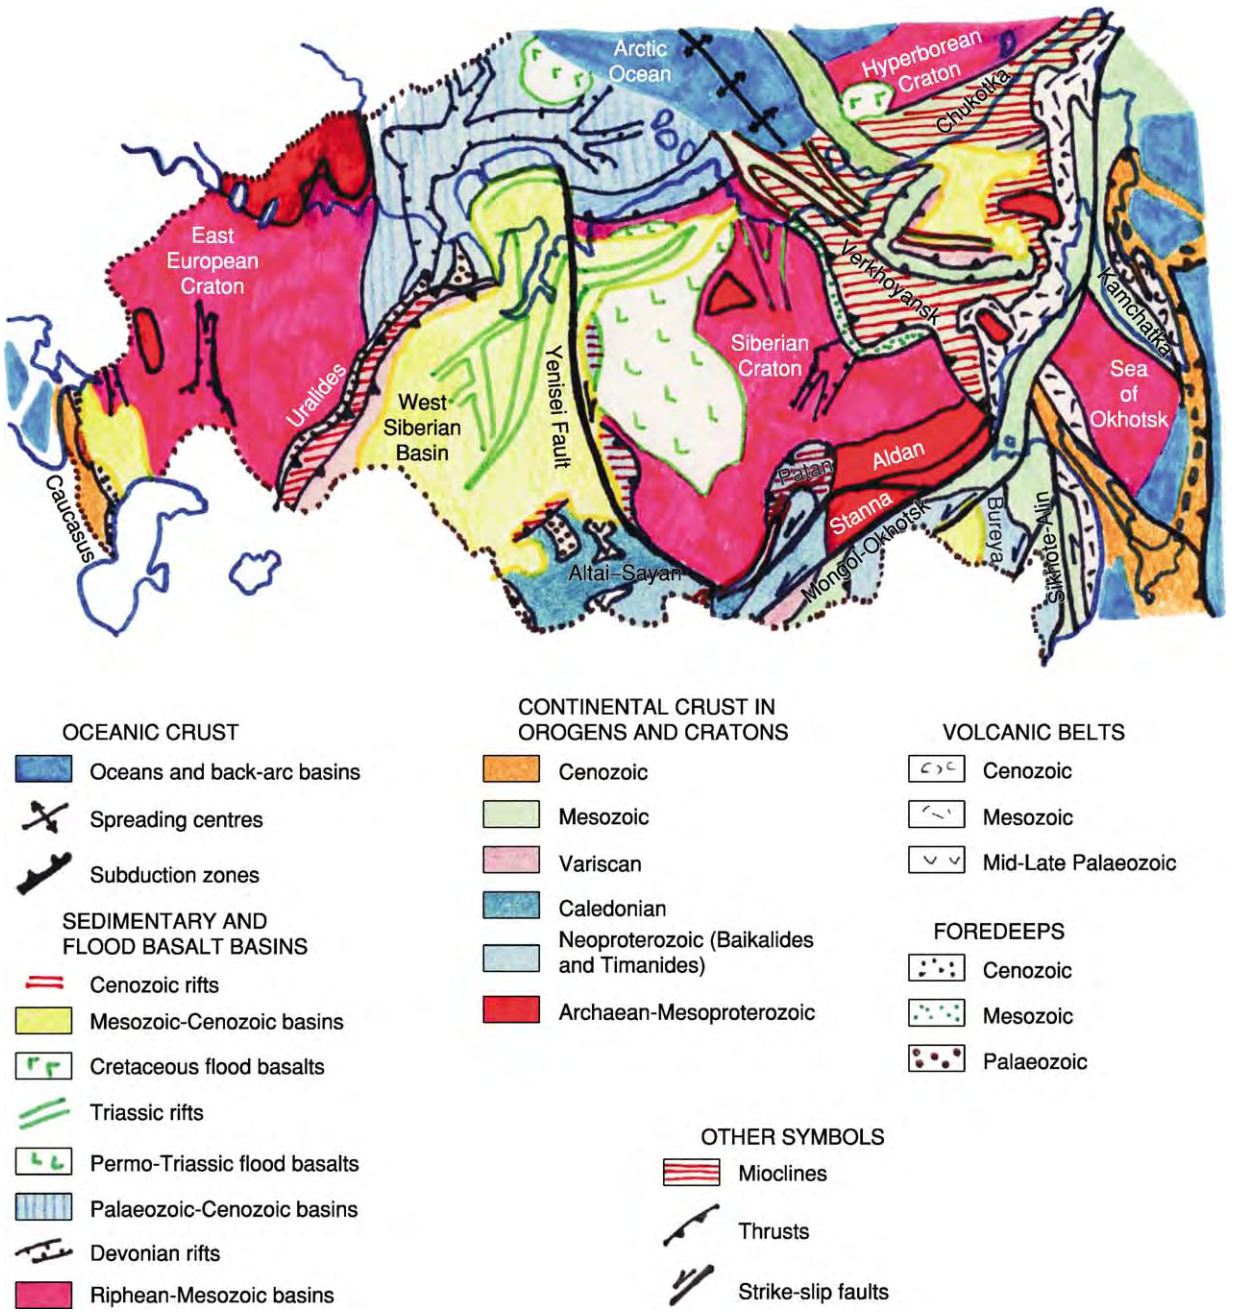

Figure 1 Outline Tectonic map of Russia and adjacent shelves (newly compiled by Nikishin and Yakubchuk). Note the presence of vast Mesozoic Cenozoic sedimentary basins superimposed onto the Palaeozoic Collage between the East European and Siberian cratons. Devonian rifts were superimposed onto cratons. Red cratons: deep blue, Ocean basins: light blue, Palaeozoic tectonic areas: horizontal red shading, Mesozoic to Cenozoic areas: yellow, Mesozoic Cenozoic sedimentary basins.

Kola, and Murmansk Archaean terranes. The Karelia Terrane is a typical 3.0–2.7 Ga granite-greenstone province. The Central Kola Terrane is a classic block with amphibolite metamorphism and it consists of various volcanic and sedimentary rocks with numerous granitoids and gneisses. The Murmansk Terrane consists of Late Archaean granitoid batholiths. Between the Karelia and Kola terranes is the linear White Sea Belt, in which the Archaean crust was reworked in the Early Proterozoic, producing 1.9 Ga granulites. The Archaean nuclei of the Baltic Shield are overlain by Early Proterozoic sedimentary basins and volcanics. Similar terranes exist in the unexposed part of the craton.

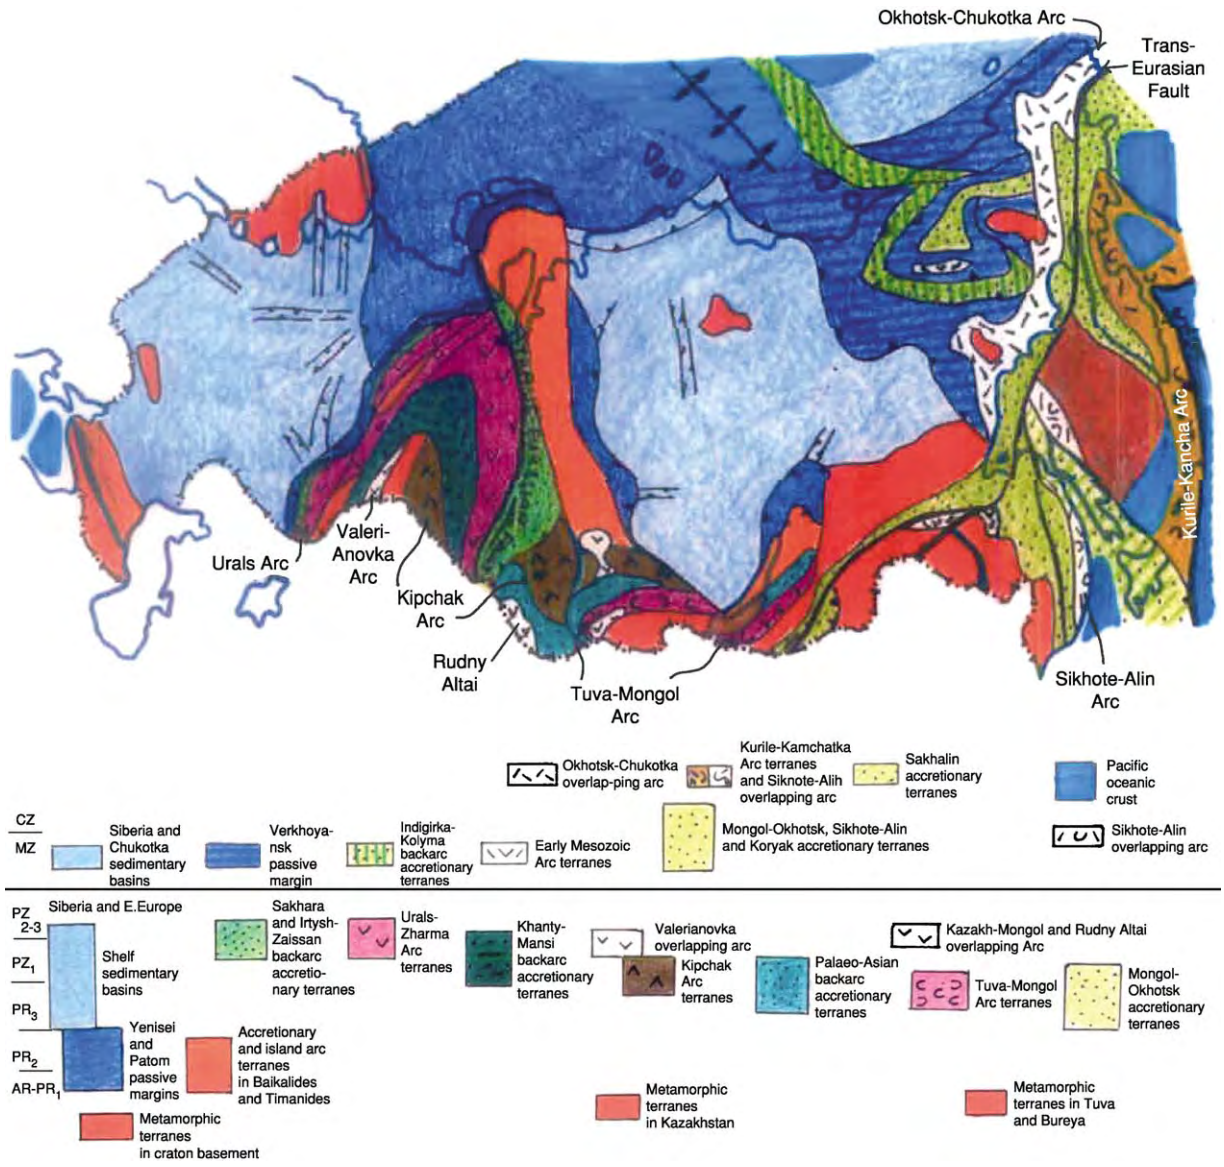

Figure 2 Tectonic map of Russia and adjacent shelves without Mesozoic Cenozoic sedimentary basins (newly compiled by Yakub chuk and Nikishin). Note the oroclinal structure in the Palaeozoic and Mesozoic orogenic collages. Riphean rifts are shown on the major cratons. Late Palaeozoic to Early Mesozoic Trans Eurasian strike slip faults separate the Altaid Collage into two domains.

The sedimentary basins of the East European Craton (Figure 4) consist of several stratigraphic units: (i) Riphean (1.6–0.65 Ga); (ii) Vendian–Early Cambrian; (iii) Middle Cambrian–Early Devonian; (iv) Middle Devonian–Permian; (v) Triassic; (vi) Jurassic–Lower Cretaceous; (vii) Upper Cretaceous–Eocene; (viii) Oligocene–Neogene; and (ix) Quaternary.

Riphean palaeorifts (or aulacogens) are filled with basalts, continental and marine clastic rocks, and carbonates. The Riphean stratigraphy is poorly studied. Three epochs of rifting at 1.6–1.3 Ga, 1.3–1.0 Ga, and 1.0–0.65 Ga have been identified, although some dates are approximate. Palaeorifts mainly occur on the flanks of the craton, but Central Russian palaeorifts crosscut the entire craton.

Vendian-Early Cambrian rocks form the sedimentary cover of the entire craton. The Lower Vendian (~650–600 Ma) consists of tillites, representing the Lapland glaciation. On the south-western edge of the craton are Lower Vendian Volynian plateau basalts (in Ukraine), which were formed prior to the opening of the Tornquist Ocean. Upper Vendian to Early Cambrian rocks are mostly shallow-water sandstone and clay. Upper Vendian rocks have many occurrences of the Ediacaran fauna (*see* **Precambrian:**

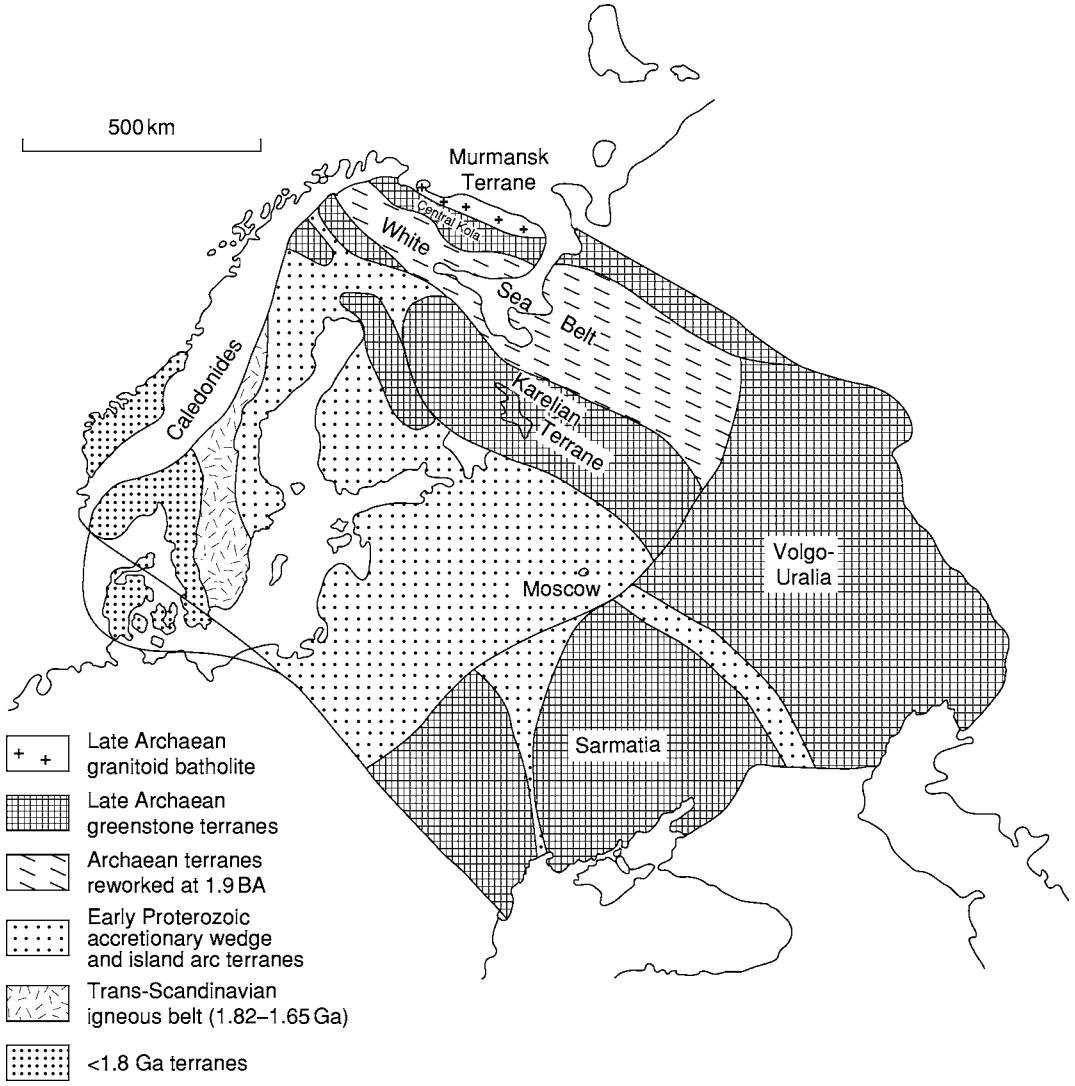

Figure 3 Crustal provinces of the East European Craton (compiled using data by Gorbatschev and Bogdanova).

Vendian and Ediacaran). Accumulation of the sedimentary basins was controlled by the Iapetus and Tornquist Oceans to the west (modern coordinates) and the foreland basin of the Timanides to the east (*see* **Europe:** Timanides of Northern Russia). The craton was elevated at the end of the Early Cambrian synchronously with the final orogenesis in the Timanides.

Middle Cambrian to Early Devonian rocks form a wide basin that might have fully covered even the Baltic Shield. The principal basins are Baltic, Moscow-Mezen-Pechora, Peri-Urals, and Peri-Caspian, but they formed a united system of epicontinental seas. In the Ordovician, to the east of the craton, was the Urals Ocean or oceanic back-arc basin, and the poorly studied Scythian Ocean was to the south. Marine sedimentation was controlled by climate: for the Middle Cambrian to Middle Ordovician strata, clays, sandstones, and carbonates are typical; in the Late Ordovician to Silurian, carbonate rocks are dominant; in Early Devonian times, red clastic rocks began to dominate against a background of arid climate and regression, culminating in total sea regression.

The Middle Devonian to Permian cover was formed in the epicontinental marine basin. The Middle Devonian rocks are typical clastic and carbonate sediments. At the Givetian-Frasnian transition was a magmatic event and rifting, with a system of rifts (Figure 4), such as Pripyat-Dnieper, Donets, Peri-Caspian, Barents Sea, Kola, Timan-Pechora, and Vyatka. During that time, diamondiferous kimberlites formed in the Arkhangelsk region, and the world's largest alkaline ultramafic massifs were emplaced in the Kola Peninsula. Middle to Late

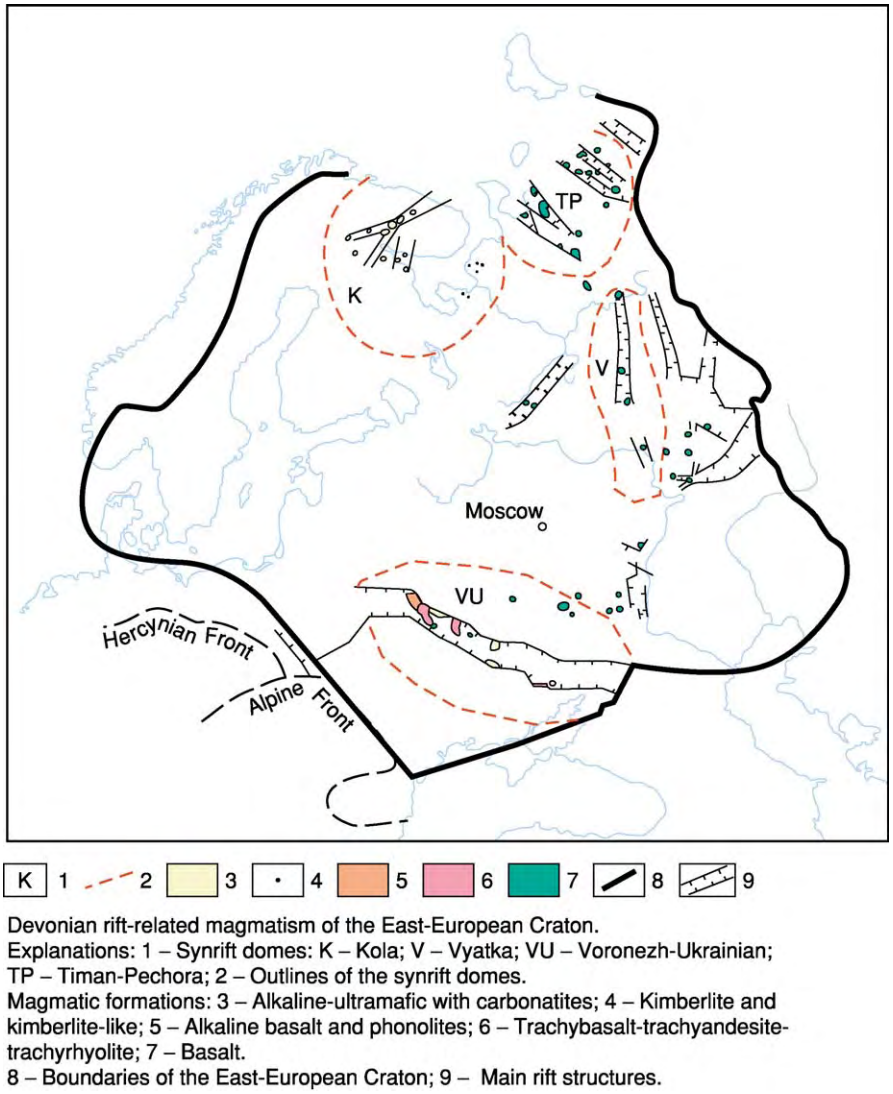

Figure 4 Sedimentary basins of the East European Craton (compiled by Nikishin and Fokin).

Devonian rifting and magmatism can be explained by the influence of mantle plumes, in combination with regional continental extension and possible back-arc processes.

The Middle Devonian to Permian rocks are mostly carbonates. An epicontinental marine basin changed its depth many times due to sea-level fluctuations. Carboniferous strata include typical buried river valleys and limnic coal. The Peri-Caspian Basin was a deep-water basin framed by reefs. In the Donets Basin, there was a large delta system that accumulated 15–20 km of sediments with numerous coal seams. In the Peri-Urals Basin, the Domanik Horizon, enriched in organic material, was formed during the Frasnian, and it is a regional oil-bearing stratum. In Kungurian time, the Peri-Caspian Basin was almost completely separated from the ocean by the Uralide Orogen, and in it was accumulated up to 5 km of evaporites. In the Late Carboniferous, the main Urals collision began, and the Peri-Urals foredeep formed in front of the Uralide Orogen in the Permian. From the mid-Permian, there was a major regression, and mostly shallow-water marine, limnic, and continental sediments were accumulated in the Late Permian. By the end of the Permian, most of the craton had experienced regression, but the giant Pechora-Barents Sea sedimentary basin survived in the north, accumulating 3–5 km of sediments.

At the Permian-Triassic transition, the East European Craton was affected by the Siberian Superplume (Figure 4). The main Triassic sedimentary basins formed on the flanks of the craton are the Peri-Caspian, Pechora-Barents Sea, and Baltic-Polish-German. On the craton, thin continental sediments accumulated in the Moscow-Mezen and Dnieper basins. At the Triassic-Jurassic transition, the

Caucasus-Black Sea-Turkish Orogen formed to the south of the craton; to the north was the Novaya Zemlya orogen. Almost complete regression took place synchronously with these deformations and it continued until Aalenian time.

In Middle Jurassic to Early Cretaceous times, the main sedimentary basins were in the south and north of the craton. In the south were the Peri-Caspian, Ulianovsk-Saratov, Dnieper, and Peri-Black Sea Basins of the Northern Peri-Tethys area. In the north was the Pechora-Barents Sea Basin of the Boreal area. The Boreal and Peri-Tethys basins were periodically linked to form a single basin. The Peri-Tethys area has typical shallow-water marine carbonate and clastic rocks, whereas the Boreal Basin has marine and continental clay and sandy rocks. In the internal part of the craton are shallow-water marine and continental clastic sediments with multiple hiatuses. Organic-rich sediments are typical in the Late Jurassic.

In the mid-Cretaceous, the Peri-Tethyan and Boreal basins were separated. Carbonate rocks dominated in the Late Cretaceous to Eocene in the Peri-Tethys basins, whereas sandy-clay sediments dominated in the Boreal Basin. In the Late Cretaceous-Paleocene there was an intracratonic inversion of palaeorifts.

Oligocene-Neogene shallow-water sediments accumulated in the south of the craton against a background of maximum orogeny in the Caucasus and a colder climate.

In the Quaternary period, there were five major glacial and interglacial epochs. The main glaciers were on the Baltic Shield. To the south, they expanded as far as the Ukrainian Shield, producing moraine and fluvioglacial accumulations.

Siberian Craton

Most of the Siberian Craton is covered by its sedimentary and flood basalt basins. Its basement outcrops are in the Anabar Shield in the north, the Aldan-Stanovoy Shield in the south, and in the Sayan-Yenisei area in the south-west. East of the Anabar Shield is the small Olenek Rise. All the basement rocks are older than 1.6 Ga, but the southern part of the Aldan-Stanovoy Shield was magmatically reworked in the Palaeozoic and Mesozoic. The Sayan-Yenisei area was deformed in the Neoproterozoic.

The Siberian Craton is the largest craton on Earth, with a pre-1.6 Ga crust. Its structure is dominated by Archaean terranes. Some of them were reworked during Early Proterozoic times, and juvenile Early Proterozoic crust occupies a relatively small area (Figure 5). It amalgamated as a single craton by the end of the Early Proterozoic.

There are three principal sedimentary basins (Figure 6): Vilyui in the east, Tunguska in the north-west, and Taseevo-Angara-Lena (or Irkutsk Amphitheatre) in the south-west. The thickness of the sedimentary cover is up to 5–8 km and it consists of several rock complexes: (i) Riphean (1.6–0.65 Ga); (ii) Vendian–Early Devonian; (iii) Middle Devonian–Early Carboniferous; (iv) Carboniferous–Permian; (v) Triassic; (vi) Jurassic–Cretaceous; (vii) Tertiary; and (viii) Quaternary.

Riphean palaeorifts (aulacogens) are widely distributed and are filled with carbonates, continental clastic rocks, and basalts. Their stratigraphy is poorly studied, but there are at least three epochs of rifting distinguished at 1.6–1.3 Ga, 1.3–1.0 Ga, and 1.0–0.65 Ga. Most of the palaeorifts are perpendicular to the craton margins: their palaeotectonic setting is not clear, but some data indicate that 0.8 Ga rifts in the east of the craton could be related to the opening of the ocean. In addition to the palaeorifts, wider Riphean cover overlaps northern parts of the craton.

Vendian to Early Devonian rocks cover almost the entire craton. The Vendian, known in Siberia as the Yudomian, consists of clastic rocks at its base which were overlain by carbonates. During the Early Cambrian, carbonate sedimentation dominated in the Yudoma-Olenek shelf in the east, and a carbonate-evaporite shallow-water basin existed in the Tunguska-Irkutsk Basin. These two basins were separated by carbonate reefs with archaeocyathid-algae buildups. From the Middle Cambrian to the Late Ordovician, carbonates dominated in all basins. Silurian rocks are carbonates, clastic sediments, and evaporites. The maximum regression occurred in the Late Silurian-Early Devonian and coincides with orogeny in Transbaikalia, where the Patom Highlands were thrust onto the Siberian Craton, causing thin-skinned deformations of its cover north of Lake Baikal.

In the Middle Devonian to Early Carboniferous, there was rifting and magmatism. The main rifts formed in the east (Figure 6). Vilyui was the largest system, consisting of the Ygyata, Kempendyai, and other rifts. Rifting started with flood basalt magmatism and the intrusion of basalt dyke swarms. Later, there was the main phase that continued until Tournaisian times. In the Early Carboniferous, the Verkhoyansk branch of the rift system was transformed into the passive margin of the oceanic back-arc basin. As a result, the continental rifts became extinct, but the passive continental margin continued to evolve until Jurassic times. Middle-Late Devonian rifts possibly formed in the Tunguska Basin and

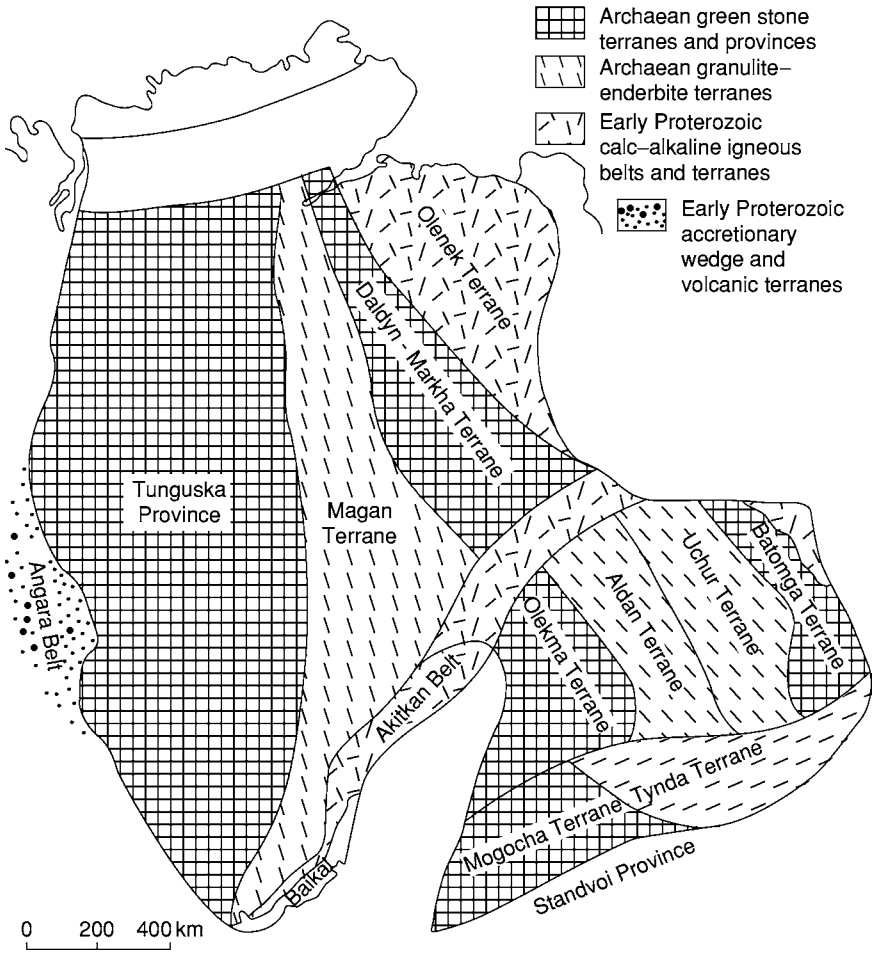

Figure 5 Crustal provinces and terranes of the Siberian Craton (simplified and modified after Rozen).

along the northern flank of the craton. In addition, numerous diamondiferous kimberlites were emplaced into Archaean nuclei, reflecting the impact of Middle-Late Devonian plumes, in a similar way to the East European Craton.

Carboniferous and Permian rocks occur in the Vilyui and Tunguska basins. In the Vilyui Basin, Middle Devonian rocks form thick grey clastic shallow-water and limnic-alluvial formations. This setting persisted until the end of Jurassic time, when numerous coal beds accumulated in the Vilyui Basin. At the end of the Jurassic and in the Early Cretaceous, orogenesis occurred in the Verkhoyansk Orogen, and a foredeep basin formed in its front. In the Carboniferous to Permian, the Tunguska Basin was filled with clastic continental and shallow-water marine sediments with numerous coal beds.

The latest Permian and Triassic was dominated by mantle plume tectonics. Large-scale flood basalt magmatism (often termed the Siberian Traps) took place in the north of the Siberian Craton and southern Taimyr (a probable northern continuation of the craton). The total thickness of basalts in the Tunguska Basin reached 2–4 km. This was the largest intracontinental Phanerozoic magmatic event (Figure 6), and it affected an area extending from the northern Urals to Verkhoyansk and from Taimyr to Central Asia, revealing it as a superplume event.

Jurassic rocks occur in the Vilyui and Irkutsk Basins. They also form a chain of foredeep basins between the Aldan and Stanovoy blocks. Typical rocks are continental coal-bearing sediments. The Stanovoy Block was an Andean-type margin in Jurassic times. Cretaceous clastic rocks are known in the Verkhoyansk foredeep.

During Tertiary times, the Siberian Craton was relatively elevated, possibly in response to the India-Asia Himalayan collision. The altitude of its plateaux was 1–1.5 km. Tertiary sediments occur locally and consist mostly of continental clastic rocks. The Popigai meteorite crater of Eocene age (80 km in diameter) occurs north of the Anabar Shield.

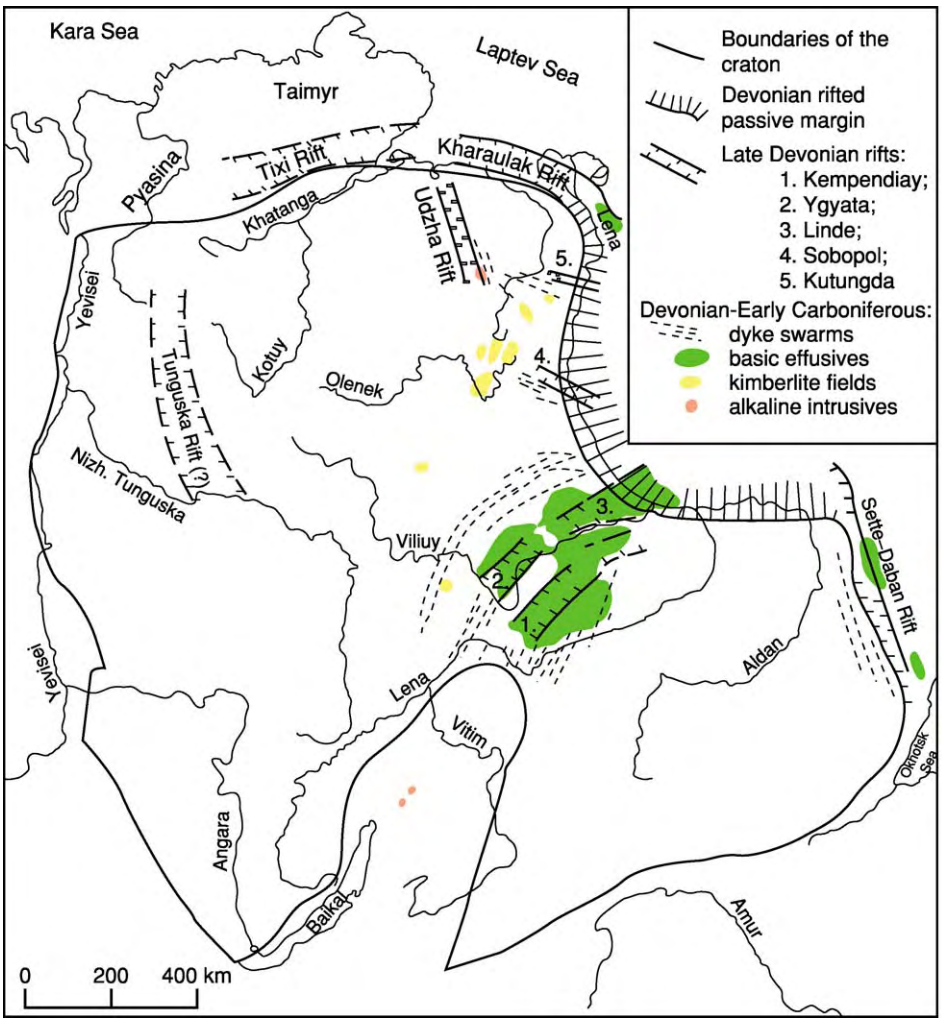

Figure 6 Sedimentary basins of the Siberian Craton (compiled by Nikishin and Fokin).

In Quaternary times, the craton was glaciated many times, but thick glaciers formed only in its northern part and the rest of the area was affected by thick permafrost that survives until the present day.

Neoproterozoic Orogens

Shatsky proposed the term Baikalides for the Neoproterozoic orogens on the flanks of the major cratons of Russia. Their type locality is in the Patom Highlands in northern Transbaikalia, but they were also distinguished in the Yenisei ridge, northern Taimyr, and Timan. Their slivers are recognized inside the Palaeozoic to Cenozoic orogens.

Until the 1980s, the interpretation of Baikalide age was mostly based on stratigraphic data. Recently, the Neoproterozoic age of the type locality in northern Transbaikalia was questioned. Some researchers suggested that the Baikalides are Early or Middle Proterozoic structures, whereas others proposed a Caledonian age. However, the deformed sequences in the Patom Highlands are unconformably overlapped by less deformed Vendian to Cambrian sedimentary rocks, indicating Neoproterozoic deformations. In addition, isotopic dating of syn- and postmetamorphic granitoids in the Yenisei ridge, Taimyr, and Timan also demonstrate the validity of Neoproterozoic deformations.

Patom Highlands This is an oroclinal embayment in the south of the Siberian Craton, extending from Lake Baikal towards the Patom Highlands (Figure 1). In the 1970–1980s, the Baikalides were interpreted as an Early Proterozoic orogen. Subsequent regional mapping re-confirmed that the orogen is Neoproterozoic. Most of this area is occupied by the Barguzin granitoid batholith. In the 1960s, it was considered as Proterozoic. In the 1970–1980s, the first K-Ar data showing its Early Palaeozoic age were obtained. However, application of more advanced techniques

in the 1990s revealed a Carboniferous age. In addition, isotopic dating of some regionally metamorphosed rocks in the Patom Highlands also revealed a Carboniferous age. This raised speculations that the Baikalides might be a Caledonian Orogen.

Geologically, the Patom Highlands consists of two major parts. In the north is a Baikal-Patom passive margin of Middle to Upper Riphean carbonate-terrigenous rocks deformed into linear folds. These rocks are unconformably overlain by Vendian-Cambrian molasse. Together they were thrust onto the Siberian Craton in the Middle Devonian. To the south is the Barguzin-Vitim Terrane which is separated from the passive margin by a suture with Riphean ophiolites. The Barguzin-Vitim Terrane is exposed in small fragments, consisting of metamorphosed Riphean accretionary wedge and island arc rocks.

Yenisei Ridge The Yenisei Orogen in the west of the Siberian Craton (Figure 1) is considered as an equivalent and continuation of the Baikalides. Deformed passive margin rocks occupy the bulk of the ridge. It has been demonstrated that in the west there is a suture with Late Riphean ophiolites and an island arc terrane. The folded structure is intruded by Neoproterozoic granites. Passive margin rocks were thrust onto the Siberian Craton, possibly in mid-Palaeozoic times.

Northern Taimyr, Arctic Shelf and Timanides The east–west trending Taimyr Orogen is an imbricated structure produced during Mesozoic thrusting to the south (Figure 7). It has been suggested that this orogen was a result of collision between the Kara Plate to the north and the Siberian Craton to the south. Northernmost Taimyr is a deformed Neoproterozoic to Early Palaeozoic passive margin of the Kara Plate, consisting of flysch and carbonate sequences which were regionally metamorphosed. They were earlier considered as Precambrian rocks: however, recent study has showed that metamorphism is Late Palaeozoic in age and might have taken place during the emplacement of 300–264 Ma collisional and post-collisional granitoids. The Main Taimyr Thrust separates northern and central Taimyr. The latter hosts two terranes (Mamont-Shrenk and Faddey) with Neoproterozoic island arc rocks and ophiolites (740–820 Ma) which were obducted 650 Ma ago onto Neoproterozoic carbonates, which are also thrust on top of Vendian to Early Carboniferous terrigenous-carbonate rocks of central Taimyr, part of the Siberian Craton. Another ophiolite belt inside northern Taimyr might be a root zone where the actual suture might be located. If so, northern Taimyr should be separated into two terranes, the northern one representing the Kara Plate and the southern one a deformed passive margin of the Siberian Craton.

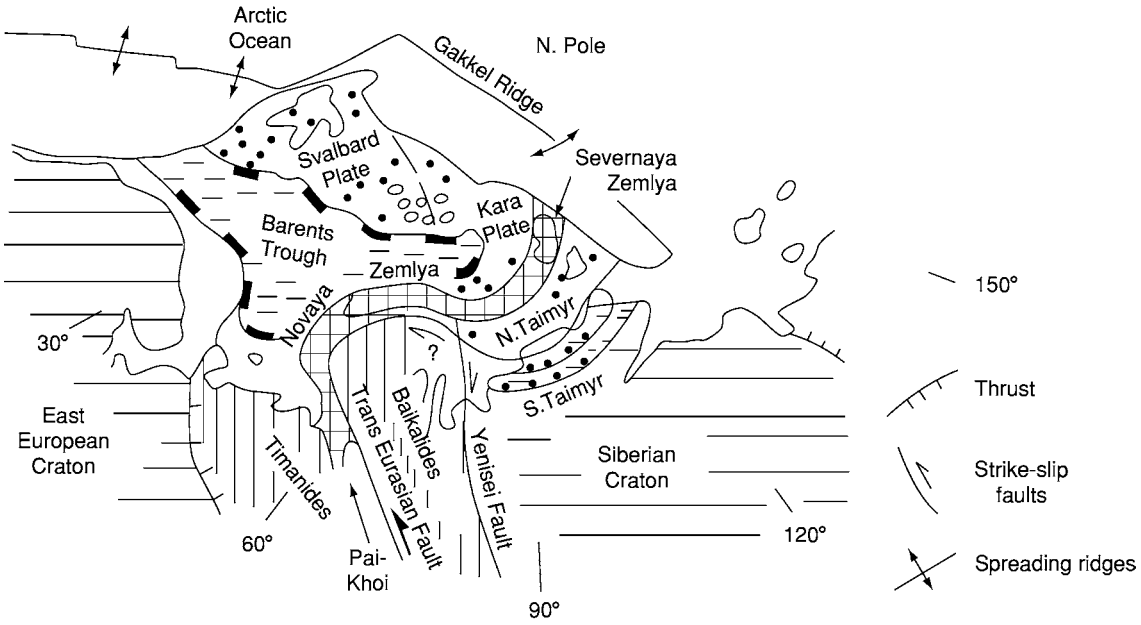

Figure 7 Tectonics of the Arctic shelf and adjacent regions (compiled by Yakubchuk, using data by Bogatskiy *et al.* and Bogdanov *et al.*). The Yenisei Fault separates the Arctic shelf into the Kara and Svalbard plates. Severnaya Zemlya is probably a continuation of Novaya Zemlya. The Barents extensional trough bounds the Svalbard Plate in the south. A major strike slip fault might separate the west east trending structures of the Arctic shelf and Siberian Craton.

Central Taimyr was thrust southward to form the southern Taimyr thrust zone which consists of an imbricated Middle Carboniferous to Triassic sequence. Its stratigraphy is generally similar to the Siberian Craton in the Tunguska Basin.

The position of Taimyr relative to other structures has been controversial. It has been proposed that it might represent a continuation of Novaya Zemlya. However in the 1980–1990s, the Arctic shelf was actively explored for oil. New data were obtained, and it was suggested that the northern Taimyr is an exposed part of the Kara Plate, which occupies the adjacent Arctic shelf. To the east, the Taimyr structures are truncated by Arctic oceanic floor. Its western continuation is far from clear, but magnetic data suggest correlation of Pai-Khoi and Novaya Zemlya with Severnaya Zemlya and not with Taimyr (Figure 7).

The Severnaya Zemlya islands consist of 6–7 km of Ordovician to Devonian deformed shallow-water sedimentary rocks with evaporites and felsic alkaline volcanics (456 Ma). They conformably overlie Cambrian rocks and their fossils are similar to those of the Novaya Zemlya archipelago. Folded Ordovician to Devonian rocks are unconformably overlain by Carboniferous-Permian redbed sequences. The timing of deformation is assumed to be Late Triassic, as in Taimyr, but no structural relationship has been recorded.

Novaya Zemlya and Pai-Khoi consist of Riphean to Lower Cambrian metamorphic rocks unconformably overlain by deformed Ordovician-Devonian terrigenous-carbonate rocks. These are also unconformably overlain by Carboniferous-Triassic continental rocks deformed prior to Jurassic times.

Pai-Khoi, Novaya Zemlya, and Severnaya Zemlya reveal similar lithologies and similar unconformities. The two regions are dextrally offset relative to each other along the Yenisei strike-slip fault that separates the Arctic shelf into the Kara and Svalbard plates and bounds the western margin of the Siberian Craton. Tectonically, Severnaya Zemlya and Novaya Zemlya might represent an inverted rift structure.

West of Pai-Khoi and Novaya Zemlya are the Timanides, where Puchkov reported relic Late Vendian fold belts (600–540 Ma). The Timanides are poorly exposed, and an understanding of their structure is based on geophysical and drilling data. There are two major terranes: in the south-west is the Izhma-Pechora passive margin with Riphean shales, felsic volcanics, and minor ultramafic intrusions; in the north-east is the Bolshaya Zemlya Terrane with Riphean intermediate volcanics and granitoids. The passive margin of the terrane can be traced along the northern coast of the Kola Peninsula, whereas the island arc terrane is truncated by the East Barents Trough and Pai-Khoi structures.

The Timanides are overlain by Devonian to Jurassic rocks of the Pechora sedimentary basin. The whole orogen and its sedimentary basin were thrust onto the East European Craton prior to Jurassic times. Numerous listric compressional faults in the Pechora basin reflect the Urals collision.

In the middle of the Arctic shelf is the 1500 km long East Barents depression, extending parallel to the proposed Pai-Khoi–Novaya Zemlya–Severnaya Zemlya inverted rift. Aplonov and his colleagues proposed that this depression might have a Palaeozoic oceanic crust over which lies up to 15–17 km of Middle Palaeozoic to Cretaceous sediments. In the south, the East Barents depression continues as continental rifts in the base of the Pechora Basin. In the north-east, it is truncated by the Arctic oceanic floor.

Altaid Collage

The area between the East European and Siberian cratons and south of the Arctic shelf is occupied by the Altaid Orogenic Collage (Figure 2). The Russian portion of the Altaid Collage is concealed under the Mesozoic-Cenozoic sedimentary basin of western Siberia, being exposed in isolated orogens in the Urals, Altai-Sayan, and Transbaikalia. Other exposures are in adjacent Central Asia (*see* **Asia:** Central; **China and Mongolia**), Mongolia, and China.

The Altaid Collage is separated into two domains along the giant Trans-Eurasian strike-slip fault, which strikes from Novaya Zemlya towards western Mongolia and then to the Mongol-Okhotsk suture, south of the Siberian Craton. To the west is the Kazakhstan-Khingan Domain and to the north-east is the Altai-Mongol Domain. Both domains have similar Terranes which were sinistrally offset during the Late Palaeozoic to Triassic by 1000 km. The internal structure of the domains is oroclinal, and their axes are also sinistrally offset by 1000 km.

Altai-Mongol Domain

The Altai-Mongol Domain consists of the 'Caledonides' and 'Variscides' (these terms are used here in different ways from their West European counterparts). The Caledonides, which occur in Altai-Sayan and Transbaikalia, represent a portion of the Altaid Collage attached to the Siberian Craton and Neoproterozoic orogens (Figure 8). In the south-west, it is truncated by the Trans-Eurasian Fault. The 'Variscides' occur in the Tom-Kolyvan Terrane in Siberia and the Khangai-Khentei Superterrane in Transbaikalia.

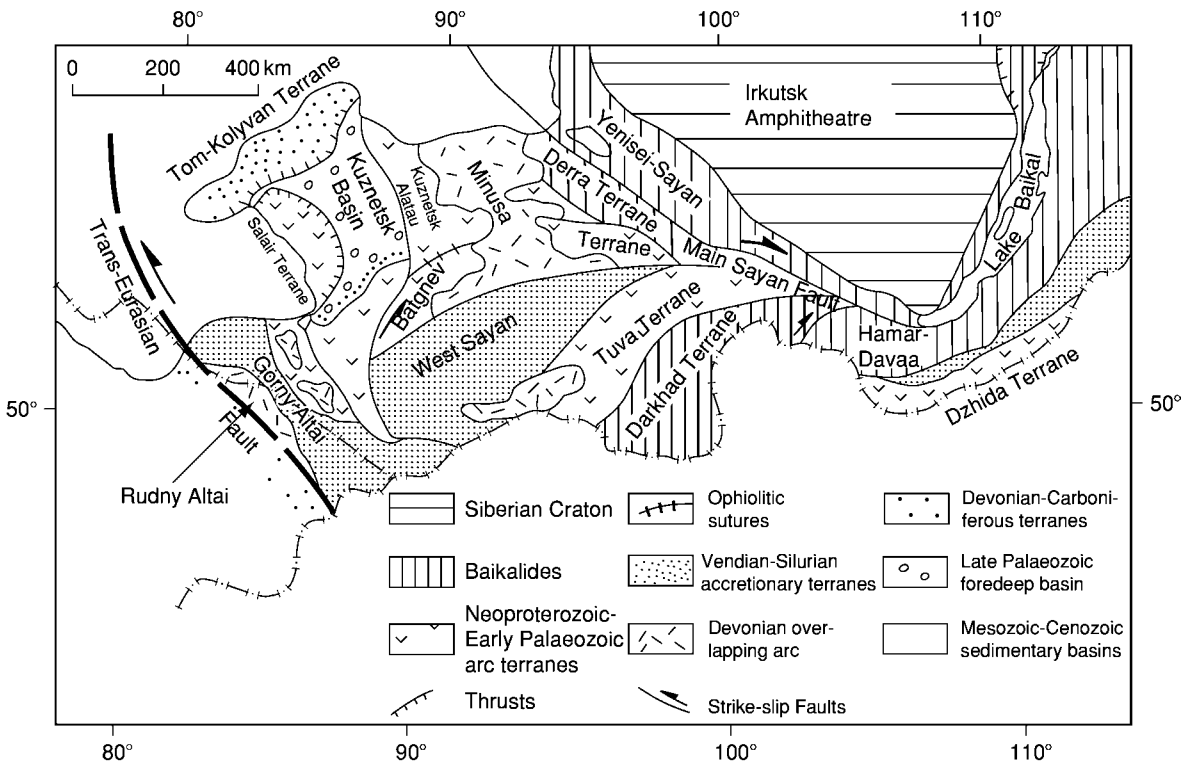

Figure 8 Tectonics of the Altai Sayan area (compiled by Yakubchuk). The mosaic pattern reflects significant strike slip faulting in the area. The Main Sayan fault is a southern continuation of the Yenisei fault in the north that separates the Baikalides and Siberian Craton (**Figure 7**). Offset equivalents of the West Sayan and Tuva terranes are proposed in southern Transbaikalia.

The 'Caledonides' incorporate Neoproterozoic metamorphic terranes and Vendian to Early Palaeozoic magmatic arc and turbidite terranes. In Russia, there are terranes of two Neoproterozoic to Early Palaeozoic arcs – Kipchak and Tuva-Mongol, overlapped by the Middle Palaeozoic Kazakh-Mongol and Rudny Altai and Late Palaeozoic to Early Mesozoic Orkhon-Selenga-Khanka arcs.

The Kipchak Arc includes the Salair and Batenev immature arc terranes separated by sutures with Vendian-Early Cambrian ophiolites from the adjacent Neoproterozoic terranes of Kuznetsk Alatau and Derba. These structures are stitched by Cambrian to Silurian granitoids, but they are offset by the Kuznetsk-Teletskoye sinistral strike-slip fault for as much as 200 km. In the north, the Variscan Tom-Kolyvan Terrane is thrust southward onto the 'Caledonides'. It consists of flysch that might represent an accretionary wedge of an arc, presently hidden under the West Siberian sedimentary basin.

To the south and west, the 'Caledonian' island arc terranes are bound by the accretionary and forearc complexes of Gorny Altai and West Sayan. They consist of Vendian to Silurian flysch with slivers of cherts, basalts, and Vendian–Early Cambrian ophiolites. In the east, they have a T-shaped junction with the Main Sayan Fault, a continuation of the above-mentioned Yenisei Fault that strikes for more than 3000 km. It truncates the accretionary terranes of West Sayan, and their dextrally offset equivalents can be found 600 km to the south-east in Transbaikalia.

South of the accretionary terranes are the 'Caledonian' terranes of Central Mongolia. These are Precambrian metamorphic and Vendian-Cambrian immature arc terranes, known as the Tuva-Mongol Arc. The arc starts near the Stanovoy ridge of the Siberian Craton and continues to the west. It then turns to the south and east, forming the Mongol and then the Khingan oroclines. The 'Caledonian' terranes are stitched by Cambrian-Ordovician and Silurian granites and Devonian calc-alkaline and alkaline volcanicsin Minusa, Rudny Altai, and other locations.

In the core of the Mongol Orocline are Neoproterozoic to Early Mesozoic accretionary wedges of the Khangai-Khentei Superterrane. In Russia the superterrane is exposed in southern Transbaikalia, from where its analogues can be traced to the Circum-Pacific orogens via the Mongol-Okhotsk Suture. In

Mongolia, these terranes are overlain by the Carboniferous to Early Mesozoic Orkhon-Selenga-Khanka Arc. The huge Barguzin Batholith was emplaced behind this arc in Transbaikalia. The northern edge of this arc is present in Transbaikalia and its eastern edge overlaps the Bureya Terrane, but this latter structure belongs to the Kazakhstan-Khingan Domain.

Kazakhstan-Khingan Domain

In Russia, the Kazakhstan-Khingan Domain includes the Urals and buried continuation of the Kazakh uplands. Outside Russia, it is exposed in Kazakhstan, western China, and southern Mongolia, appearing again in the Russian Far East.

The Urals is a 2000 km long isolated Variscan Orogen (Figure 9). In the Urals, there was no 'Caledonian' deformation. Its tectonic cycle started in the Late Cambrian-Ordovician. The Urals is traditionally subdivided into western and eastern slopes. The western slope consists of a deformed passive margin, which records the Urals history from Cambrian to Devonian times.

The eastern slope consists of ophiolite sutures and island arc terranes of Ordovician to Carboniferous age. The Sakmara suture separates the East European Craton and Magnitogorsk and Tagil arc terranes thrust westward onto its deformed passive margin. Due to this position, the island arc sequences represent one of the world's best preserved ancient arcs, with well pronounced internal zonation and famous volcanic-hosted massive sulphide deposits.

To the east is the East Uralian Megazone, considered as a north–south trending Late Palaeozoic 'granite axis of the Urals'. However, its Middle

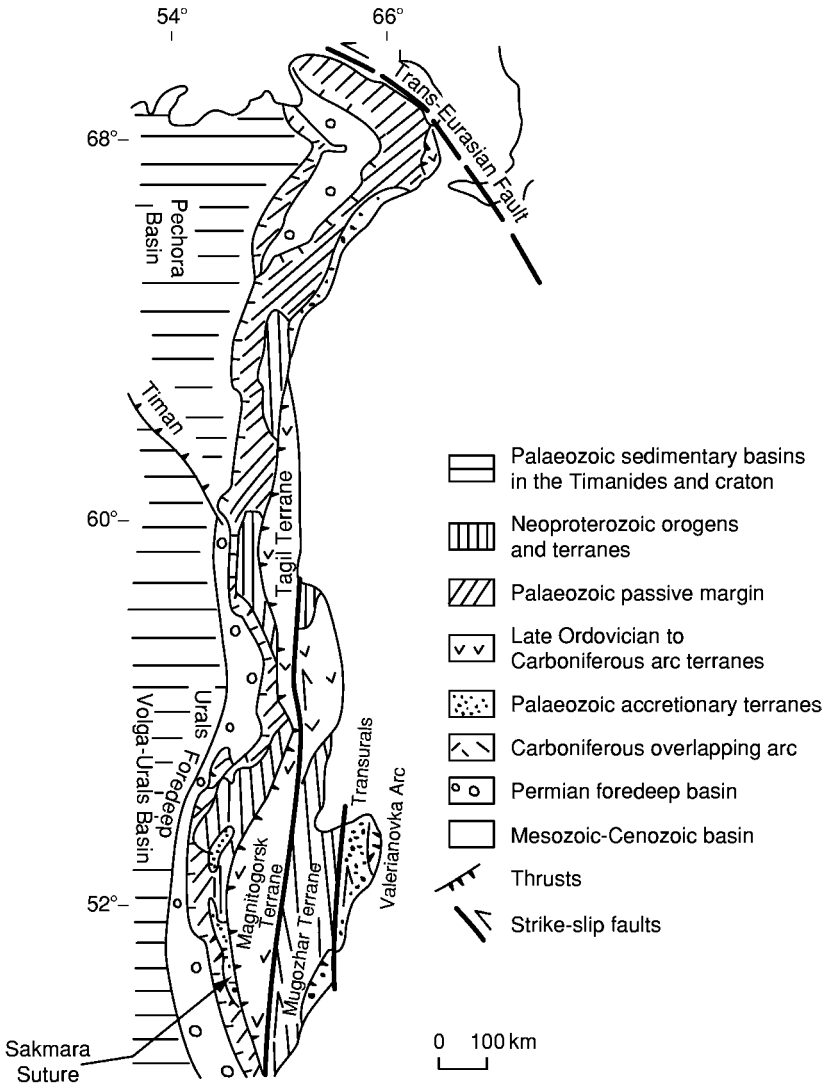

Figure 9 Tectonics of the Urals Orogen (compiled by Yakubchuk, using data by Puchkov and Sobornov). The traditional East Urals Zone consists of several NE trending terranes truncated in the west and east by strike slip faults. The sinistral amplitude of their displacement is at least 300 km.

Palaeozoic pre-granitic terranes strike obliquely relative to its western and eastern fault limits. These are two Precambrain metamorphic terranes and one Palaeozoic island arc terrane inbetween. The latter is principally similar to the Magnitogorsk Terrane, but it is offset sinistrally for 300 km. This suggests that the boundary faults are likely to be strike-slip faults. Seismic studies revealed that they dip to the west, producing an apparent divergent structure of the orogen.

Further to the east is the Trans-Uralian Terrane, consisting of Ordovician to Devonian accretionary wedge rocks. The easternmost structure in the southern Urals is the poorly exposed Carboniferous Valerianovka Volcanic Arc. It has been considered as an accreted arc, but regional airborne magnetic maps suggest that it can be traced to the Kurama Arc of Uzbekistan. This indicates that the Uralides can be interpreted as the result of arc-arc-continent collision.

This collision was accompanied by the formation of flysch in the Famennian to Early Carboniferous, which continued on into the Middle Carboniferous. This collision progressed northward, because in the northern Urals the accumulation of flysch and thrust deformations started in the Early Visean and ended by Kungurian time, when accumulation of salt and molasse took place. The collisional deformations terminated at the end of the Permian. In the Early Triassic, graben structures filled with clastic rocks and basalts formed in the Urals. They were deformed in Early Jurassic times.

The northern continuation of the Urals is a long-lasting debate. Some researchers suggested that Pai-Khoi and Novaya Zemlya represent its 'degraded continuation'. However, airborne magnetic data clearly suggest that magmatic arcs in the Polar Urals turn to the south-east under Mesozoic-Cenozoic sediments and might also be exposed in eastern Kazakhstan, forming a giant orocline. In the core of this orocline are Early and Middle Palaeozoic accretionary, magmatic arc and 1.0 Ga metamorphic terranes, identified on the basis of geophysical and drilling data. They are well exposed in the Kazakh uplands. The bulk of the Palaeozoic orogenic structures in Russia lie under the West Siberian sedimentary basin.

Mesozoic-Cenozoic Sedimentary Basins of Western Siberia

The West Siberian Basin is one of the three world's largest supergiant oil and gas reservoirs. It occurs between the Urals Orogen and the Siberian Craton (Figure 1). Its basement consists of various Neoproterozoic to Palaeozoic terranes that were amalgamated in the Permian. It has steep eastern and western borders and a flat bottom that dips to the north.

At the Permo-Triassic transition, all western Siberia experienced orogenic collapse which was followed by Triassic rifting and voluminous basalt magmatism of the Siberian Superplume. Rifts formed between the Urals and the Siberian Craton and in the western Kara Sea Basin. Urengoi is the largest rift, which was drilled down to a depth of more than 7 km. At the Triassic-Jurassic transition was a weak inversion and uplift, followed by post-rift subsidence for 4–7 km in the Jurassic-Cenozoic.

In Early-Middle Jurassic times, continental sedimentation dominated in the south, whereas there was a shallow-water marine environment in the north. The shoreline frequently migrated north or south. The dominant rocks are clastic alluvial, limnic, and marine sediments. In the Late Jurassic, the proportion of marine sandy and clayey sediments increased. At the Jurassic-Cretaceous transition, West Siberia subsided for 500 m, accompanied by the accumulation of the Bazhenovo oil-bearing facies which are enriched in organic matter. This subsidence was possibly facilitated by synchronous dextral strike-slip faulting along the western flank of the Siberian Craton.

In the Neocomian it became a relatively deep basin, which was quickly filled with sand-clay clinoforms. The main flux of clastic rocks was from the Siberian Craton and the Altai-Sayan Orogen. In the Aptian-Albian, the sedimentation environment became shallow-water. In the Late Cretaceous, Paleocene, and Eocene, the typical rocks are clay and sand with some cherty sediments. At the end of the Eocene, the northern part of the basin was uplifted and its link with the Arctic Seas was terminated. The Oligocene-Neogene in the central and southern parts of the basin is represented by shallow-water marine, limnic, and alluvial facies. Quaternary sediments are widely distributed. These are various sandy-clay facies which accumulated during several episodes of glacial and interglacial events and development of limnic-alluvial systems.

Circum-Pacific Orogenic Collages

The Circum-Pacific orogenic collages started to form in the Palaeozoic and their growth has continued until the present time. They occupy the Russian North-east and Far East. In the Russian North-east is the Verkhoyansk-Chukotka Orogenic Collage, bordered by the Nipponides.

Verkhoyansk-Chukotka Orogenic Collage The Verkhoyansk-Chukotka Orogenic Collage (Figure 10)

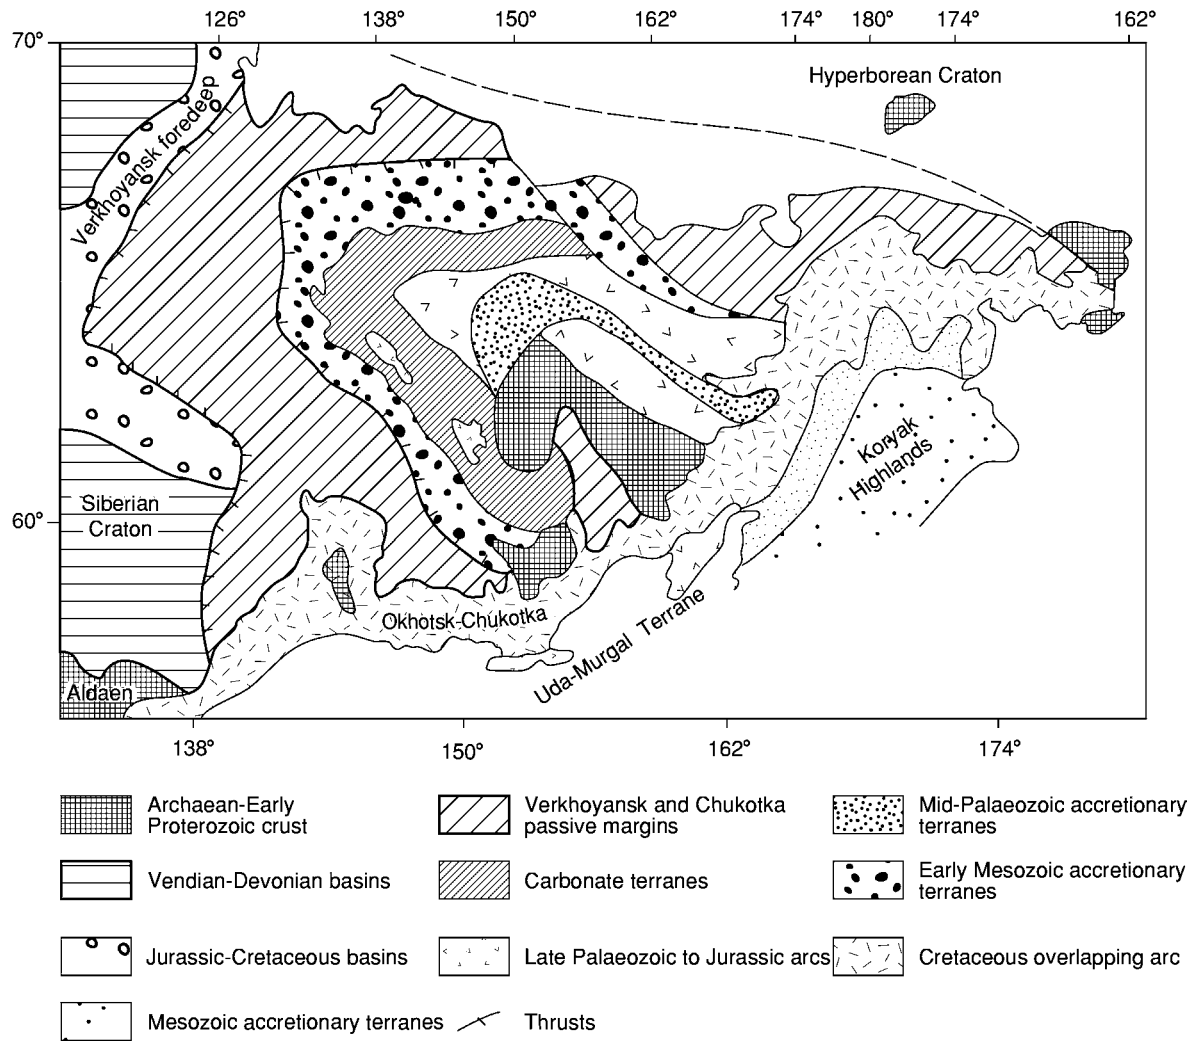

Figure 10 Tectonics of the Verkhoyansk Chukotka Orogenic Collage (compiled by Yakubchuk and Nikishin). Note oroclinal structure of the collage. Mid Cretaceous Okhotsk Chukotka Arc stitched the terranes that constitute the collage. Terranes of the Koryak Highlands represent an accretionary wedge that formed in front of this arc.

evolved from the Early to Middle Palaeozoic until the Cretaceous. In the north, it is bounded by the Hyperborean Craton. To the south-west is the Siberian Craton. The eastern boundary of the collage coincides with the Okhotsk-Chukotka Andean-type arc that stitched various terranes in the Late Cretaceous.

The Hyperborean Craton is a possible fragment of the North American Craton. It was incorporated into the collage after spreading in the Canadian basin in the Late Jurassic to Early Cretaceous. Plate tectonic reconstructions suggest that its arrival in the Early Cretaceous was the major reason for the amalgamation of the Verkhoyansk-Chukotka Collage. This craton occurs almost completely in the shelf zone, and its small fragments are exposed in eastern Chukotka, Novaya Sibir, and the Wrangel Islands. In the south, it is bounded by the deformed passive margin terrane of Chukotka and Arctic Alaska. It consists of Triassic-Jurassic terrigenous rocks deformed in the Early Cretaceous. In the south, the Chukotka Terrane is bounded by the South Anyui Suture, hosting Late Palaeozoic to possible Early Mesozoic ophiolites and accretionary wedges.

The Verkhoyansk passive margin is a mirror image of the Chukotka Terrane, but it includes Ordovician to Middle Jurassic turbidite sequences which are present in the imbricated structure thrust onto the Siberian Craton. These assemblages extend along the north-east margin of the Siberian Craton and can also be traced along the western flanks of smaller cratonal terranes of Okhotsk, Omolon, and Prikolyma, forming the Kolyma Orocline.

The Verkhoyansk passive margin rocks are structurally superimposed by the Jurassic accretionary terranes. Inside them, in the core of the Kolyma Orocline, are the Early Palaeozoic carbonate terranes

and Middle to Late Palaeozoic terranes of the Alazeya Arc which are overlain by the Middle–Late Jurassic to Early Cretaceous Uyandina-Yasachnaya magmatic arc. The opposite ends of this arc collided with each other in the Early Cretaceous to form the Oloy Suture which extends to the east towards the Nipponides.

The 2500 km long Okhotsk-Chukotka continental arc stitched this collage in the mid-Cretaceous. This arc was active from the Albian until the Eocene due to subduction of the oceanic crust under the Siberian Craton. It reveals classic transverse zonation and Andean-type retreat of its magmatism towards the continent in time.

Nipponide Collage The term Nipponides was proposed to describe the structures whose tectonic style is similar to the Japanese islands. In Russia, the Nipponide Collage occupies Sikhote-Alin, Sakhalin, Sea of Okhotsk, Koryak Highlands, Kamchatka, and the Kurile Islands, where it is growing due to subduction of the Pacific oceanic plate (Figure 11).

In Sikhote-Alin, these are Middle Palaeozoic to Early Cretaceous accretionary terranes and forearc

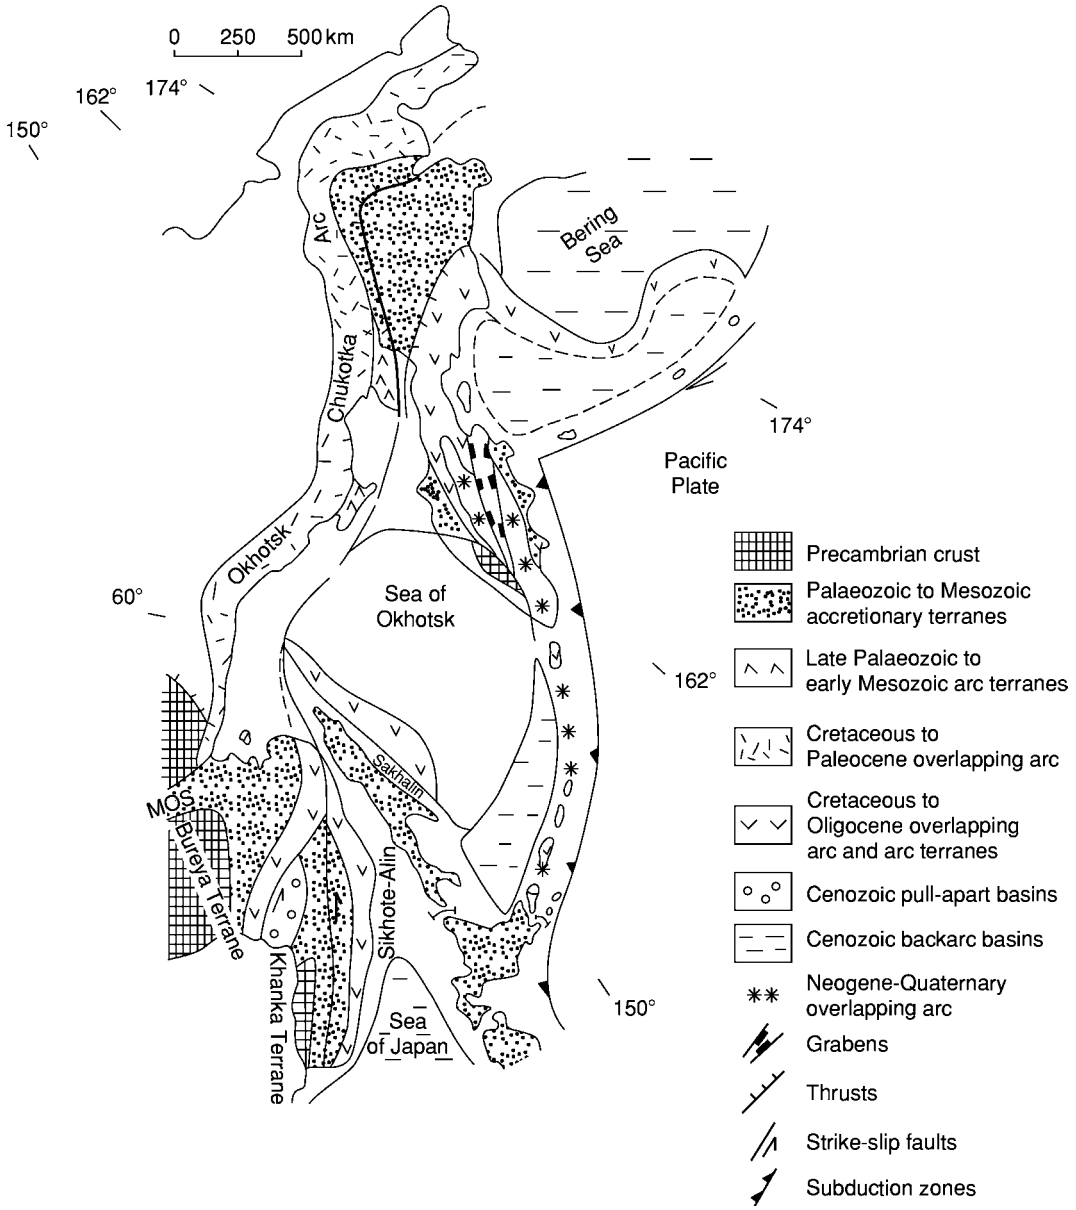

Figure 11 Tectonics of the Nipponides (compiled by Yakubchuk). Oroclinal bending and strike slip duplication is typical for the Nipponides. Behind the active subduction zone of the Pacific plate, new oceanic crust formed in the Sea of Japan and southern Sea of Okhotsk basins. The Central Kamchatka Graben represents back arc rifting.

turbidites. Similar accretionary terranes occur in front of the Okhotsk-Chukotka Arc in the Koryak Highlands. In Sikhote-Alin, they are overlain by another Late Cretaceous to Oligocene magmatic arc that extends towards the Sea of Okhotsk. Magnetic data and outcrops on the islands indicate that this arc turns to the south, so that the Mesozoic accretionary terranes of Sakhalin are squeezed between its two branches. The arc then turns to the north-east and continues to Kamchatka, where it forms several island arc terranes, continuing into the Aleutian island arc.

Inside this orocline is the Sea of Okhotsk. In the 1980s, a Precambrian cratonal terrane was proposed as its basement, but more recent work suggests that this is an accreted Cretaceous oceanic plateau. Whichever is correct, this structure is a major undeformed block inside the Nipponides.

Along the eastern flank of the Nipponides is the Kurile-Kamchatka chain of active volcanoes that have been superimposed on the older arc since the Neogene. In front of them are the actively growing accretionary wedges in the deep subduction-related trenches. Behind this arc are active back-arc basins with newly formed oceanic crust in the south of the Okhotsk Sea and Sea of Japan.

Alpine Belt

The Alpine Orogenic Belt intersects Russian territory south of the East European Craton, in the Scythian Platform located near the Sea of Azov and the northern Caucasus (Figure 1). Its sedimentary cover is 3–5 km thick. Its basement is intersected in numerous drillholes, but because of poor dating there are many problems in the interpretation of this region.

In its basement are the Karpinsky Swell and Scythian Orogen. The Karpinsky Swell is a buried eastern continuation of the Donets Basin that accumulated up to 15 km of Carboniferous shales. Devonian rifting was followed by formation of a Carboniferous back-arc deepwater basin was proposed to explain the Karpinsky Swell. This basin was deformed and thrust northward onto the Peri-Caspian Basin in the Early Permian. The structure of the Palaeozoic Scythian Orogen is poorly known, but in the Palaeozoic it was a continuation of the Greater Caucasus Orogen. The basement of the Scythian Orogen consists of Devonian and Carboniferous schists, Precambrian terranes, Palaeozoic ophiolites, and island arc terranes. Some interpretations suggest that this area was a Cordilleran-type orogen framed by the Palaeotethys Ocean to the south at the end of the Palaeozoic. In the Carboniferous to Early Permian, along the southern flank of the orogen in the Greater Caucasus, an Andean-type magmatic arc accompanied by molasse basins was formed. The other fragments of the orogen are in the Dzirula Massif in Georgia, the Eastern Pontides in Turkey, and Dobrudja in Romania. It was proposed to call it the Euxinian Orogen. To the west, this orogen continued into the Variscides of western Europe.

In Mesozoic to Cenozoic times, the Caucasus-Black Sea region had a complex history of a supra-subduction continental marginal system. In the Triassic, a back-arc basin represented by shales in Georgia and Dobrudja opened. In the Late Triassic, a volcanic arc formed in the north of the Greater Caucasus. At the Triassic-Jurassic transition, the entire north Caucasus region was deformed and its rifts were inverted. In the Early Jurassic, a Greater Caucasus deep back-arc trough was formed on the rifted and thinned continental crust. This trough was inverted in pre-Callovian times. In the Callovian to Late Jurassic, a new deep back-arc rift on the continental crust was formed along the present southern slope of the Greater Caucasus. This basin survived as a deep-water structure until the end of the Eocene, but it also experienced several phases of extension and compression. In the Middle Cretaceous, continental back-arc rifting occurred in the Black Sea and transformed into spreading in the West and East Black Sea Basins in the Late Cretaceous. At the Eocene to Oligocene transition, the main collision in the Greater Caucasus took place. Since that time Cis-Caucasus foredeeps – Kuban in the west and Terek-Caspian in the east – began to form. The collisional shortening in the Greater Caucasus is estimated to be at least 200–300 km, and the orogen was uplifted by 5 km. This elevation was a result of Arabian Plate collision, and it was accompanied by intrusive and explosive volcanism in such volcanoes as Elbrus. In contrast, the molasse basins subsided by 5–7 km.

Modern Plate Tectonics

Russian territory occupies two major modern plates. These are the Eurasian and North American Plates, and their boundary goes from the Arctic Ocean towards Sakhalin Island (Figure 12). In the ocean it is a spreading ridge, whereas in the continent it is a system of diffused continental rifts. It behaves as a transform (strike-slip) fault boundary near Sakhalin island. In the east, the North American Plate is bounded by a subduction zone of the Pacific Plate that produced the active volcanoes of the Kurile-Kamchatka Arc.

Some researchers subdivide the North American Plate into smaller plates, suggesting identification of

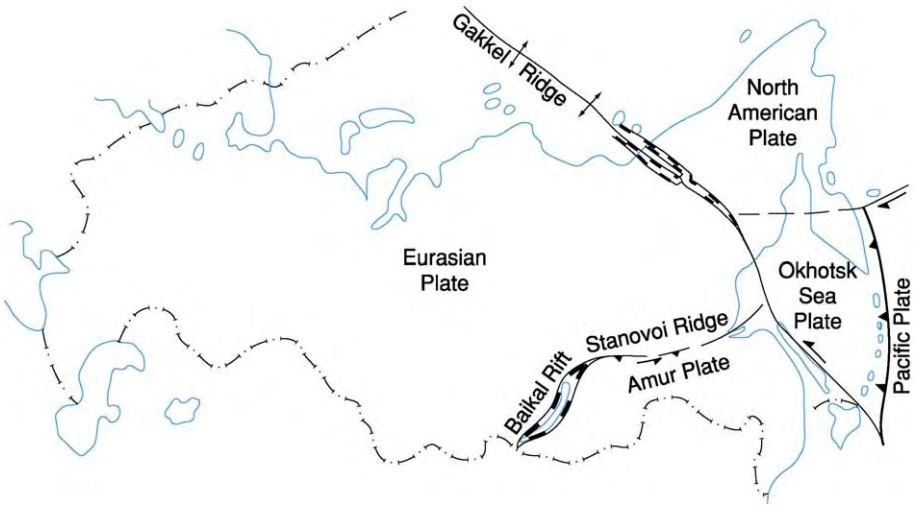

Figure 12 Modern plates in the territory of Russia (compiled by Yakubchuk and Nikishin). Parts of the two major plates of Eurasia and North America can be separated as smaller plates of Okhotsk and Amur.

a separate Okhotsk Sea Plate. Following the active seismic belt extending along Lake Baikal and the Stanovoy Ridge, it was proposed to recognize the area to the south as the Amurian Plate that includes most of (China *see* **China and Mongolia**). The Eurasian-Amurian plate boundary in this case is a zone of active continental rifting produced in response to India-Asia collision.

Mineral Resources

Russia has a large variety of mineral resources, many world class. Numbers on Figure 13 will be referred to as a basis for the following brief description.

Energy Resources

Russia is the world's second largest producer of oil and the world's largest producer of gas. Its supergiant oil and gas fields are in the Mesozoic-Cenozoic West Siberian Basin (Oil basin N1 in Figure 13). Smaller Cenozoic provinces are in the Scythian Basin (2) and in Sakhalin (3). Mesozoic oil is known in the Verkhoyansk foredeep (4). Middle Palaeozoic provinces are in the Cis-Urals (5), Pechora (6), and Lena (7) basins. Russia's significant coal resources occur in several basins. Palaeozoic coal is in the Donets (1) and Kuznetsk Basins. Most of the Mesozoic coal is in the Urals (2), Pechora (3), Kuznetsk (4), Bureya (5) and Aldan (6) provinces. The supply for generation of nuclear energy comes from a domestic source in Transbaikalia as well as from other CIS countries.

Mineral Deposits

Russia has enormous mineral wealth due both to the size of its territory and world-class quality of some of its deposits. Russia is ranked fourth or fifth in the world in terms of iron ore reserves. Its most productive deposits are in the Early Proterozoic Kursk Magnetic Anomaly (Fe-1), Palaeozoic intrusions in Karelia (Fe-2), and Triassic plume-related pipes in the Siberian Craton (Fe-3). Russia is the world's largest producer of nickel, whose ores are mined from the Early Proterozoic Pechenga deposit in the Kola Peninsula and lateritic deposits in the Urals, but most of the nickel production (as well as 50% of Russian Cu, 60% of the world's Pd and 20% of the world's Pt) is extracted from the Norilsk-Talnakh supergiant deposit formed during the activity of the Siberian Superplume.

Russia's other producing base metal (Cu-Pb-Zn) deposits are volcanic-hosted massive sulphides in the Middle Palaeozoic arcs in the Urals and Altai. Despite significant aluminium production, Russia has only small- to medium-size bauxite deposits, such as in Timan. Domestic tin production is almost suspended, but in recent years Mesozoic tin was extracted from Sikhote-Alin (Sn-1), Transbaikalia (Sn-2), and Yakutia (Sn-3). Russia is famous worldwide due to its precious metals and diamond production. 25% of the world's raw diamonds are extracted annually from the Palaeozoic and Mesozoic kimberlite pipes in the Siberian Craton, such as Mir (1), Udachnaya (2), Aikhal, and Ebelyakh (3).

In terms of gold resources, Russia is second in the world after South Africa. Russia's first gold mine was established in the Urals at the Berezovskoe deposit (Au-1) in the nineteenth century. Today most of production comes from the Yenisei Ridge (Au-2), Patom Highlands (Au-3), Aldan (Au-4), Far East (Au-5), Kolyma (Au-6), Indigirka (Au-7), Sette-Daban (Au-8), Chukotka (Au-9), Transbaikalia (Au-10), and eastern Sayan (Au-11). Russia's largest silver mine is at Dukat in the north-east. A new epithermal gold–silver province was discovered in Kamchatka. In addition to Norilsk, Russian Pt production comes from placer deposits in the Urals (PGE-1), Kondyor (PGE-2), and the Koryak Highlands (PGE-3).

SEAMOUNTS

S M White, University of South Carolina, Columbia, SC, USA

Introduction

Maps of the seafloor reveal a surface that is dotted with a vast number of cones and truncated cones, arranged in lines, grouped in clusters, or isolated. These are known as seamounts, the name given to any steep-sloped more-or-less conical feature on the seafloor. The overwhelming majority of seamounts are volcanoes. In fact, seamounts are the most common volcanic landform on Earth, but one of the least studied, owing to their wide dispersal and relative inaccessibility. As a consequence, much of the information presented here is derived from a small number of well-studied seamounts and applied to the general population of seamounts.

Seamounts are officially defined as volcanic cones on the seafloor with at least 1 km of relief. This distinction arose during the days of seafloor mapping with wide-beam echosounders when only these relatively large features could be unambiguously identified. Technological advances in remote sensing have improved our ability to locate and image seamounts of increasingly smaller size. Modern shipboard multibeam echosounders provide high-resolution maps showing the morphology and distribution of small (>50 m high) seamounts. Deep-towed sonars reveal tiny (<20 m high) seamounts along the axes of mid-ocean ridges. Satellite altimetry has enabled complete mapping of the ocean basins, but is capable of imaging only relatively large (>2 km high) seamounts. There is little scientific justification for a 1 km height cut-off for seamounts. All volcanoes start growing from the seafloor, regardless of their current size. For the purpose of this work, seamounts are defined broadly to include submarine volcanic edifices of any size.

Seamounts, ocean islands, and guyots form a natural continuum in the process of submarine volcanic construction from submerged, through emergent, to erosional. This article focuses on the processes that build and erode seamounts and their distribution in the oceans. The quasi-conical shape and volcanic origin of seamounts distinguish them from other relief-forming features on the seafloor, such as abyssal hills and carbonate reefs, which are not dealt with here. One exception is the process of serpentine mud volcanism, which builds seamounts in convergent-margin settings.

Geochemical and Geophysical Characteristics

Nearly all seamounts, aside from some in island arcs, are composed of basalt. Geophysical studies also suggest that seamounts have densities, magnetizations, and seismic velocities that are consistent with porous basalt. Most seamounts consist of a base layer of alkali basalt that grades into voluminous edifice-building tholeiitic basalt, which is capped by alkali basalt. Occasionally differentiation products of alkali basalt (hawaiite, mugearite, benmoreite, and trachyte) are observed in the latter stages of growth. However, not all seamounts exhibit all these growth stages, and small seamounts in particular may cease activity before reaching the main tholeiite stage. Smaller seamounts located near mid-ocean ridges have a composition that strongly resembles that of the lava erupted at the mid-ocean ridge but have a tendency to be both more primitive and more depleted than ridge-axis basalt.

Seismic, geodetic, and gravity studies have identified magma chambers beneath several ocean islands. Geophysical studies of the Kilauea volcano on Hawaii provide perhaps the clearest picture of a magma system anywhere. These studies define a partly molten conduit that rises to about 5 km beneath the summit caldera, with large blade-like dikes running laterally down the rift zones. Large positive gravity anomalies centred beneath many of the islands of French Polynesia suggest large (100 km^3) frozen magma chambers at shallow levels (2–4 km). At Krafla on Iceland, attenuation of seismic shear waves suggests a large

magma body (10–100 km^3) at a depth of 3 km below the surface. Small melt bodies that have been detected seismically in the uppermost mantle near the EPR (East Pacific Rise) may be evidence that even very small near-ridge seamounts have ephemeral magma chambers.

Distribution

Global Distribution and Spatial Arrangement

The earliest studies of seamount distribution and abundance in the ocean basins relied on estimates of height and volume obtained from single-beam echosounder crossings of seamounts. Since single-beam data provide only a cross-sectional view of the topography, with no guarantee of crossing the summit, approximations were required to estimate true seamount height and shape. Nevertheless, these early studies provided valuable indications of the distribution of seamounts in the ocean basins. Modern multi-beam echosounders have revealed the complexity and variety of seamount shapes and distributions, but still only cover regional areas (a few hundreds of square kilometres). The development of satellite altimetry has allowed the complete mapping of the larger seamounts in the ocean basins (Figure 1). Studies of seamounts suggest that satellite altimetry reliably detects seamounts that are at least 2 km high.

The global distribution of seamounts is best approximated by power-law models. Power-law models predict that there are in the order of 10^5 seamounts over 1 km high in the ocean basins and in the order of 10^7 seamounts including seamounts that are much less than 1 km high. Over 50% of all seamounts are found in the Pacific Ocean. Statistical studies of seamount distribution find very clear differences in the distributions of seamounts in different oceans and in different tectonic settings (Table 1).

Seamounts are distributed in several spatial patterns. The most widely known pattern is the seamount chain (Figure 2). In seamount chains, several very closely spaced individual volcanoes occur in a line. The Hawaiian–Emperor Seamounts are a classic example of a seamount chain. In this chain, as in many others, the bases of individual seamounts nearly touch or may completely overlap, but each volcano creates an individual peak. When seamounts are even more closely spaced, so that individual seamounts along the chain are difficult to recognize, the arrangement is called a volcanic or aseismic ridge. Aseismic ridges often occur along the track of a hotspot, for example the Ninety

East Ridge in the Indian Ocean. However, some aseismic ridges seem to emerge from mid-ocean ridges, such as the Sojourn Ridge and the Pukapuka Ridges in the southern Pacific. Seamounts also appear in clusters. Classic examples of the cluster pattern include the Mid-Pacific Mountains and the Hawaiian North Arch volcanic field. Finally, isolated seamounts are fairly common around fast-spreading mid-ocean ridges, where large numbers of very small seamounts (less than 1 km high) occur randomly on the seafloor.

Tectonic Setting: Intraplate Seamounts

The largest seamounts and the longest seamount chains known on Earth are intraplate seamounts. In the Atlantic, several intraplate seamount chains can be traced back to the edge of the continent, indicating 80–120 Ma of continuous activity. Probably the most famous example of an intraplate seamount chain, the Hawaiian–Emperor chain, stretches for 5000 km from its source to 80 Ma seamounts at its end (Figure 2). The oldest parts of this chain may have been subducted, so its true longevity is unknown. The Hawaiian chain also boasts the largest volcano on Earth: Mauna Loa (with an estimated volume of 42 500 km^3). What causes this great volume of volcanic activity is still a subject of debate.

The most widely accepted hypothesis for the origin of intraplate seamounts is that they are formed above hotspots supplied by mantle plumes (*see* **Mantle Plumes and Hot Spots**). The widely accepted model for hotspots states that they are fixed with respect to the Earth's centre of mass and thus leave a trail of consecutively older seamounts as the plate moves over the stationary hotspot. The trend and age progression of the hotspot seamount chain should record the absolute (relative to the Earth's centre of mass) plate-motion vector. The strongest evidence supporting the hotspot model is the linear arrangement and age progression along seamount chains. When a hotspot occurs underneath a mid-ocean ridge it can send out seamount chains or ridges on both sides of the plate boundary. The Carnegie and Cocos ridges from

the Galapagos hotspot, and the Walvis Ridge and Rio Grande Rise from the St Helena hotspot are two examples of this dual-ridge phenomenon.

However, many intraplate seamount chains fail to show the simple age progression predicted by the hotspot model. Cocos Island on the Cocos Ridge has lavas that are much younger than predicted by a simple age-progression model consistent with a hotspot origin. Likewise, the Line Islands, the Cameroon Line, and the Pratt–Welker chain show no regular age progression. The lack of age progression in many, even most, seamount chains has resulted in the advancement of several hypotheses to the explain them. Recent palaeomagnetic studies suggest that the hotspot source of the Emperor seamount drifted south at a rate of approximately 30 mm a $^{-1}$ before becoming stationary at 43 Ma. Several other seamount chains in the Pacific exhibit changes in direction near 43 Ma (the Gambier–Tuamotus, Gilbert–Marshall, and Austral chains) but the significance of these kinks in the seamount chains is not yet clear. Lack of age progression and hotspot fixity make it unlikely that all intraplate seamounts result from mantle plumes rising from the deep mantle. Other hypotheses for the origin of seamount chains are extensional stress across zones of pre-existing weakness in the lithosphere, feedback between plate flexure and tectonic stress, and small-scale convective rolls in the upper mantle.

Tectonic Setting: Mid-Ocean Ridges

Seamounts are most abundant near mid-ocean ridges (*see* **Tectonics:** Mid-Ocean Ridges). These seamounts are predominately small; thus, high-resolution bathymetric mapping is necessary to detect them. Most of the studies mapping seamounts near mid-ocean ridges rely on morphometric assumptions that they have an aspect ratio of 2 : 1 or less and that their heights are several times the resolution of the mapping instrument to distinguish them from abyssal hills or other tectonic seafloor topography. The near-ridge population consists mostly of seamounts less than 1 km high, with the overwhelming majority being small isolated seamounts less than 100 m high (Table 1). On slow-spreading ridges, such as the Mid-Atlantic Ridge, seamounts occur directly over the spreading axis within the rift valley of the ridge, while on fast-spreading ridges, such as the East Pacific Rise, there is no rift valley and no seamounts along the spreading axis. The largest on-axis seamount yet discovered (more than 5 km high) is on the ultra-slow spreading Gakkel Ridge, while recent surveys have found tiny (less than 20 m high) pillow-lava mounds as the largest edifices on the axis of the fast-spreading East Pacific Rise. Thus, seamounts over the spreading axis grow larger but become less abundant as the spreading rate decreases. However, small (less than 200 m high) seamounts are ubiquitous away from the axis of fast-spreading ridges and increasingly rare on slower-spreading ridges. Small but ubiquitous seamounts form on lithosphere younger than 0.2 Ma, regardless of spreading rate. This suggests that the thickness of the brittle lithosphere controls the near-ridge seamount population.

Many seamount chains originate at mid-ocean ridges. Near-ridge chains are typically shorter and composed of smaller volcanoes than the intraplate seamount chains. Near-ridge chains become more common as the spreading rate increases, with the largest seamount chains being associated with locations where the ridge axis exhibits signs of a high magma budget. For example, the Axial seamount on the Juan de Fuca ridge is a place where excess magma has produced the Cobb–Eikelberg seamount chain. The highest concentration of seamount chains is adjacent to the most inflated and shallowest part of the super-fast-spreading southern East Pacific Rise (Figure 3). Rarely seamount chains are found near fracture zones, but these are smaller lower-volume seamounts than those found near the middle of ridge segments. Unlike the hotspot chains discussed above, most near-ridge seamount chains are orientated between the direction of absolute plate motion and that of relative plate motion at the ridge. Most of the chains are aligned with the direction of shallow asthenospheric flow beneath the ridge flanks.

Tectonic Setting: Island Arcs

Seamounts occur in island arcs as a product of subduction-zone volcanism. Seamounts are distributed in a linear or curved pattern following the curvature of the trench. Tectonic segmentation of the arc by cross-faults creates discontinuities in the seamount distribution, illustrating the strong tectonic control on the distribution of volcanoes in island-arc settings. Seamounts in island arcs are more diverse in both morphology and composition than seamounts in the other two tectonic settings. The Izu–Ogasawara Arc

Figure 2 Bathymetry surrounding the Hawaiian Islands, a prominent intraplate seamount chain stretching across half of the Pacific plate (see inset), reveals several long rift zones and smaller seamounts. Volcanically and hydrothermically active Loihi, to the south east of Hawaii, is the youngest volcano in the chain. Reproduced with permission from Eakins BW, Robinson JE, Kanamatsu T, *et al.* (2003) *Hawaii's Volcanoes Revealed*. Geological Investigations Series I 2809. US Geological Survey.

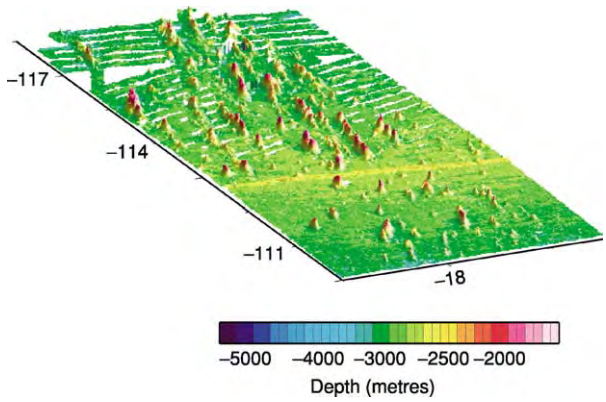

Figure 3 Seamount chains in the Rano Rahi Field adjacent to the southern East Pacific Rise. The shaded relief bathymetry reveals a remarkable abundance of seamounts near the part of the spreading axis with the greatest inferred magma budget in the region.

contains eight submarine calderas that have erupted large (more than 100 km^3) volumes of rhyolite pumice. In contrast, Kick-Em-Jenny, the southernmost island in the Lesser Antilles, is an island-arc seamount that has erupted 10 times since 1939, forming lava domes of basaltic magma within the summit caldera of its very steep-sided edifice. Almost every island arc has a number of seamounts that are smaller versions of the emergent volcanic islands making up the arc.

Mud volcanoes are a unique amagmatic type of seamount found in the fore-arc regions of several subduction zones. The widely accepted explanation for mud volcanism is the upwelling of overpressured serpentinite diapirs from the subduction décollement through normal faults in the fore arc. One of the largest and best-studied mud volcanoes is the Conical Seamount (25 km in diameter and 2 km high), which is located in the fore arc of the Marianas Arc. As more seafloor mapping is done along outer fore arcs, more examples of mud volcanoes are discovered.

Distribution through Time: Cretaceous Seamounts

During the Cretaceous (85–120 Ma) incredibly intense seafloor volcanism occurred throughout what is now the western Pacific (Figure 1). Not only were many of the large oceanic plateaus emplaced in the Pacific during the Cretaceous (Ontong–Java, Manihiki, Shatsky), but also the topography of the seafloor reveals a striking abundance of large seamounts (Mid-Pacific Mountains, Magellan Seamounts, Wake Guyots, etc.). Both the highest density of seamounts per unit area and the highest density of large (more than 3.5 km high) seamounts occur in the Pacific. Satellite altimetry data reveal that the concentration of Cretaceous seamounts is almost double that of Cenozoic seamounts.

Morphology

The vast majority of seamounts are predominately constructed of effusive lava flows. Thus, the overall shapes of seamounts are primarily controlled by the geometry of the magma plumbing system, the eruption rate, the lava type, and the local stresses on the volcano edifice. The cooling effect of water leads to the construction of much steeper edifices than those on land. Most seamounts have steep (10° – 30°) sides but nearly flat summit areas, in contrast to the low slopes of shield volcanoes (5° – 10°). As a seamount grows, it is subject to more complex stresses and tends to develop a more complex shape (Figure 4). In map-view, seamount shape evolves from nearly circular small seamounts to the more complex stellate forms of large seamounts and ocean islands. As a seamount grows larger, mass wasting from gravitational instability or wave erosion becomes more important in modifying its morphology.

Seamount Growth and Development

Deep-water stage Basaltic magma erupted under high hydrostatic pressure produces non-explosive eruptions forming edifices built from lava flows (Figure 4A). Repeated eruptions build extrusive edifices composed of pillow lavas with minor sheet lava flows. Intrusion of magma into the pelagic sediments on the seafloor produces a mixture of lava and wet sediment called peperite. Small seamounts (less than 1 km high and less than 10 km^3 in volume) usually form edifices that can best be described as low lava domes. Many seamounts even of this small size have relatively steep slopes and flat summits, unlike subaerial lava shields. Studies of small isolated seamounts near mid-ocean ridges show that a few seamounts of this size develop complex shapes, including relatively large summit craters. The seamount shape becomes generally more complex as the seamount grows. When seamounts reach a somewhat larger size (*ca*. 1 km high and 10–100 km^3 in volume) they more often have an irregular outline and an 'overturned soup bowl' or truncated-cone shape.

Shoaling stage Large seamounts (more than 2 km high and with volumes of over 200 km^3) may develop a stellate shape as a result of long rift zones concentrating lateral eruptions of lava from a central feeding system (Figure 4B). Not all large seamounts develop rift zones (e.g. Galapagos), but the rift zones on some seamounts become very pronounced ridges extending for more than 100 km (e.g. Hawaii). The presence of a magma chamber above the level of the seafloor and

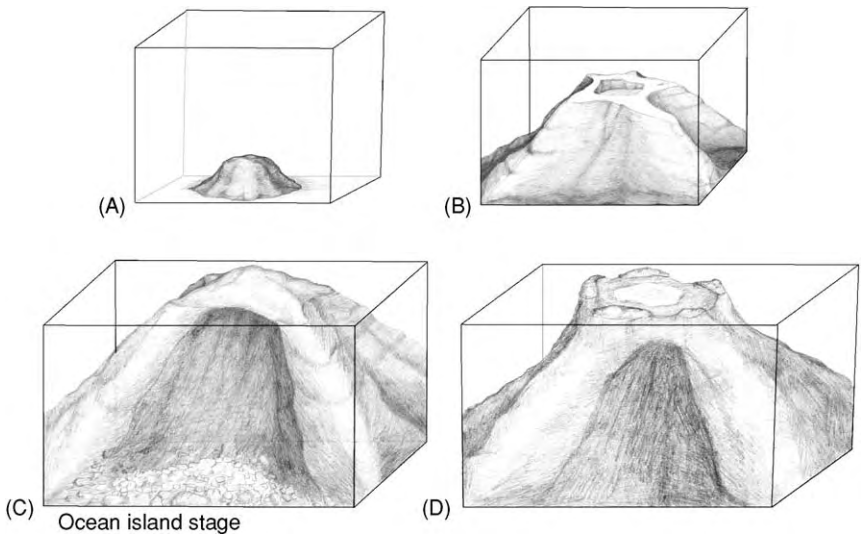

Figure 4 The growth stages of seamounts from (A) early deep water stage, through (B) shoaling stage, showing the development of rift zones, and (C) ocean island stage, including the development of a subaerial shield volcano and mass wasting, to (D) an atoll in the guyot stage.

within the edifice itself aids the development of rift zones on large seamounts by enabling lateral dikes and flank eruptions in focused zones of weakness. Within about 1 km of sea-level, reduced hydrostatic pressure allows exsolution of gas, and explosive eruptions become frequent. Lava flows of scoriaceous pillows and lapilli breccia become important lava types.

Emergent stage At sea-level, eruptions become surtseyan in type, producing fine-grained base surge and air-fall tephra deposits. Besides the famous and well-described eruption of Surtsey off Iceland (1963–1967), the only recorded observations during the emergent stage are from Graham Island (1831), Metis Shoal (1968, 1979), Myujin-sho (1952–1953), and Shin-Iwo-Jima (1986). Phreatomagmatic eruptions form tuff rings and cones consisting of easily eroded deposits of loose lapilli and ash. If eruptions stop at this stage, wave action will quickly erode the seamount. The small islands of Myujin-sho disappeared within months of formation.

Ocean island stage Once the volcanic vent rises above sea-level, phreatomagmatic eruptions become rare and effusive eruptions resume (Figure 4C). Pahoehoe and aa are the important lava types, and in most cases a lava shield is created from numerous low-relief lava flows. Giant landslides may cover the flanks of the island with debris from slumping or debris avalanches. Some of the largest landslides on Earth (involving volumes of 5000 km^3) have occurred around the Hawaiian Islands (Figure 2), and some studies speculate that up to 50% of the original volume of the older Hawaiian Islands has been lost owing to mass wasting.

Guyot stage Thermal subsidence and erosion combine to drown all islands after volcanic activity ceases. Wave erosion planes off a flat summit plateau, but the sides of the volcano remain steep, creating the distinctive guyot cross-section. Atolls (including the Marshall, Tuamotu, Kiribati, and Maldive Islands) are a type of guyot found in tropical oceans, where coral forms a fringing reef around an ocean island. If the upward growth of the coral reef keeps pace with the subsidence of the seamount, a ring of coral islands form, encircling a lagoon, and a thick layer of carbonate sediment develops, which caps the old seamount basement rocks (Figure 4D).

Why Seamounts Have Flat Tops

The characteristic steep-sided flat-topped shape of seamounts is a morphology rarely seen in subaerial volcanoes. The flat tops of guyots can be explained by wave erosion, but many seamounts with flat tops have never been near the wave base. Several models have been advanced to explain why so many seamounts have a summit plateau or flat-topped shape. It is still unclear whether one model can explain all the occurrences of flat-topped volcanoes, or whether each of various models is appropriate under certain conditions.

In the ring-dike model proposed by Batiza and Vanko, eruptions occur from a series of circumferential dikes encircling the summit area rather than from

a central feeder vent. The steep slopes and flat summits of the Galapagos volcanoes, which essentially have the same form as flat-topped seamounts, are attributed to lateral extension by ring-dike intrusion. Circumferential fractures observed in the summit areas of some near-ridge seamounts support the ring-dike model. Ring dikes are thought to form when magma stalls within the crust, creating a small laccolith. Ring dikes shoot upwards from the edge of the laccolith as it inflates. A variation on this model proposes dipping cone sheets instead of more vertical ring dikes as the intrusive body.

In the caldera-fill model proposed by Clague and others, large calderas form early in seamount growth and are filled by later eruptions. A repeated sequence of caldera collapse and re-filling allows the seamount to grow upwards and outwards while maintaining a flat top. This model is based on new high-resolution mapping that suggests that lava shields (erupted from central vents) formed on the summits of flat-topped volcanoes in the north-eastern Pacific.

In the neutral-buoyancy model proposed by Barone and Ryan, low-density basaltic crust counterbalances the buoyancy of the magma so that eruptions will rise only to a limited height. Seamounts will grow only to the height that balances the magma pressure in their magma chambers and will then grow laterally instead of upwards, forming a flat top. Other studies, however, have questioned why this model would lead to circular volcano outlines and what continues to drive eruptions once the critical height is reached.

Broader Effects of Seamounts

Subduction Asperities

Seamounts being subducted erode the fore arc and may also cause erosion at the base of the overriding plate. Huge furrows, mass wasting, and structural disruption of the fore arc are the effects attributed to seamount subduction (Figure 5). There are many areas that exhibit the morphological signs of seamount subduction, but proving the existence of buried seamounts depends on interpreting seismic and magnetic data. However, seamounts being subducted are sometimes directly visible, for example Daiichi-Kashima Guyot in the Japan Trench and the Bannock (Seamount) Structure in the Mediterranean. Seamount subduction may also be responsible for seismic asperities on the subduction thrust-fault interface. Seamount tunnelling, the process by which a seamount going down on the subducting plate scrapes material off the overriding plate, has been inferred to have an important role in crustal development and fluid flow in the margin. The subduction of large seamount chains and aseismic ridges coincides with a reduced dip angle in the subducting plate, for example in the case of the Juan Fernandez chain and the flat slab in northern Chile.

Hydrothermal Circulation

Active seamounts may host high-temperature focused hydrothermal flow. The Loihi seamount in the Hawaiian chain hosts high-temperature hydrothermal vents within its summit caldera, which are very similar to vents found at mid-ocean ridges (Figure 2). Most seamounts have neither the magma supply volume nor the longevity of Loihi, but sulphide hydrothermal deposits have been found on the summits of several other seamounts during submersible dives. These hydrothermal deposits indicate that seamount and mid-ocean ridge hydrothermal systems are broadly similar and contribute the same ions to seawater. Possibly more significant is the role that inactive seamounts play as basement outcrops that provide easy paths for the escape of fluid and heat.

Oceanographic Circulation

The topography created by seamounts has a large effect on the local water masses, primarily generating upwelling and enhancing currents. Anticyclonic circulation over the tops of seamounts creates a so-called 'cold dome' as a result of enhanced upwelling along the sides of the edifice. Also, long aseismic ridges and seamount chains are barriers to deep- and mid-water circulation. Aseismic ridges standing 2–4 km above the seafloor and stretching for hundreds of kilometres across the Pacific deflect north–south currents at depth.

Critical Habitat

Seamounts play a key role in ocean environments by providing habitats for fishes and suspension feeders. The enhanced upwelling combined with the potential for a reef environment in very shallow seamounts make large seamounts sites of high primary productivity. Seamounts have been known as productive fishing grounds for centuries, but their role in oceanic biodiversity has been appreciated only in the last 50 years. Seamounts host a relatively large percentage (estimated at 15–35%) of endemic species and may be important sites of speciation for deep-sea fauna. Seamounts in the south-west Pacific show highly localized species distributions and fairly limited recruitment among seamounts, even between closely spaced seamounts. The formation of atolls by coral growth on subsiding seamounts creates an important habitat niche for filter feeders and reef fishes. Finally, many humans find ocean islands and

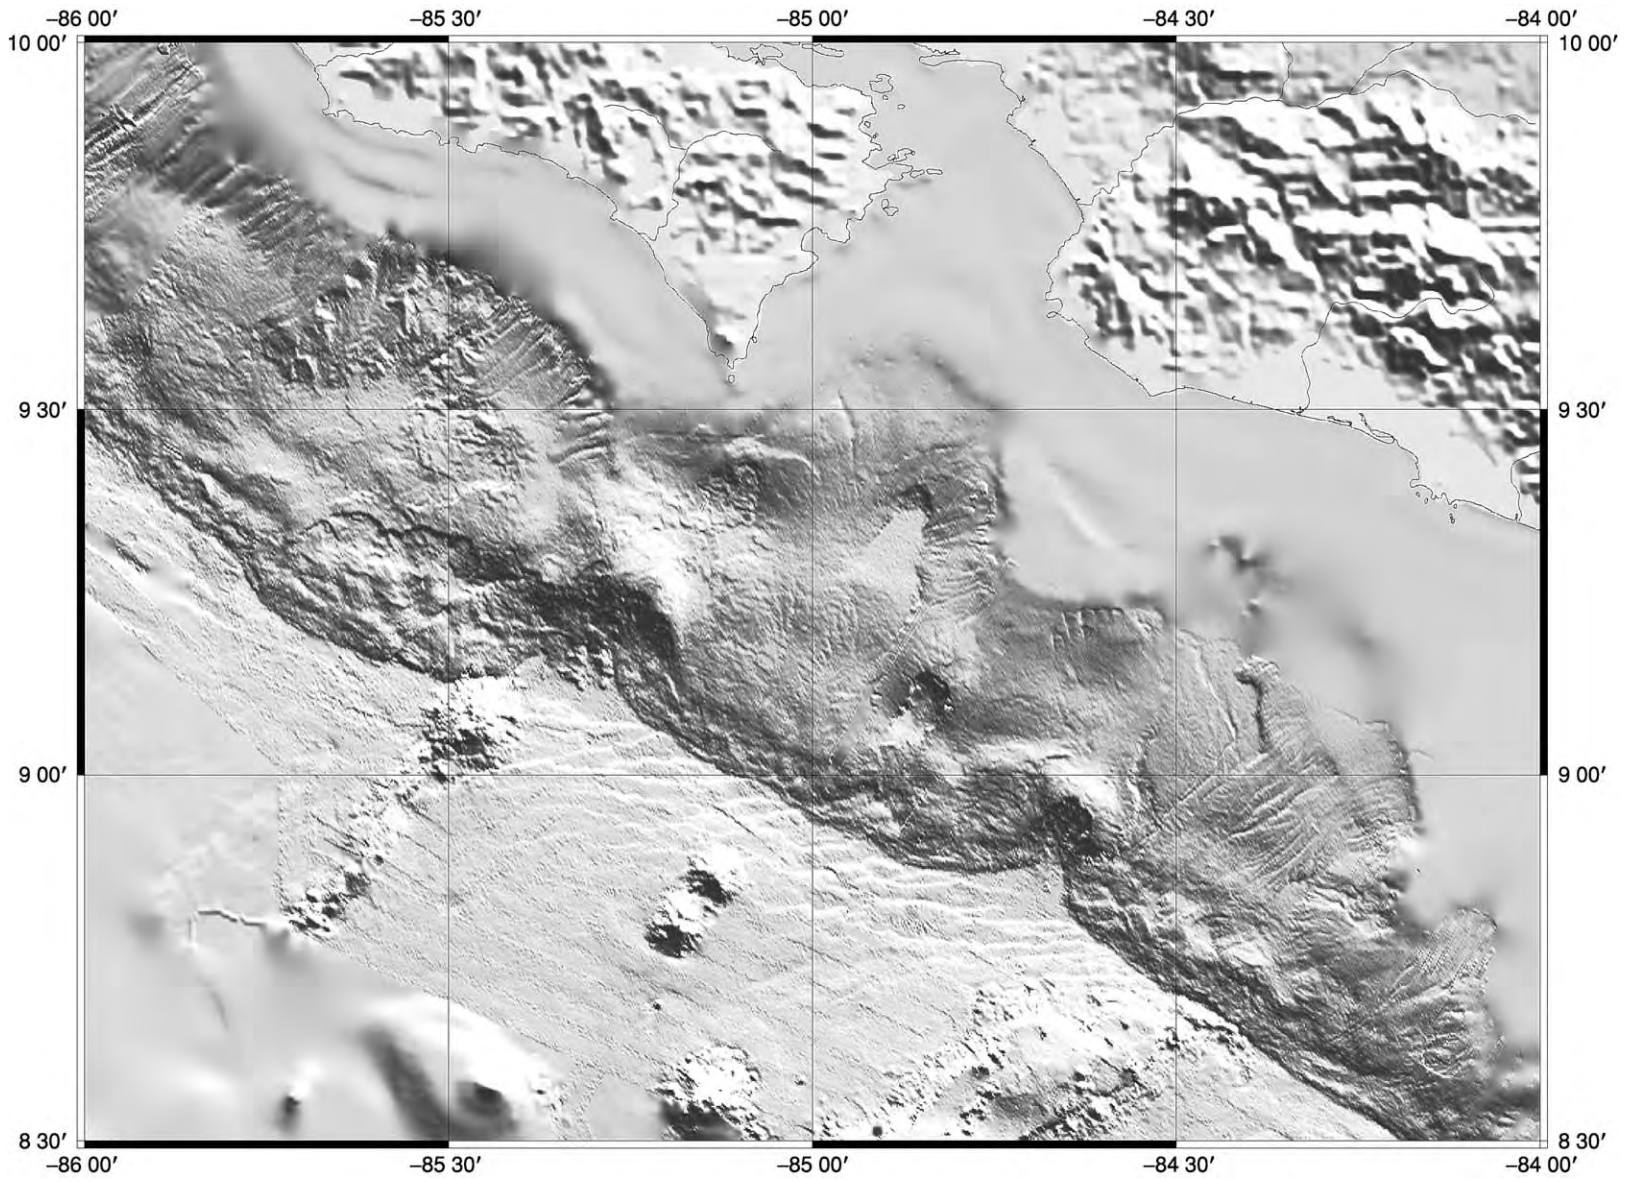

Figure 5 Seamount subduction has produced huge furrows and re entrants in the fore arc margin of Costa Rica. atolls highly desirable locations for settlement and vacation.

Glossary

Abyssal hill A low-relief elongate hill formed by horst-and-graben style faulting around a mid-ocean ridge.

Alkali basalt A variety of basalt that has relatively high sodium and potassium contents.

Atoll A ring of carbonate reef islands enclosing a lagoon built atop a subsiding seamount in tropical latitudes.

Pillow lava A type of subaqueous lava flow consisting of spherical or elongate tubes formed by the rapid quenching of lava. Tubes seen in cross-section often resemble pillows, with a flat base and a convex upper surface.

Scoria Glassy porous pyroclastic lava.

Surtseyan A type of volcanic eruption, based on observations at Surtsey in Iceland, which is the phreatomagmatic equivalent of a Hawaiian or quiescent lava flow eruption.

Tholeiitic basalt A variety of basalt characterized by the presence of orthopyroxene in addition to clinopyroxene and calcium-plagioclase.

SEDIMENTARY ENVIRONMENTS

Contents

Depositional Systems and Facies

J Collinson, John Collinson Consulting, Beech, UK

Introduction

The concept of facies as applied to sediments is a means of classifying and grouping deposits in such a way that objective differences, usually with genetic significance, are highlighted. In present-day settings, the relationships between processes and environments are self-evident, but in sequences of ancient sediment various analytical procedures are needed to reconstruct environments. 'Facies analysis' is such a suite of techniques and is based on an assemblage of facies and the relationships of the facies to one another. The results of facies analysis may be expressed as facies models, which summarize and, to some extent, idealize the relationships and allow the facies of a stratigraphical interval to be predicted in areas where it cannot be directly observed. Facies analysis also provides a major input to 'sequence stratigraphy' (*see* **Sequence Stratigraphy**), whereby facies successions are placed within a stratigraphical framework defined by key stratal surfaces that are related to changes in relative sea-level or base-level.

Facies

The concept of facies dates back to the early nineteenth century, when A Gressly introduced the term to summarize those descriptive features of a rock that distinguish it from other rocks. Historically, the concept has been applied at a wide range of scales and, therefore, with varying significance. At the largest scale, 'facies' has been applied to major stratigraphical units in particular tectonic contexts. 'Flysch' and 'molasse' are examples of this and are used particularly in the description of the Tertiary fold belts of Europe. At a large scale, 'facies' is also used to describe regional differences of depositional environment within a particular stratigraphical interval. For example, in Britain, one might contrast the 'basinal facies' of the Silurian of Central Wales with the coeval 'shelf facies' of the Welsh Borders. These usages are generally accepted and understood but, in order to arrive at an interpretation of the depositional environment, it is necessary to go through a process of facies analysis. This involves establishing an appropriate facies scheme for the succession being studied and then analysing the spatial relationships of those facies.

Facies schemes are established using a variety of physical, chemical, and biological criteria, and there is no such thing as a universally applicable facies system. Different sedimentary successions demand different schemes because of their contrasting character or because the intended end products of facies analysis may differ. A simple facies scheme may suffice for a rather basic interpretation, whilst a more elaborate scheme may be appropriate for a more refined interpretation. The facies scheme therefore depends on the scale and detail of the study.

In successions of dominantly clastic sediments, a facies scheme would commonly be based largely on

the physical properties of the sediments. Grain size is a common starting point for subdivision. Not only dominant grain size but also secondary features, such as sorting, might be considered. Any differences in composition would also be used for primary subdivision. A subdivision based on grain size may be refined by considering sedimentary structures (e.g. styles of lamination), so that facies such as 'fine-grained, ripple cross-laminated sandstone' or 'horizontally laminated siltstone' might result. Facies defined in this way are called lithofacies, and they can commonly be interpreted in terms of depositional processes by applying knowledge of the relationships between hydrodynamics, particle size, and sedimentary structures. However, many depositional processes occur in a range of sedimentary settings, and, therefore, few lithofacies are fully diagnostic of depositional environment.

Other features, formed soon after deposition, permit more refined facies schemes. Bioturbation by animals or plant roots can provide clues about the environment, and highly distinctive facies such as coal may also allow a specific environment of deposition to be deduced. Where burrowing is important, the assemblage of burrow types and the intensity of burrowing may necessitate schemes of ichnofacies. Early-formed concretions and textures in palaeosols can indicate the drainage conditions of emergent surfaces soon after deposition and can lead to pedofacies. If sediments are fossiliferous, the types and diversities of the fossils may lead to biofacies, and consequent facies analysis may incorporate palaeoecological considerations. Analysis of very fine plant debris or spores may lead to palynofacies.

For carbonate sediments, the nature of the constituent grains is important in establishing the depositional setting, and their characterization through petrographical description may lead to microfacies. In complex sequences, combinations of these different approaches may be appropriate.

Where two contrasting lithologies are interbedded, it may be appropriate to recognize event deposition (Figure 1). In many successions of interbedded muds and sands, sand beds commonly have sharp bases and may show internal grading and vertically changing styles of lamination. They were clearly deposited by sudden high-energy events in otherwise low-energy settings. Establishing the nature of the events may depend on interpreting quite subtle features of both the sand beds and the finer interbeds. Where the muddy component lacks evidence of higher energy and the sands show only current-generated structures and lamination, the events are likely to be turbidity currents in a deep-water setting. If the finer sediments are strongly bioturbated and show signs of fluctuation energy and the sand beds show evidence of wave action, perhaps reworking their tops, then storm events on a shelf may be the appropriate inference. If the finer sediments show evidence of emergence, with soil textures, and the sands are current dominated, then river floods (crevasse events) on a floodplain may be the appropriate interpretation. In all these cases, it would be valid to regard the finer and coarser components as separate facies, but it may prove practical to use composite facies based on the thicknesses and proportions of the coarse and fine components. This approach is particularly applicable to turbidite successions.

Figure 1 Interbedded sandstones and mudstones showing the distinction between the quiet background sedimentation of muds and the high energy events that delivered the sands. In this case, the high energy events were turbidity currents in a deep water marine setting. Paleocene, Zumaia, Spain.

Facies Analysis

Most facies defined according to the criteria outlined above may be interpreted in terms of processes of deposition, but these are seldom unique to a

particular environment. In order to identify the depositional settings of ancient sediments, it is necessary to understand the processes active in present-day environments and the ways in which sediments are deposited and preserved there. In other words, it is necessary to interpret the patterns of facies seen in the rocks by comparison with the patterns of processes established in modern settings. Understanding the interrelationships of facies and processes allows environments of deposition to be inferred with greater precision.

Process-based facies analysis, which began in earnest in the early 1960s, concentrated initially on understanding the vertical succession of facies observed in a borehole core or stream section. Key to this approach was an appreciation of the importance of the nature of the contacts between vertically adjacent facies. In some cases, the contact is a gradational transition, whilst in other cases it is sharp or even erosive. These distinctions are important in interpretation, which is usually based on the application of Walther's Law of the Correlation of Facies, which was first formulated in 1884, but has been applied critically only since the late 1950s. This law, simply stated, points out that facies that are laid down side-by-side in their depositional environment will come to lie vertically on top of one another in the same order as their lateral distribution, or, conversely, only those facies that are superimposed one upon the other without a break can have been deposited in laterally adjacent settings (Figure 2). The importance of the nature of the vertical facies contacts is apparent in Figure 2, which shows that an erosion surface can allow the superposition of facies deposited in widely separated settings. Sedimentary hiatuses can have the same result. A rapid transgression can lead to shallow-water facies being directly overlain by deep-water facies, with facies representative of intermediate environments missing across the contact because of a lack of deposition or condensation, though not necessarily requiring a temporal break in sedimentation.

Some facies successions show systematic trends of vertical change, expressed through grain size or other properties. In other cases, a less organized succession may occur. Trends of vertically increasing and decreasing grain size (coarsening-up and fining-up units) are amongst the most common patterns encountered in clastic successions, and these may, for example, be equated with prograding shorelines and laterally migrating channels, respectively (Figure 3). Such facies trends may occur as single examples or as vertically repeated patterns. Where repetition occurs, successions are commonly described as cyclic, and the idea of cyclic sedimentation has a history extending back to the early nineteenth century. In cyclic successions, it is important to distinguish between interpreting the facies sequence within cyclothems (i.e. the environment) and explaining the cyclicity (i.e. the repetition). Facies patterns may repeat vertically because of inherent properties of the depositional environment, such as the tendency for river or distributary channels to switch positions on a floodplain or delta top. Such processes are termed autocyclic. Where external controls, such as fluctuating sea-levels or subsidence rates, are thought to cause the repetition, the processes are termed allocyclic.

In cyclic successions, it is rare for all cyclothems to show an identical facies sequence. Rather, they are variations on a theme (Figure 4). Various statistical techniques can be employed to extract a 'complete' or 'ideal' cyclothem, the interpretation of which can be developed into a facies model. However, it is also instructive to consider the variations in the facies successions of cycles and their relationships with the ideal cycle, since the variability itself may help to refine the model. For example, a series of coarsening-up cycles may record successive progradations of a delta, whilst the differences between individual cycles may reflect differences between subenvironments of the delta, stacked in vertical succession through autocyclic delta-lobe switching. Comparison of the facies in the upper parts of several

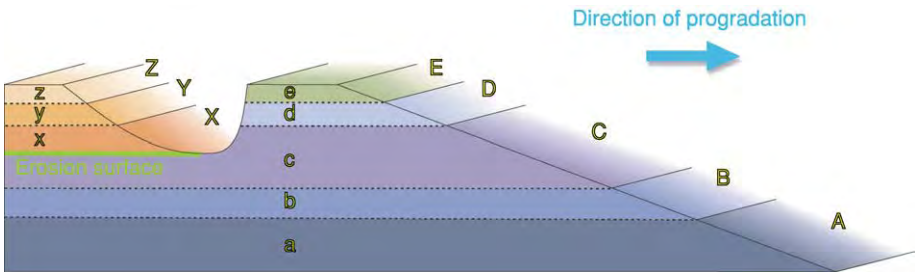

Figure 2 An illustration of the operation of Walther's Law of the Correlation of Facies. The subenvironments A E lie side by side and, through progradation, generate a vertical facies succession a e. The development of an erosion surface through the migration of a channel triggers a new facies sequence, x z, which is independent of the earlier one. The erosion surface separates facies that were generated in settings that have no predictable lateral relationship.

Figure 3 A large scale coarsening up unit generated by the progradation of a major delta. The unit ends abruptly at a flooding surface (arrowed), above which are stacked smaller scale coarsening up units (parasequences). Namurian, County Clare, Ireland.

cycles may lead to inferences about the variability of the delta front and delta plain and hence allow a more refined characterization of delta type. The validity of such an approach depends, of course, on the successively prograding deltas having been of broadly similar character.

In successions where no cyclicity is apparent and no patterns of vertical facies change can be identified, mathematical investigation such as Markhov chain analysis may help to detect an underlying pattern beneath the random noise. However, the demonstration of statistical significance may be limited by insufficient data.

Architectural Elements and Bounding Surfaces

Where sedimentary successions are very well exposed in extensive desert or coastal cliffs, it is clearly not sensible to rely solely on the vertical sequence of facies to reconstruct the depositional environment. Lateral facies relationships, where they can be

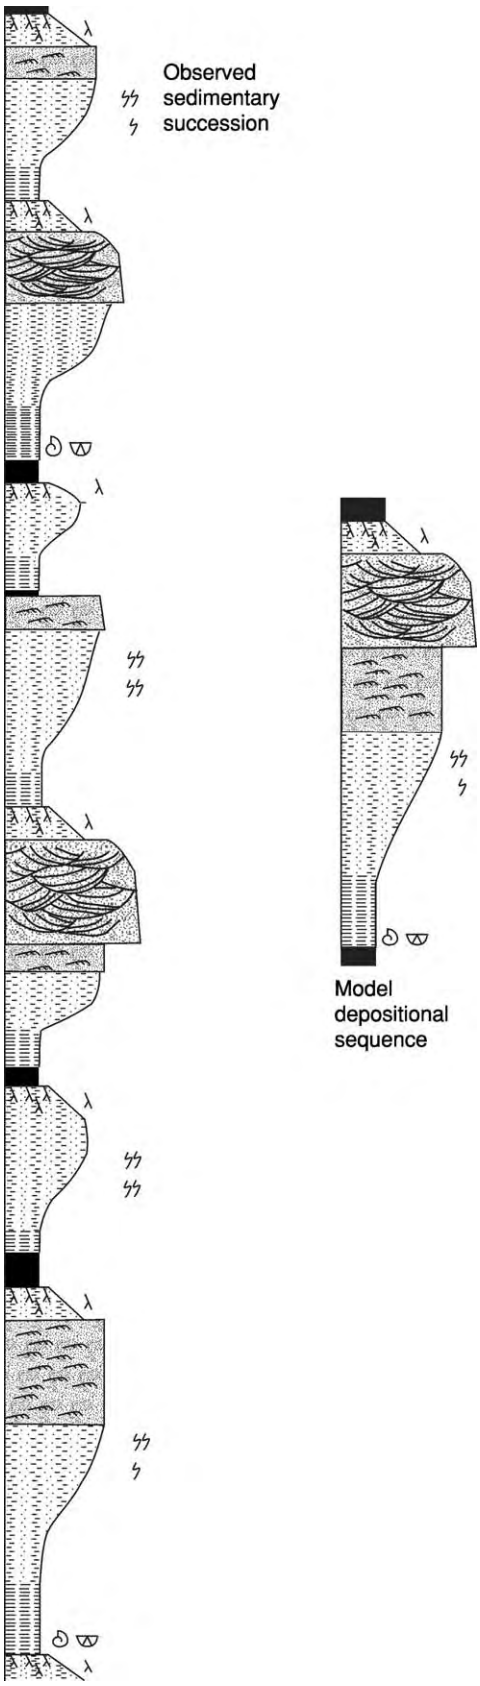

Figure 4 The facies succession of an idealized model cyclothem compared with the observed facies successions upon which it is based.

observed, are highly instructive, and the two- and three-dimensional shapes and sizes of facies units may be highly diagnostic. Lateral changes in facies or in the thicknesses of facies units (architectural elements) may help to localize particular elements of the depositional environment. For example, the thickening of crevasse splay sands within a floodplain succession may be linked to the proximity of a channel sandstone.

Laterally extensive exposures may reveal subtle low-angle dipping surfaces that would remain undetected in one-dimensional sections such as borehole cores. Such surfaces may be confined within channel sand bodies, indicating lateral accretion of the channel or downstream accretion of a channel bar. They may also occur on a larger scale within coarsening-up units such as progradational clinoforms deposited in a delta-front setting. Such surfaces contribute to facies definition and, more importantly, they aid interpretation by constraining the context of the facies.

Within complex channel sandstones, the usefulness of Walther's Law is often limited by abundant erosion surfaces. In a narrow one-dimensional section, the significance of a particular erosion surface may be difficult to establish. The basal erosion surface of a channel sand body, where it rests on contrasting, probably finer-grained, facies, is likely to be extensive, but erosion surfaces within the sand body, perhaps picked out by pebble-lag or intraformational conglomerates, may have more local significance. Within large complex channel units, laterally extensive exposures commonly show that erosion surfaces fall naturally into a hierarchy of scale, lateral extent, and genetic significance. The bodies of sediment that they bound are termed architectural elements, facies building blocks of differing genetic significance that are linked to the geomorphology of the channel system (Figure 5). Within aeolian dune deposits, similar hierarchies of bounding surfaces are critical to the discrimination of dunes and larger compound bedforms.

It is clear that the more fully the three-dimensional patterns of facies are established, the more precise can be the environmental interpretation. Where only subsurface data are available, the one-dimensional facies information provided by boreholes may sometimes be suitably supplemented by three-dimensional seismic data. However, in most cases, the lateral extent of facies units and lateral facies relationships must be predicted intuitively using Walther's Law and judiciously chosen analogues, usually from extensive outcrop exposures.

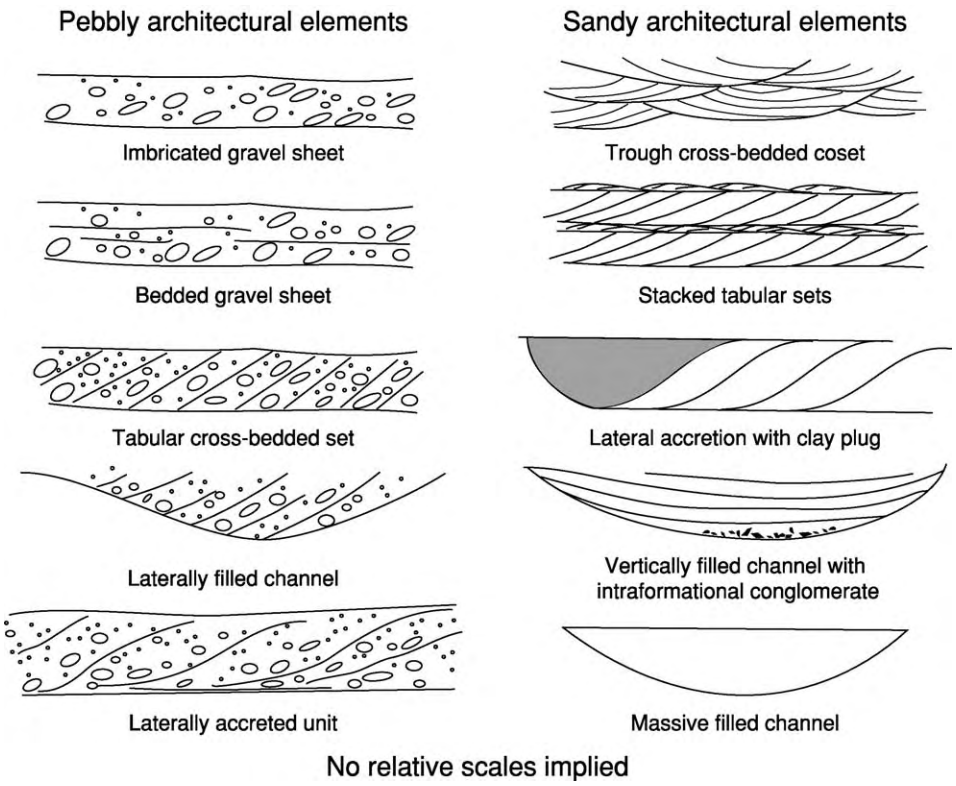

Figure 5 Examples of the various 'architectural elements' that can commonly be identified in alluvial channel deposits. The architectural elements are the products, usually only partially preserved, of various morphological features (bedforms, bars, channel fills) that occupied the channel floor.

Facies Models

Facies models are attempts to summarize the essential aspects of facies sequences and relate them to inferred depositional environments. They are usually most effectively conveyed graphically as three-dimensional block diagrams that relate the environment and its behaviour to the facies pattern. Facies models have been proposed for most major depositional environments, and there is a large measure of consensus about their general aspects, particularly for fluvial, aeolian, deltaic, and other shallow-water settings. For deep-water sand settings, differences of opinion about what constitutes a 'submarine-fan model' have largely been resolved by recognizing that there is a whole spectrum of fan types and, accordingly, a spectrum of valid models. General rather idealized models of major depositional settings have their place as educational tools. They also form a basis with which to compare an actual sedimentary succession, where differences between the ideal and the actual may be important in refining the interpretation. However, it is important to recognize that some settings are inherently more organized and predictable than others and that lateral variation takes place on a variety of scales. This is important when a model is used to predict the nature of a succession between or beyond known data points. In a well-organized setting, it may be appropriate to build a predictive model that is deterministic, and predicted interpolations and extrapolations can be expected to reflect reality closely. In more complex, less organized settings, the stochastic component means that such predictions must be generalized and expressed in probabilistic terms.

Sequence Stratigraphy and Key Surfaces

At outcrop or in a borehole section, the establishment of a sequence stratigraphical framework depends on distinguishing key surfaces of potentially widespread significance that can be related to episodes of rising or falling base level, which in marine settings is relative sea-level, in lacustrine settings is lake level, in fluvial settings is the graded fluvial profile, and in aeolian settings is the water table.

Erosion surfaces at the bases of channel units or elsewhere in a sequence are, in many cases, simply consequences of the depositional processes operating within the environment, for example the migration of a river channel on a flood plain. Such surfaces are autocyclic and have only local significance. Other channel bases may have much more widespread stratigraphical significance and may be related to valley incision caused by a fall in base level (i.e. allocyclic control) (**Figure 6**). These are one expression of sequence boundaries in sequence stratigraphical terminology. Distinguishing between the two types of erosion surface can be difficult, based on features of the erosion surface alone, especially

Figure 6 A major erosion surface (arrowed) at the base of a thick multistorey channel complex. The erosion surface is regional in extent and has a mapped relief of several tens of metres. It is inferred to be the base of an incised palaeovalley and would be regarded as a sequence boundary, related to a major fall in base level (relative sea level). Namurian, County Clare, Ireland.

where local channel bases are nested within a larger-scale palaeovalley. However, deeper incision as a result of base-level fall may cause the erosion surface to cut down into facies that differ from those beneath autocyclic channel bases. Outside the confines of an incised valley, the long-term emergence of the sedimentary surface and the resulting nondeposition may allow highly mature soil profiles to develop, so that recognition of palaeosol facies in interfluve areas may have widespread stratigraphical significance. Non-erosive sharp contacts at the bases of coarser facies may also indicate that regressions were forced by falling base level. Falling base level or relative sea-level, therefore, may be manifested in a variety of different ways leading to uncertainty in discrimination and correlation.

Rises of base level or relative sea-level produce more uniform facies expressions, as they tend to be associated with transgression and a cut-off of sediment supply to more distal settings owing to sediment being trapped closer to its source. The results are flooding surfaces (**Figure 3**) characterized by condensation, often to the point of nondeposition. In marine settings, such surfaces are commonly characterized by intense bioturbation, reflecting the increased time available for animals to rework the sediment before burial. When flooding occurred in humid near-emergent settings, peat developed as plant productivity balanced increasing accommodation space. Coal seams, the compacted products of peat, may be of local or regional significance. Where flooding occurred through autocyclic processes, for example by cut-off of sediment supply through distributary switching on a delta plain, the seam extent reflects the area of an interdistributary bay or floodplain lake. Where the control was allocyclic, coal seams may be regionally important stratigraphical markers. Flooding surfaces, however expressed in the sediments, commonly mark the bases of coarsening-up units, termed parasequences, that record the progradations that eventually filled the resulting bodies of water. Where flooding is associated with the transgression of a high-energy shoreline, the transgressive surface may be an erosional pebble lag ravinement surface, separating nearshore sediment below from more offshore sediment above.

Alluvial Fans, Alluvial Sediments and Settings

K D Jäger, Martin Luther University, Halle, Germany

The term alluvia (alluvions) comprises clastic sediments, deposited by the running water, on river bottoms as well as on the surface of adjacent riverside areas inundated temporarily by floods. This material has to be attributed to the particular catchment area. Within the respective boundaries the sedimentary material supply is dominated by the area shared by open ground where protection by the vegetation cover has been reduced or entirely removed. Consequently, forest clearance, as well as arable land, have caused soil erosion by the clearance, development, and use of this open ground.

The varying intensity of soil erosion during different historical periods following each other reflects – especially in manmade landscapes – the alternating intensity of settlement and agrarian landuse over the course of time. This interrelation may be exemplified by numerous archaeological datings of alluvial layers in stratigraphical sequences of riverside exposures. Frequently, the dated development of such layers is linked with events structuring the development of settlement and landuse.

The petrographic composition of alluvial deposits reflects the superficial substrates (as rocks or loose earth masses) of the particular catchment area. However, the composition is dominated by components from superficially exposed open ground.

Consequently, since the first occurrence of agriculture, more and more alluvial deposits came into being. However, regional chronological differences of the global advance of agriculture have to be considered. As a rule, alluvions have been originated and developed during the Holocene to date. Moreover, usually the deposits are still unconsolidated.

The composition of alluvions is determined substantially, but not exclusively, by the material supply from the particular catchment area. Other decisive factors consist in continuity, discontinuity, and velocity of water flow. Their effect is reflected by the granulation of the sediment: high flow velocity results in course granulation, less velocity in fine granulation. Therefore, mainly gravels and sands occur more often at the upper courses of running waters provided with steeper inclination, for example, in mountain terrains. On the other hand, courses characterised by low inclination, as in the lowlands and near to the mouth of rivers, result in clay deposition. Frequently, the granulation of the deposits is mixed, and this feature is reflected by the nomenclature of alluvions in many languages as German ('Auelehm'), Russian ('пойменная глина'), Czech ('nivní hlína'), whereas other terms try to avoid a concrete relation to the granulation of the deposit as English ('alluvium'), French ('alluvion'), or the proposed German term 'Klock' (adapted from popular use in Lower Lusatia). Independent of granulation, is the term alluvial substrates, soil types in pedological nomenclatures using the term 'vega' (from the Spanish meaning of 'riverside').

On riversides, a two-dimensional differentiation of the distribution of alluvial deposits frequently occurs and corresponds to regular patterns. The pattern of superficial relief differentiation is determined by the buildup of embankments and channels. The spatial differentiation of processes and patterns of the relief, as of the sediment distribution on riversides, has been modified frequently, especially as a consequence of extreme flooding of the respective rivers. Therefore, a high- and narrow-scale heterogeneity characterises the area of stratigraphical subdivision of alluvions. A temporal modification of the spatial pattern of the riverside has been exemplified in the case of the lower Vistula in Poland.

Frequently, the alluvions are linked with alluvial and colluvial fans. The former occur at the confluence of tributaries to their main valley, the latter mainly in slope foot positions of the riverside margins. Floods from tributaries can rearrange the superficial shape of the stratigraphy of alluvions in the respective main valley, too, which has been exemplified by detailed investigation in the region of Ulm (Germany), where the River Iller flows into the Danube (so-called 'Iller-Schwemmkegel'). The appearance of colluvial fans covering flood-plain soils, concealing alluvial deposits, has been proved recently by examples from the Upper Rhine Lowlands region surrounding the Kaiserstuhl massif: Endingen, Emmendingen. A common feature of these investigations, with other detailed stratigraphical studies devoted to the alluvions in the valleys, is provided by archaeological observations proving precise Holocene origin. These datings include two other important indications. They are evidence of man's presence and impact on the landscape by irrigation and drainage works, as well as soil erosion, as a consequence of land use. On the other hand, the datings prove the alternation of sedimentation and erosion, respectively, incision into previous valley bottoms with their alluvions, as well as into alluvial fans.

The same situation for determining datings and the sequence of processes and events is valid regarding the stratigraphy of alluvions in more extended riversides and main valleys. The detailed regional examination and the comparability of the results may be exemplified by the studies described in the further reading section at the end of this chapter.

Sometimes the archaeological datings of single layers within alluvial strata evidence the covering of ancient sites of human presence and settlement by subsequent floods, as is the case of urban centres connected with the medieval Slavonic state of Greater Moravia (actually in Czechia: Pohánsko, Mikulčice, Staré Město, and Uherské Hradiště).

Other chances of achieving more specific and precise dating of the sequence of Holocene events and processes in the stratigraphy of alluvions, are provided by trunks of trees engulfed by the fluvial deposits. Trunks have been found frequently, for instance, in many central European valleys, as Elbe and Spree, Rhine and Main, or the Danube with its tributaries. In the German literature, they are called 'Rannen'.

On a regional scale, there are numerous trunks within the sediment. In the brown coal seams of central Germany (Saxonia, Saxony-Anhalt, Lusatia) the respective fluvial deposits are frequently well-exposed. However, independent of the conditions of exposure, these trunks have provided the opportunity of dendrochronological datings. Using this method can be applied to examination of the valley development in many cases. This may be exemplified for some catchment areas in central Europe as that of the Danube and its tributaries, or that of the River Main.

The regional development of valley-net systems is reflected by the stratigraphy of alluvions. A detailed documentation of varying stratigraphical observations in different parts of one and the same valley-net illustrates the regional differentiation in the course of events. This differentiation has been exemplified carefully in the case of the River Vistula (Weichsel) with its tributaries in Poland. The chronological foundation of this investigation has been completed by radiocarbon datings and pollen analysis.

However, in other parts of temperate Europe, careful and detailed stratigraphical examinations have covered different sections of the same catchment area. Such investigations may be exemplified by the valley system of the River Severn in the British Isles (counties of Shropshire and Worcestershire, England).

Alternating layers in the stratigraphy of alluvions reflect temporally changing conditions of accumulation, as in single valleys or valley segments, such as completely examined valley-net systems. These changes record climatic consequences, with the varying amount of precipitation in the respective catchment area and its temporal peaks caused by floods. They also reflect the changing intensity of human impact influencing the sedimentary yield of the respective river or creek. This yield comprises effects resulting from the extension of open grounds, forest clearance, and utilisation of arable land in the respective catchment area.

The same causes have ruled the origin, development, and stratigraphy of alluvions in the Mediterranean. Evidence has been provided previously for the Mediterranean and more recently, in particular, from the Iberian Peninsula.

In all the investigated catchment areas, the effect of human impacts depends on the respective regional course of settlement and land-use intensity. The climatic causes take effect in extended regions of the European continent in a comparable way. However, the detection of palaeoclimatic fluctuations, and especially of oscillations of the water balance in the course of the Holocene, is based on other stratigraphic observations as in exposures of freshwater lime deposits. Among geostratigraphical, palaeontological (especially palynological and palaeomalacological), and archaeological evidence supporting the resulting concept concerning the palaeoclimatic development during Holocene, the stratigraphy of alluvions claims an important but not essential role.

Related to the youngest alluvions, historical record archives especially support the linking of distinct stratigraphical facts with particular palaeofloods.

However, irrespective of all other sources clarifying the palaeoenvironmental development as a whole and on the valley bottoms in particular, significant contributions to the reconstruction of previous conditions during the Holocene are provided by the alluvions and their stratigraphy.

Anoxic Environments

P B Wignall, University of Leeds, Leeds, UK

Introduction

Nearly all modern environments, on both land and sea, are well oxygenated, thanks to the ample levels of oxygen available in the atmosphere. This also seems to have been the case for much of Phanerozoic history. Lack of oxygen appears to have been a critical feature for life only during specific time intervals (see below). However, you do not have to look very far to find anoxic environments in many terrestrial and marine settings. Oxygen is consumed by respiration, particularly by bacteria that use this powerful oxidant to break down organic matter. Therefore, in settings where abundant organic matter accumulates (e.g. swamps, estuarine muds, deep lakes, and shelf sea sediments) the oxygen is rapidly consumed, producing an oxygen-free (anoxic) zone that may, in some sediments, be only a few centimetres beneath the surface. Within the anoxic zone anaerobic bacteria continue to oxidize organic matter by using a series of increasingly less efficient oxidants, starting with nitrates, then sulphates, and finally fermentation processes that use carboxyl groups in the organic matter as oxidants. In the marine realm, sulphate ions are the most readily available oxidant after oxygen, and a sulphate reduction zone is therefore often well developed. The by-product of this activity is hydrogen sulphide, which rapidly reacts with iron oxides in the sediment to produce the mineral pyrite, which therefore often provides tell-tale evidence of sulphate reduction zone activity. In non-marine anoxic environments, such as swamps and lakes, sulphate is often not available, with the result that the surface oxic layer of sediment is often directly underlain by a methane-generating (methanogenic) zone.

Modern Anoxic Environments

The development of open-water anoxia is a relatively rare phenomenon in the modern world. Anoxia develops where the supply of oxygen is exceeded by the demand for oxygen by decaying organic matter, with the result that the chemical zones summarized above move up out of the sediment and into the water column. This occurs in two distinct modern environments: silled basins and upwelling zones (Figure 1). Silled basins arise where a body of deep water is semi-isolated from the world's oceans by the presence of a shallow-water sill that can restrict deep-water circulation. This occurs particularly if the basin receives a lot of freshwater run-off and thus exports a low-density surface layer of water across the sill into the open sea. The basin is therefore said to have a positive water balance and to display an estuarine circulation. This can effectively seal the deeper waters from vertical mixing and oxygen supply. The present-day Black Sea is a giant example of a silled anoxic basin, although many fjords provide smaller examples. These modern examples owe their density stratification to the differences in density caused by variations in salinity. However, temperature contrasts can also produce stratification, since warmer waters are less dense than colder waters, and it is often mooted that some ancient examples of silled anoxic basins may have been thermally stratified.

Silled anoxic basins are essentially the product of a failure of oxygen supply to deeper waters. Upwelling-zone anoxia, in contrast, is the product of an overabundance of organic matter and therefore an excessive oxygen demand. West-facing continental margins are often characterized by prevailing offshore winds, which drive surface waters offshore (Figure 1B). This water is replaced by water that upwells from a considerable depth and has usually originated in polar areas. Because this deep water has not resided in the photic zone for some considerable time, it is often nutrient rich, and its arrival at the surface of the ocean stimulates very high plankton productivity. It is when this plankton dies and descends that decay processes rapidly consume oxygen, producing an oxygen-minimum zone (OMZ) within the water column. Intense OMZs are known off the coasts of California and South America, although truly anoxic conditions are not developed. The zone of oxygen-poor deposition beneath an upwelling zone is at an intermediate water depth, where the OMZ intersects the continental slope (Figure 1B). This contrasts with the silled-basin environment, where the anoxic deposition is in the deepest-water locations.

Identifying Ancient Anoxic Environments

Recognizing anoxic environments in sedimentary rocks is relatively straightforward because of the distinct range of attributes produced by anoxic conditions. Probably the most diagnostic feature of

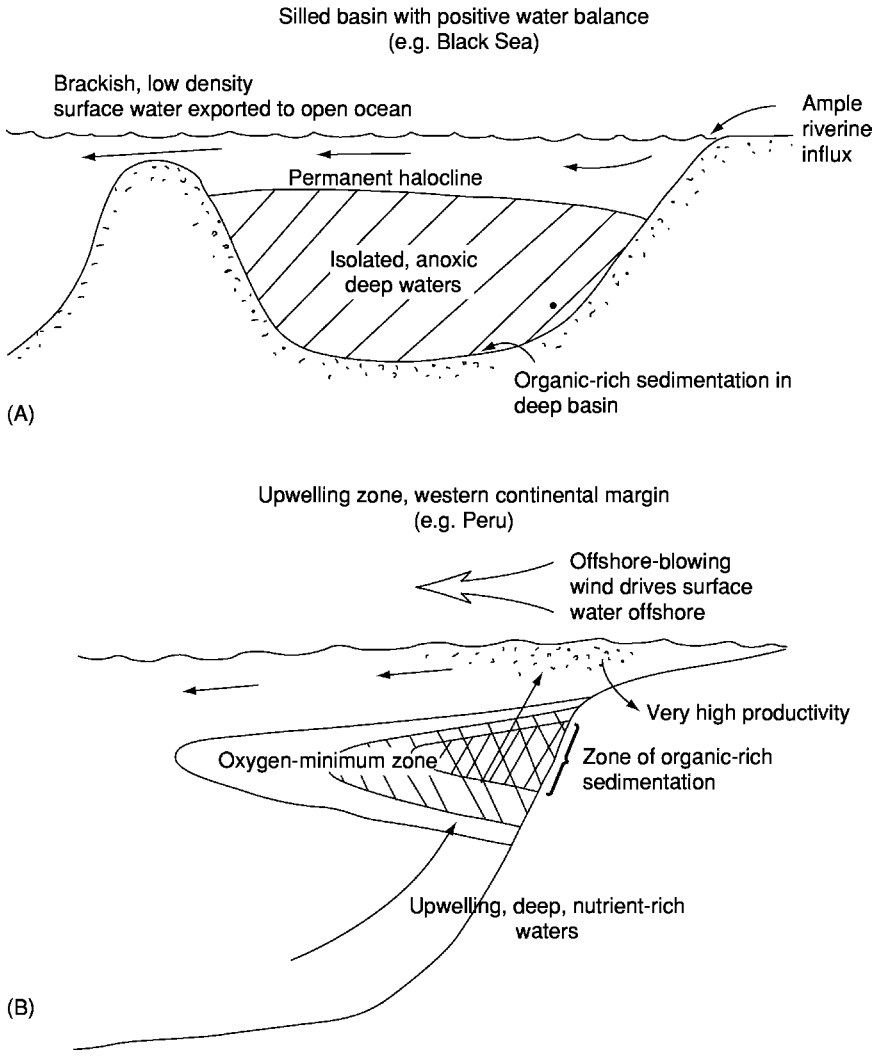

Figure 1 Models of the production of open water anoxic environments. (A) The modern Black Sea is the type example of silled basin anoxia, whilst (B) the high productivity upwelling environments are encountered along the western seaboard of several countries, including Peru and the USA. Note that in silled basins the site of organic rich deposition is in the deepest waters, whereas beneath upwelling zones organic rich deposition occurs at intermediate water depths, often on continental slopes, as depicted here, or in deep shelf locations.

marine anoxia is the presence of abundant pyrite – particularly its framboidal form – produced in the sulphate reduction zone. Framboids are named after the French word for raspberry (because that is what they look like, at least superficially); they are spherical aggregates of tiny pyrite crystals (microcrysts) a few microns in size (Figure 2). The framboids themselves range from a few microns to a few tens of microns in size, although a diameter of 5–6 μm is typical. Framboids form today in weakly anoxic conditions above well-developed sulphate reduction zones where reduced iron reacts rapidly with the hydrogen sulphide produced in the zone beneath. When these conditions are developed within the water column only small (up to 6 μm in diameter) framboids are able to form before they sink out of the water column. Populations of tiny framboids are therefore produced when sulphide is present in the lower water column. This is sometimes called a euxinic environment. Note that very minor amounts of crystalline (non-framboidal) pyrite also form in some sediments beneath oxygenated bottom waters, but pyrite-rich sediments are highly diagnostic of anoxic environments.

The change from oxygenated to anoxic conditions causes a valence change in most metals with the result that anoxic sediments contain different concentrations of these elements from normal shales. Many metals (e.g. vanadium, molybdenum, and nickel) often precipitate as impurities in pyrite with the result that they are relatively enriched in black shales. Other elements occur in a more soluble state in anoxic conditions (e.g. phosphorus and manganese) and are therefore lost from the anoxic environment, although they often precipitate at the anoxic–oxic boundary.

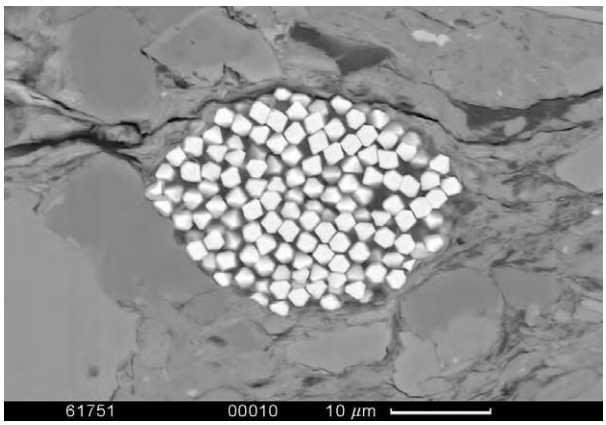

Figure 2 Scanning electron microscope image of a pyrite framboid, from the *annulata* Shale (Upper Devonian) of northern Germany. Such spherical accumulations of tiny pyrite microcrystals (microcrysts) form in prolific numbers in anoxic marine environments.

This is particularly the case for manganese, which is often concentrated as a carbonate on the margins of anoxic areas.

Although a subject of controversy, anoxic conditions are thought by many to favour the preservation of organic matter, and many anoxic sediments are organic-rich. This is manifest in the dark colour of the sediments, and the epithet 'black shale' is often used to describe anoxic sediments. Such sediments often also display very fine lamination, and they characteristically weather into thin sheets to produce a rock known as a paper shale. The preservation of fine laminae is testimony to the fact that animals cannot live in anoxic conditions. Thus, the worms and other creatures that normally disrupt delicate laminae by their burrowing activities are absent. On the face of it, fossils should also be absent from anoxic sediments because the anoxia inhibits all but microbial life. However, on the contrary, many black shales contain abundant and well-preserved fossil remains. Many of these belong to creatures that swam, such as fishes (*see* **Fossil Vertebrates:** Fish) and ammonites (*see* **Fossil Invertebrates:** Ammonites), and so their presence is readily explained: they presumably lived in the oxygenated surface waters and sank into the anoxic deeper waters only after death (Figure 3A). However, many fossils in anoxic sediments belong to ostensibly bottom-living forms, notably bivalves (*see* **Fossil Invertebrates:** Bivalves) and brachiopods (*see* **Fossil Invertebrates:** Brachiopods) (Figure 3B). For a long time such occurrences have been a subject of debate, but most workers now agree that they are dysaerobic fossils. The term 'dysaerobic' was first coined for modern forms found living on the seafloor within the OMZ of the Californian Borderland. Low-oxygen bottom waters provide harsh conditions for animals with the result that only a low-diversity, but often abundant, community of creatures can survive. Low diversity–high abundance is a common attribute of black-shale fossil assemblages too, and they are generally regarded as representing a community tolerant of low oxygen. Ancient dysaerobic assemblages are often dominated by bivalves that display a shell morphology of broad, flat, often circular valves, sometimes with dense, fine radial ribs. These are loosely termed 'paper pectens', and this characteristic morphology has evolved again and again in black-shale depositional environments (Figure 3B).

By implication, the presence of fossils in a black shale suggests the presence of oxygen during deposition, although levels need not have been very high. However, the geochemistry of anoxic sediments implies that there was no oxygen at all during deposition. For example, uranium is concentrated in sediments only in the complete absence of oxygen; otherwise it occurs as a highly soluble ion that is not precipitated. Thus, there is often a discrepancy between geochemical and palaeontological evidence for oxygen levels. This can be resolved if it is appreciated that black shales record a range of depositional environments in which the average depositional conditions were anoxic but seafloor oxygen was present during some, probably brief, intervals. These oxygenation events would allow transient colonization by rapidly dispersing species such as paper pectens. This is a distinctly different concept from that originally proposed for dysaerobic faunas, which envisaged persistently low seafloor oxygen levels, and as a result the alternative names 'episodically dysaerobic' and 'poikiloaerobic' have been proposed. However, neither has really caught on in the literature, and the term dysaerobic continues to be used. In order to get away from these generic terms, a simple descriptive oxygen-restricted biofacies scheme has been provided based on fossil and sediment attributes (Figure 4). Based on British Jurassic examples, the scheme recognizes a gradient of features thought to record improving seafloor oxygen levels. Oxygen-restricted biofacies 3 and 4 are very common, and they typically combine attributes of anoxic deposition (lamination and trace-metal enrichment) and dysaerobic deposition (presence of low-diversity benthic fossils); they undoubtedly formed in the variably oxygenated conditions described above.

Oceanic Anoxic Events

The modern oceans are extremely well ventilated, and deep waters are everywhere supplied with high levels of oxygen, thanks primarily to a vigorous thermohaline circulation regime. It therefore came as

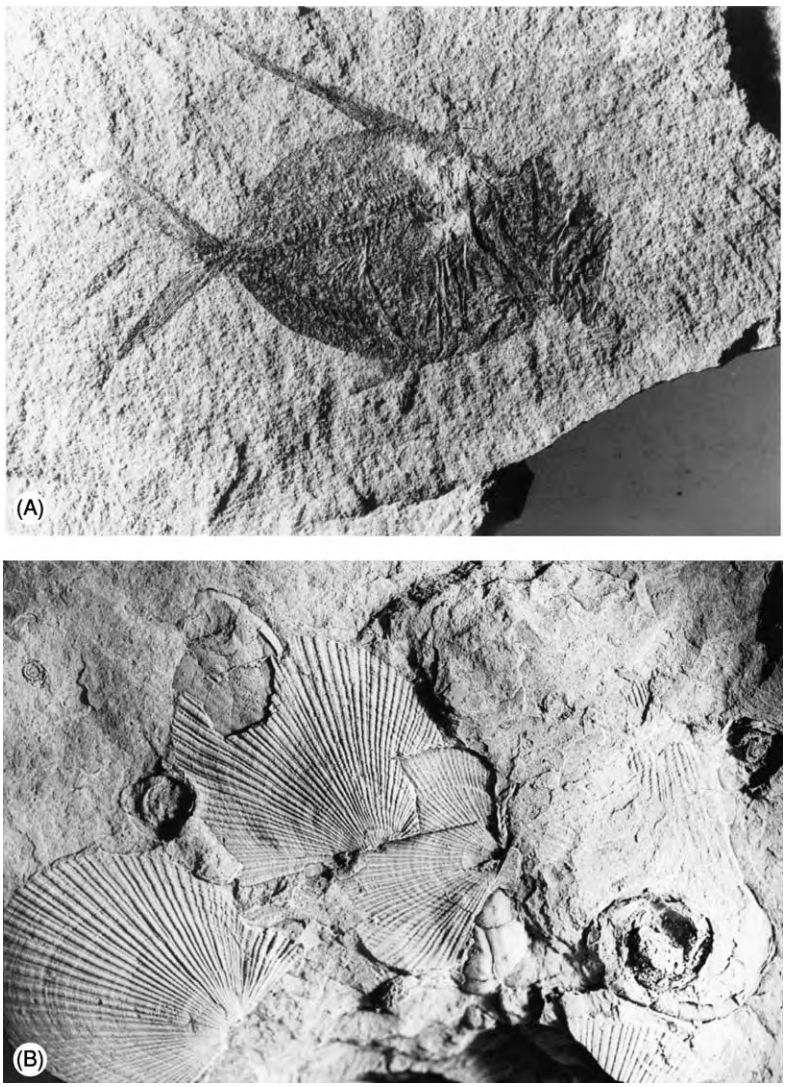

Figure 3 Fossils from ancient anoxic environments. (A) Well preserved skeleton of the deep bodied fish *Dorypterus*, from the Upper Permian Marl Slate of north east England. The lack of predation in anoxic environments often favours the preservation of fragile skeletons such as this magnificent example. The fish is 10 cm long. (B) Typical dysaerobic bivalve assemblage dominated by a single species of the radially ribbed bivalve *Dunbarella* from the *Reticuloceras subreticulatum* zone, Upper Carboniferous, Fisherstreet Bay, County Clare, western Ireland. Flat valved bivalve morphologies such as this are common in black shales from the Devonian to the Jurassic. The circular impressions on this slab are poorly preserved specimens of the zonal goniatite *R. subreticulatum*. The left hand bivalve is 3 cm high. Both specimens were coated in ammonium chloride for photography.

something of a surprise in the 1970s when the cores of the Deep Sea Drilling Program revealed the presence of thin black-shale layers sandwiched between the more normal oxygenated deep-ocean sediments. Many of these oceanic black shales were found to be contemporaneous with black-shale horizons encountered in shelf sections. Based on these observations, the concept of global oceanic anoxic events (OAEs) was proposed. Several are known from the Cretaceous, with the Bonarelli Event (named after a shale in Italy) providing the best-known and best-studied example. This event occurred at the transition between the Cenomanian and Turonian stages in the Late Cretaceous and saw anoxic or oxygen-poor waters develop over a broad area of the globe and over a broad range of water depths from the ocean floor in the Atlantic to many deep shelf sections. Ample evidence indicates that this event and probably most other OAEs coincided with phases of extreme global warmth (the Bonarelli Event may coincide with the peak of Cretaceous warmth). Many models for the origin of OAEs are therefore linked with this climatic observation. Potentially, warming of waters in high latitudes can shut down the supply of cold

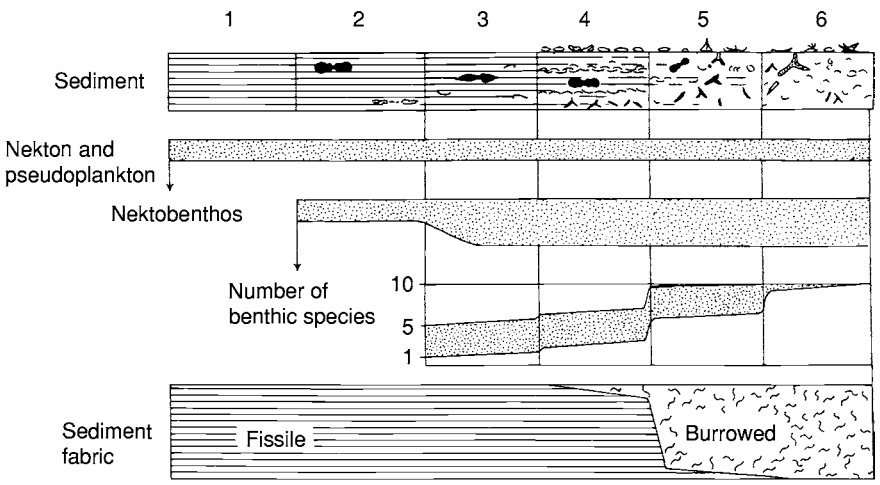

Figure 4 Oxygen restricted biofacies based on fossil content and sediment properties. The fossils have been divided into three categories. First, nekton are free swimming animals and pseudoplankton are forms that attach to floating objects, such as driftwood, in the surface waters. Such species are not affected by bottom water oxygen levels and so are found in a broad range of sediments. Second, nektobenthos are swimming forms, such as ammonites, that probably lived near the seafloor and so were absent from environments developing bottom water anoxia. Third, benthic species live on the seafloor and cannot tolerate bottom water anoxia. Reproduced from Wignall PB (1994) *Black Shales*. Oxford Monographs in Geology and Geophysics. Oxford: Oxford University Press.

dense water that drives much of the present-day oceanic circulation. Oceanic deep waters are therefore envisaged to have been replaced by dense, warm, saline waters generated in evaporitic tropical-shelf seas. Warm water holds considerably less dissolved oxygen than colder water, and this factor alone will tend to encourage deep-sea anoxia. Some modelling experiments suggest that an ocean with warm saline deep waters will circulate more rapidly than one with colder waters, with the result that upwelling may have been more vigorous. This in turn would stimulate more plankton productivity, thereby intensifying the mid-water OMZ. Intense oceanic volcanism, which is also correlated with the OAEs, may also have supplied increased levels of nutrients to the oceans and fostered further productivity.

The Cretaceous OAEs were originally intended to denote intervals when oxygen-poor marine deposition was widespread, without implying that all oceans, beneath the surface waters, were simultaneously anoxic. In essence they refer to intervals when anoxic environments were very widespread. However, there is evidence to suggest that true global oceanic anoxia may have in fact happened, with the most notable example occurring at the transition from the Permian to the Triassic. Appropriately enough, this has been termed a superanoxic event, and it is probably no coincidence that this interval is also marked by the greatest marine mass extinction of all time (*see* **Palaeozoic:** End Permian Extinctions). Like the Bonarelli Event, the Permo-Triassic superanoxia coincides with an extreme greenhouse climate and with the eruption of a giant volcanic province. In fact, the marine anoxia–global warming–massive volcanism triumvirate is seen several times in Phanerozoic history, and invariably coincides with extinction events, although of considerably different magnitudes (the Bonarelli Event is marked by only a minor extinction event). The Early Jurassic provides another classic example, with volcanism in the Karoo region of South Africa being correlated with a significant marine extinction event and widespread deposition of black shales, particularly in north-west Europe, where they are variously known as the Jet Rock (England), Schistes Cartons (France), and the Posidonienschiefer (Germany). Linking these various phenomena into a cause-and-effect scenario is a key goal of much current geological research.

Productivity versus Preservation

All black shales appear to have formed in anoxic environments, and black shales are the source all the world's oil and much of its natural gas; therefore understanding and predicting the occurrence of anoxic environments is a key goal in hydrocarbon exploration. However, it is remarkably difficult to constrain the key attributes of anoxic-environment development. As noted above, study of modern environments indicates that there are two routes to producing organic-rich sediments, and they are distinctly different. In high-productivity settings, supplied with abundant nutrients, the seafloor is overwhelmed by the flux of organic matter, and there is insufficient oxygen to decay it all. As a consequence oxygen-poor or anoxic conditions develop, but this is merely due to

the abundance of organic matter. The low oxygen levels do not cause the organic enrichment. Herein lies the key difference between the productivity and preservation models. In the latter case, the development of anoxic conditions in, for example, a silled basin with a positive water balance causes enhanced preservation of organic matter because less is lost to efficient degradation by oxygen-consuming microbes. The two models also differ in terms of their water circulation: high-productivity models require a good supply of nutrients to the surface waters from, for example, vigorous upwelling, whereas high-preservation models imply stagnation or, at best, sluggish circulation.

Distinguishing between the two alternatives is considerably more difficult than it might at first appear. Both models produce anoxic conditions; therefore merely proving that anoxia occurred is not particularly useful. Similarly, high levels of organic carbon in the sediment cannot be held as evidence of originally high organic-matter input from the water column because these high levels can be achieved by the high-productivity or the high-preservation route. Indirect proxies of organic-matter flux to the sediments have been developed, but these are contentious. Barium occurs as barite in trace concentrations in organic matter. Therefore the flux of barite to the sediment is held as a proxy for organic productivity. This assumption has the advantage that barite is considered to be less labile than organic matter. Therefore, whilst only a few percent of the organic carbon settling on the seafloor is likely to be preserved within the buried sediment (even beneath upwelling zones), perhaps the majority of the barite flux is preserved. However, the total barium content of the sediments also includes a detrital component, which has to be removed from the total to leave the biogenic component. Unfortunately, this detrital barium concentration can only be guessed at (it is controlled by factors such as sediment grain size and sediment source). A typical barium content for sediments is often assumed, but this is a rather unsatisfactory approach. Furthermore, during early sediment burial it appears that barium is often lost owing to dissolution with the result that maybe less than half the flux is preserved in the sediment. Not surprisingly, barium contents have been used successfully (i.e. convincingly) to calculate productivity levels only in young sediments not subject to significant burial.

Biogenic silica produced by certain types of plankton, particularly diatoms and radiolarians, also has a higher preservation potential during sedimentation and burial than organic matter, with perhaps in excess of 90% surviving to be incorporated into the geological record. Therefore, concentrations of biogenic silica have been used as a proxy for organic-carbon productivity, and it is significant that many organic-rich sediments forming beneath modern upwelling zones also have high levels of biogenic silica. This is primarily thanks to the abundance of diatoms in upwelling settings. The problem for geologists is that diatoms have become a common component of plankton populations only in the past 50 Ma, whilst several other factors also control siliceous plankton productivity, not least the water temperature. High-latitude plankton populations have proportionately more siliceous plankton than lower-latitude ones, and unravelling this cold-water constraint from productivity constraints in ancient sediments is extremely difficult.

Many sediments accumulating beneath high-productivity upwelling zones are rich in phosphates (much of this material is derived from fish bones sourced by the prolific fisheries encountered in these productive waters), and many phosphatic black shales are therefore assumed also to have formed beneath ancient upwelling zones. The Phosphoria Formation, a thick Upper Permian rock unit seen in Idaho and adjacent states in the western USA, is a classic example of a black shale that probably formed beneath an upwelling zone. However, the simple relationship between phosphate content and productivity is confounded by the fact that phosphate-rich accumulation also develops under conditions of very low sedimentation. This is because, in the absence of any other form of sediment accumulation, biogenic phosphate is often one of the few sources of sediment. Black shales are classically very slowly accumulated sediments.

It is something of a paradox for geologists that, whereas it is very easy to identify ancient anoxic environments, it is one of the most difficult endeavours to determine the cause of this oxygen deficiency. The recent history of the eastern Mediterranean provides a classic example of this problem. Organic-rich sediments, called sapropels, have formed in the deepest waters of this region within the recent geological past. The youngest sapropel, labelled S1, ceased forming only around 6000 years ago, almost within historical times. Unfortunately, early civilizations have left little clue to contemporaneous water conditions in the eastern Mediterranean, and evaluating the cause of the anoxia has proved almost as hard as for more ancient examples. All the evidence indicates that the eastern Mediterranean water column became truly anoxic during sapropel deposition. These periods of deposition appear to coincide with glacial intervals, when increased rainfall in the Nile's hinterland

caused increased run-off into the Mediterranean. The consequences of this were probably two-fold. First, it may have generated a positive water balance, like that in the present-day Black Sea, with low-density lowered-salinity surface waters lying on top of denser saltier deep waters. This would have resulted in the lower water column becoming relatively isolated from surface waters and more prone to oxygen deficiency. Therefore, the sapropels could be a product of increased preservation. Second, the increased run-off would also have increased the nutrient flux into the eastern Mediterranean and stimulated higher plankton productivity. Therefore, the productivity model is generally favoured by sapropel workers. However, the most recent research suggests that cause-and-effect relationships are not always clear cut when it comes to understanding sapropel generation. In some instances, anoxic deposition appears to predate slightly the onset of organic-rich sediment accumulation. This is not the correct way around if the anoxia is caused by the increased flux of organic matter into the bottom waters. Within some of the thicker sapropels, palaeoproductivity indices show substantial fluctuations from high to low levels, which again suggests that productivity is somehow decoupled from the oxygenation history. Finally, some of the older sapropels are developed in the western as well as the eastern Mediterranean, a long way removed from the regional effects of the Nile's discharge.

Carbonate Shorelines and Shelves

D W J Bosence, Royal Holloway, University of London, Egham, UK

Introduction

Shorelines and shelves that accumulate sediment composed of calcium carbonate form a large, but not major, part of the world's continental-shelf seas. The best-known examples of these sediments are tropical coral reefs and the white sandy beaches of tropical and temperate coasts (Figure 1).

Most carbonate sediments are formed by the accumulation of skeletons and shells constructed by marine organisms through the precipitation of calcium carbonate (e.g. corals, molluscs, and foraminifera). These are generally known as skeletal, or bioclastic, carbonate sediments. Skeletal sediments occur in both the warm and the cold waters of the world's shelf areas (Figure 2). They are commonest on those continental shelves where they are not diluted by large amounts of eroded and transported siliciclastic sediment, as is the case near major river mouths and mountainous coastal regions. The composition of skeletal carbonates varies because of the different ecologies of the organisms that build skeletons and shells. Tropical waters (Figure 1A and B) are characterized by seafloor communities of corals (including shallow-water coral reefs), green calcareous algae (seaweed), molluscs, and foraminifera. Cold-water carbonate-forming environments (Figure 1C) are dominated by molluscs, bryozoans, red calcareous algae, and deep-water coral reefs. Other carbonate sediments are formed by the direct precipitation of crystals of calcium carbonate from seawater in the warm saline waters of some tropical seas. This

Figure 1 Examples of commonly seen environments of carbonate shorelines and shelves. (A) Coral reef on the Great Barrier Reef, Australia, constructed by the prolific growth of calcium carbonate secreting corals (coral colonies in the foreground are approximately 1 m across). (B) Tropical beach in southern Java composed of sand derived from the breakdown of the carbonate skeletons of organisms living in nearby coral reef communities. (C) Carbonate beach from the cold temperate climate of Connemara, western Ireland, composed of the skeletal debris of molluscs, coralline algae, bryozoans etc. that live in these shallow coastal waters.

process forms calcium carbonate mud and spherical sand-sized grains known as ooids (see below). These are called non-skeletal carbonate sediments and are found only in warm-water areas (Figure 2).

Shelf seas are a major environment of carbonate-sediment formation owing to the environmental conditions, which favour both the organisms that precipitate calcium carbonate skeletons and the direct precipitation of calcium carbonate from seawater. For skeletal carbonates to be produced, most organisms require well-lit oxygenated marine waters of normal salinity for the energy-consuming process of precipitating a skeleton. For non-skeletal carbonates, the chemical conditions must favour the precipitation of calcium carbonate from seawater; this occurs under conditions of increased temperature and salinity and reduced levels of dissolved carbon dioxide. All these conditions favour the faster accumulation of carbonate sediments in shallow tropical waters than in cooler temperate waters (Figure 2).

Tropical shelves typically reach rates of accumulation on the seafloor of about 1 m year ^{3} for both skeletal and non-skeletal carbonates. Cold-water shelf environments accumulate only skeletal carbonates, and these accumulate at generally lower rates (0.1–1 m year ^{3}) than their warmer-water counterparts. Both these rates of sediment accumulation are several orders of magnitude higher than rates of continental-margin subsidence (0.01–0.1 m year ^{3}), which means that carbonate sediments generally infill shallow-water areas and build up to sea-level. In ancient limestone successions this is often demonstrated by the occurrence of hundreds of metres of vertically stacked limestone beds that were all deposited in water depths of a few meters. Because the shallow-water areas are infilled, any additional carbonate accumulation must then take place in deeper more offshore regions. By this mechanism the carbonate shelf builds outwards into deeper waters, or progrades. This is well illustrated by the seismic section of the carbonate shelf area of Great Bahama Bank in the Caribbean (Figure 3), where carbonate sediments have accumulated during the last 10 Ma and are still forming today. The sedimentary layers imaged in the seismic profile (*see* **Seismic Surveys**) show how the sediments have built up to the sea surface on the Bahama Bank to the east-north-east and are building out (prograding) into the deeper waters of the Santaren Channel to the west-south-west. Thick accumulations of shelf carbonate sediments with this characteristic flat-topped morphology are known as carbonate platforms, and these are the major sites of shelf carbonate accumulation both today (Figures 1 and 3) and in the geological past (Figures 4 and 5).

The term carbonate platform is both a stratigraphical term for thick deposits of shallow-water carbonate rocks and used to describe the following carbonate shelf morphologies (Figure 4). The terms carbonate platform and carbonate shelf are often used synonymously.

- Attached carbonate platforms are carbonate shelves that are tied to a nearby continental landmass, which may mean that at times land-derived siliciclastic sediments are mixed in with the carbonate sediments.

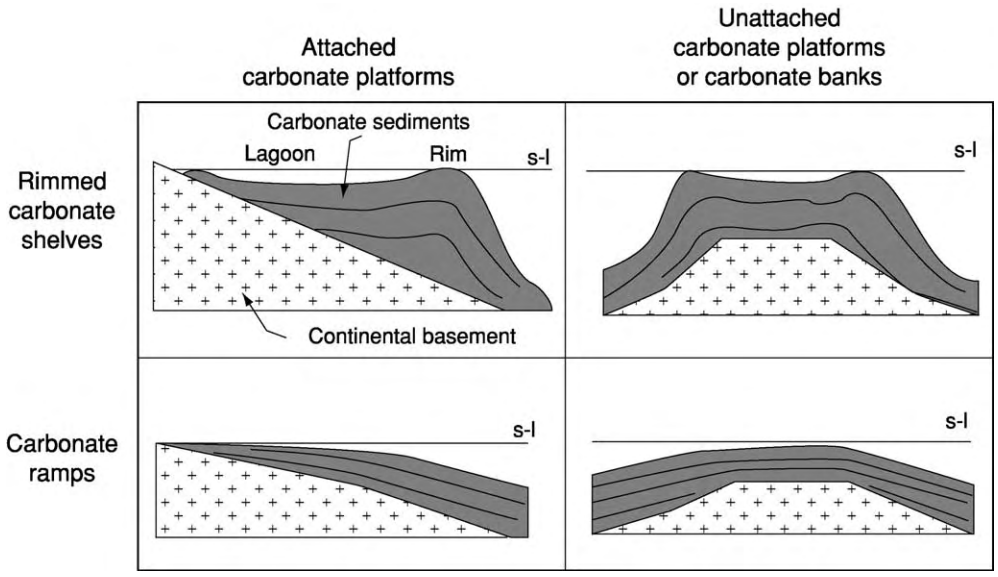

Figure 4 Morphological classification of carbonate shelves and platforms; s l, sea level.

- An isolated platform (sometimes also referred to as a carbonate bank, e.g. Great Bahama Bank) is isolated from continental landmasses (Figure 4), and an atoll is a small isolated platform that is commonly formed over a subsiding volcano.

Attached and isolated platforms may have different types of morphological profile, which fundamentally affect the accumulation of sediment on the shelf.

- A rimmed carbonate platform has a shelf margin rim or barrier, such as a reef or sand shoal, that partially isolates an inner platform or lagoon (Figure 4).
- A carbonate ramp is a platform or shelf that is gently inclined (<1°) towards an open sea or ocean with no major build-up of reefs or steep slopes (Figure 4).

When deposited in ancient shelf seas and lithified over time, carbonate reefs and sediments become limestones (*see* **Sedimentary Rocks:** Limestones) and dolomites (*see* **Sedimentary Rocks:** Dolomites), which are known collectively as carbonate rocks. The abundance of carbonate rocks formed in shelf-sea environments has varied considerably over geological time (Figure 5). Not surprisingly they were most abundant when global sea-levels were high and large areas of continents were flooded by shallow shelf seas. This occurred several times in Earth history when there were prolonged periods with no major ice-caps covering the polar regions as there are today. This meant that sea-level was higher all over the globe. These generally warmer waters formed extensive shelf seas in the past and were ideal environments for

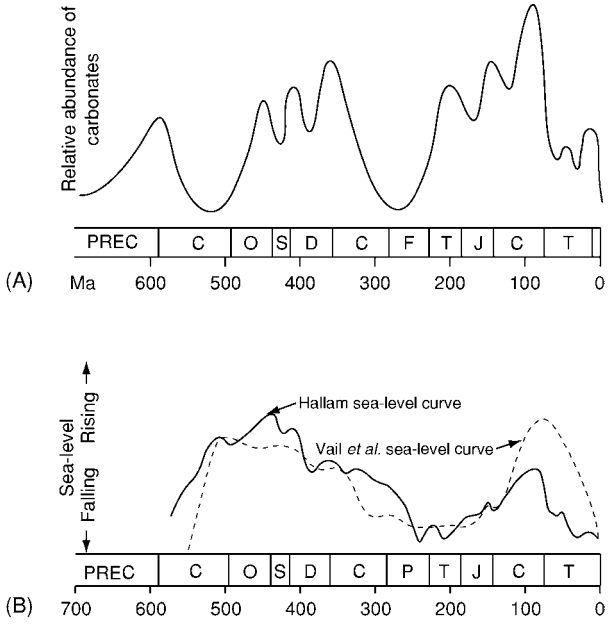

Figure 5 (A) The variation in the abundance of carbonate rocks through time, and (B) how this correlates positively with global sea level through time. (After Tucker ME and Wright VP (1990) Carbonate Sedimentology. Oxford: Blackwell Scientific Publications.)

the formation of carbonate sediments that later formed limestones and dolomites. Much of this article focuses on the sedimentary processes that operate on the different morphological types of carbonate platform, and the different types of sediment that accumulate on them. This information comes from studies of present-day carbonate shelves and is used

extensively in the interpretation of how and where ancient limestones and dolomites accumulated. These carbonate rocks have important economic uses as they host oil and gas reservoirs and heavy-metal accumulations; they are also widely used in building and in the pharmaceutical industry.

Principal Types of Carbonate Shelf

Attached Rimmed Carbonate Shelf

South Florida is an attached carbonate platform and shelf with a large low-lying hinterland (including the Everglades Swamps) set in a semi-humid subtropical climate (Figure 6). Carbonate sediments accumulate throughout this shelf area, and deep boreholes in the region tell us that this has been the case since Jurassic times. The platform comprises four main elements: a semi-enclosed lagoon (known as Florida Bay) that is partially isolated from open-marine waters by a chain of islands (the Florida Keys), a back-reef area of normal marine waters protected from high wave energy by the rimmed margin, the reef and sand shoal margin of the platform, and the fore-reef slope that descends into the deep waters of the Starit of Florida (Figures 6 and 7).

The semi-humid climate is seasonal, with a wet season from July to December (100–150 cm of annual precipitation). During this time there is considerable runoff of freshwater into the shallow-marine coastal environments, which can reduce salinities to 6‰ in Florida Bay (normal marine waters have on average a salinity of 34–38‰). By contrast, in the warmer conditions of spring and summer, temperatures increase and salinities of up to 60‰ are found in the restricted waters of Florida Bay. South Florida is within the north-easterly tradewind belt and, because coral reefs preferentially grow in shallow-water open-marine windward settings, rimmed shelf margins are found on the east-facing margin open to the waters of the Atlantic Ocean (Figures 6 and 7). The region has a very low tidal range, reaching 0.8 m ^{1} in open-water settings and reducing to zero in the semi-enclosed lagoons of Florida Bay. The reef areas experience normal marine salinities of 35–38‰, and water temperatures vary from 18°C to 30°C. In shallow-water settings Holocene carbonate sediments, which are locally lithified, rest on the eroded and cemented Pleistocene Key Largo Limestone (Figure 7). Many of the islands of the Florida Keys are limestones formed from reefs or carbonate sand shoals that accumulated during the last interglacial period, when the sea-level was slightly higher than it is today, and have since been cemented by diagenetic processes to form a rocky carbonate shoreline. The protected shorelines of Florida Bay are dominated by mangroves. These

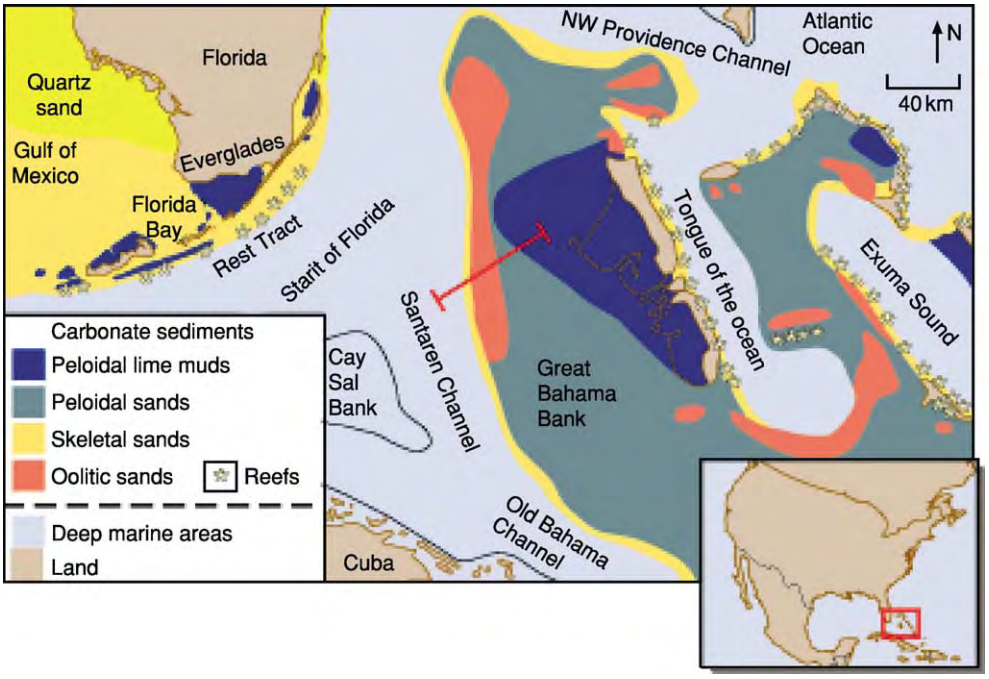

Figure 6 The distribution of major carbonate sediment types in the Florida Bahamas shelf region (for location see Figure 2). (After Jones B and Desrochers A (1992) Shallow platform carbonates. Figure 7 Cross section through the Florida shelf region normal to the coast and shelf margin, showing the main sedimentary environments. (After Bosence DWJ and Wilson RCL (2003) Carbonate depositional systems. In: Coe A (ed.) *The Sedimentary Record of Sea level Change*, pp. 209 233. Milton Keynes and Cambridge: The Open University and Cambridge University Press.) The photographs illustrate the fundamental control that organisms have on carbonate sediment production and accumulation. (A) Mangrove roots stabilizing the shoreline of Florida Bay (foreground 4 m across). (B) *Thalassia* seagrass bed; the grass leaves (20 30 cm high) act as a substrate for carbonate secreting organisms, whose debris is trapped and stabilized within the grass beds. (C) *Porites* corals (branches are 1 cm across) are common reef builders in the back reef zone. Note also the encrusted seagrass blades. (D) The shallow zone of the shelf margin barrier reef is mainly constructed by the elk horn coral, *Acropora palmata* (branches are 15 20 cm across).

trees are adapted to live in coastal waters of variable salinity and are unusual in having aerial root systems, which have a useful sedimentological function in that they trap and bind sediment so as to resist coastal wave erosion (Figure 7A).

The occurrence of fully marine organisms in semi-isolated shallow coastal waters of Florida Bay is restricted by the variable salinities, dissolved oxygen levels, and fine carbonate sediment suspended within the bay waters. Seagrass (e.g. *Thalassia*) beds (Figure 7B) and the calcareous organisms that encrust the grass blades (foraminifera, serpulid worms, and bryozoans) are common, as are other skeletal organisms such as molluscs, foraminifera, and calcareous green algae (*Penicillus* and *Udotea*). When these organisms die their skeletal debris accumulates as shelly muds, which would form bioclastic mudstones and wackestones (*see* **Sedimentary Rocks:** Limestones) if lithified into limestones. Shells are concentrated on beaches and storm ridges as bioclastic gravels and sands. Identifying the origin of the carbonate mud is a complex problem because lime mud may be produced by the breakdown of the lightly calcified tissue of green algae, by organisms that graze or bore into rocky carbonate shorelines and skeletal carbonate material (known as bioerosion), or by chemical precipitation directly from seawater. Mud production has been extensively studied in South Florida, and mineralogical (calcite and aragonite) and geochemical (calcium, magnesium, and iron levels, etc.) analyses of the muds show that they are similar to the carbonate minerals of the skeletal organisms. This implies that most of the mud is produced by the breakdown of skeletons of algae and benthic invertebrates. Once formed, the mud is reworked by burrowing organisms (mainly shrimps and worms) that digest what they can from the mud and defecate the remainder as sedimentary faecal pellets or peloids.

Within Florida Bay the peloidal muds are swept by storm waves into shallow-water mud mounds (piles of mud that accumulate from the seafloor to sea-level), which are stabilized by seagrass (*Thalassia*) (Figure 7B). These mounds have distinct windward erosional margins on their north-east sides and accretionary *Thalassia*-stabilized leeward (south-westerly) margins. Mounds therefore migrate in a south-westerly direction towards the Gulf of Mexico. Between the mounds there may be a thin cover of bioclastic (molluscan, algal, and foraminiferan) sands and muddy sands or alternatively areas may be bare of

sediment and expose the underlying Pleistocene Key Largo Limestone.

Back-reef areas are of normal marine salinity and are more exposed to waves, which generate well-oxygenated waters. These conditions favour a more diverse community of carbonate-secreting organisms, such as corals, encrusting coralline algae, calcified plate-like green algae (*Halimeda*), molluscs, echinoderms, and foraminifera. The corals are only abundant enough to form small patch reefs, which are built up by corals and coralline algae overgrowing each other to form a rigid reef framework (Figure 7C). This framework forms an attractive habitat for many other organisms, including those that eat or bore into the coral, such as sponges, worms, parrot fishes, echinoids, and molluscs. The coral debris they generate forms much of the skeletal carbonate sand and gravel that accumulates around the patch reefs. These, if lithified, would form skeletal or bioclastic packstones or grainstones (*see* **Sedimentary Rocks:** Limestones) in the geological record.

The rimmed margin of this platform comprises a barrier reef (because the reefs are detached from the shoreline and have back-reef and lagoonal areas behind them) with intervening high-energy shallow-water shoals of coarse skeletal sand and gravel. The patchiness of the reefs arises because Florida is near the northern limit of warm-water or tropical carbonates (Figure 2) and reef growth is not as prolific as it is further south in the Caribbean, where more continuous reefs occur. The shallowest zone of the reef is formed by the branching coral *Acropora palmata* (Figure 7D). The reef is built by a series of spurs and grooves that face out into the ocean. Spurs are built by seaward growth of the branching *A. palmata* and by some round-shaped (or head) corals and encrusting coralline algae. The grooves are gravel- and pebble-floored erosional channels through the reef. Deeper down the ocean-facing front of the reef, more massive and rounded coral growth forms are found, which give way to deeper-water flattened or dish-shaped corals. Lower areas of this fore-reef slope are characterized by coarse-grained reef talus deposits formed of broken and bioeroded debris from the reef. Similar reef morphologies and coral zones are preserved in ancient reef limestones, where they are called coral boundstones and are composed mainly of fossil corals.

Attached rimmed carbonate shelves are common in the geological record. In the Oligocene and Miocene of the Mediterranean, reef-rimmed shelves built out from coastlines to landmasses generated in the Alpine Orogeny. Mesozoic examples are found in the Jurassic limestones of the Jura Mountains (France and Switzerland), and Palaeozoic examples include reef-rimmed shelves (the Capitan Limestone) in the Midland Basin (USA) of West Texas and New Mexico in North America. In the Midland Basin these carbonate shelves are buried to a depth of several kilometres and contain oil and gas reservoirs in the porous limestones and dolomites that formed originally on a Permian carbonate shelf.

Unattached Rimmed Carbonate Shelf

The Great Bahama Bank is the best-studied present-day example of a large unattached or isolated carbonate platform with a rimmed platform margin. The early research of the 1950s and 1960s concentrated on the shallow platform-top environments and sediments; later work in the 1970s and 1980s studied the deeper slopes, and more recently the internal structure is being studied with seismic surveys (e.g. Figure 3) and drilling.

The climatic setting of the Bahamas is similar to that of Florida, and they are also dominated by north-easterly tradewinds. Therefore reef-fringed margins form on the east-facing windward platform margins (Figures 6 and 8). As in South Florida, the distribution of sediments across the platform is influenced by water depth, wave and tidal energy, and variations in salinity. The waters adjacent to the Bahamas Banks are open-marine waters (36‰ salinity and 22–31°C) that descend to oceanic depths. The large shallow bank-top environments are seasonally arid, and salinities up to 46‰ are recorded. The area is microtidal, with a range of about 0.8 m at the ocean margin, diminishing in the platform interior.

Many of the bank-top environments (Figure 8) are similar to those of South Florida, but there are also some important differences. The large sheltered interior of the platform accumulates an aragonite-rich mud (unlike Florida Bay mud, which is of mixed mineralogy) whose origin has long been disputed. Current theories focus on two interpretations, which are not mutually exclusive. Surveys of the skeletal marine communities of Little Bahama Bank (just north of Providence Channel; Figure 6) indicate that most of the mud is produced by the breakdown of calcareous green algae, as is the case in Florida Bay. The other proposal is that high salinities in the bank interiors may result in direct precipitation of aragonite from seawater. This is similar to the process of lime mud production in the lagoons of the Arabian Gulf (see below). In the leeward environments of Andros Island extensive mud flats are developed, which are cut by sinuous tidal channels. The channels and the mud flats are both active sites of sediment accumulation as they build out into the peloidal muds of the platform interior (Figure 8).

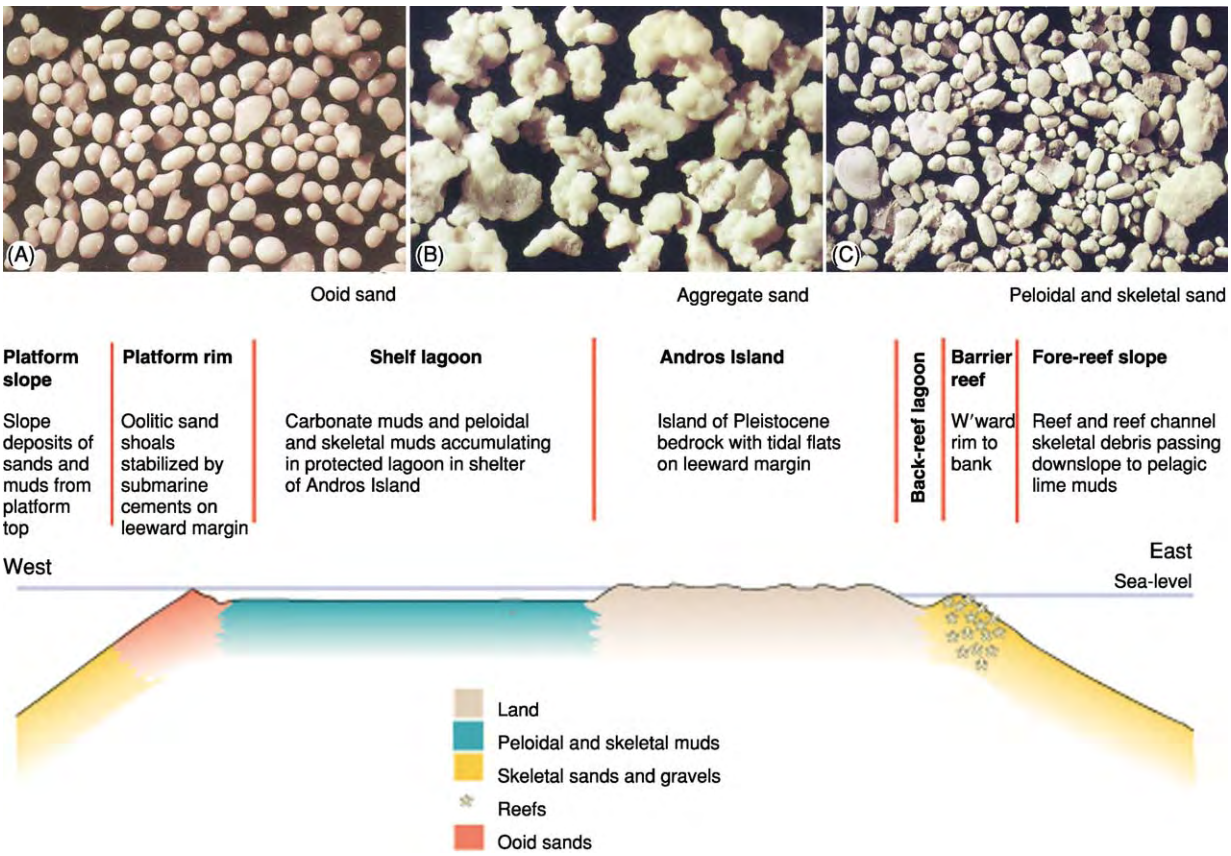

Figure 8 East west cross section through the Great Bahama Bank (for location see **Figure 6**) showing the main sedimentary environments on this rimmed platform. Photographs of sediment types (courtesy R. Till) illustrate the range of non skeletal grains on this isolated bank: (A) ooids; (B) aggregate grains; and (C) peloidal and skeletal grains (note foraminifera bottom left). All photographs are 2 cm across. (After Bosence DWJ and Wilson RCL (2003) Carbonate depositional systems. In: Coe A (ed.) *The Sedimentary Record of Sea level Change*, pp. 209 233. Milton Keynes and Cambridge: The Open University and Cambridge University Press.)

Whilst most windward margins are reef dominated and, as such, are similar to those described above from south Florida, other margins are rimmed by sand shoals. These may be formed of oolitic, peloidal, or bioclastic sands. Aragonite precipitation onto fine sedimentary particles forms ooids. These are spherical concentrically structured grains of carbonate sand (**Figure 8A**). The precipitation of aragonite crystals to form the concentric layers is favoured by the high salinity of platform interior waters, which are swept off the banks by tidal currents, and by the degassing of carbon dioxide from deeper waters off the platform margin. Tidal currents sweep the ooid sands into large submarine dunes cut by channels and interdune areas. The sand grains may also become cemented together on the seafloor by crystal growth to form grain aggregates (**Figure 8B**). Large areas may become cemented to form what are known as hardgrounds. This early cementation helps to stabilize the sand shoals and the steep margins of the platform.

The Bahaman platforms are bounded by slopes, some almost vertical, that plunge to depths of 4 km on the ocean-facing margins. These slopes may be indented by gulleys or canyons formed by slope failure followed by abrasion by sediment gravity flows. Whilst there is observable sediment production down to around 200 m on these slopes from deep-water coral and coralline algal communities, much of the sediment on the slopes and moving downslope is of shallow-water origin. In addition some is derived from erosion on the slopes themselves, and, in areas of little sediment redeposition, accumulation from pelagic organisms is important. The pelagic component, characterized by calcitic muds derived from pelagic organisms (in contrast to the aragonitic muds generated on the platform top), also increases from the toe of the slope towards the oceanic environments of the Atlantic Ocean (**Figure 2**).

The broad pattern of sediment distribution shown in **Figure 8** has probably prevailed for many millions of years, but the leeward margin of the Bank has

prograded many kilometres westwards into the Florida Strait (Figure 3). The windward (eastern) side (not illustrated in Figure 3) has remained as a steep reef-rimmed escarpment for much of this time.

Unattached rimmed shelves or carbonate banks are known from many parts of the geological record. Tertiary examples are best known from the subsurface studies of the foundations of the Bahama Banks, as discussed above and in Figure 3. Mesozoic examples come from the ancient Tethys Ocean and now form extensive Jurassic limestones in the Betic–Alpine–Apennine mountain chains of Europe. In particular, the Jurassic limestones of the Apennines of Italy once formed large unattached platforms that were isolated from the margins of the Tethys Ocean. Palaeozoic examples come from the Silurian and Devonian inland seas of Canada. Here, communities of corals and stromatoporoids helped to build reef-rimmed margins to unattached platforms known locally as pinnacle reefs. In the subsurface these platforms are encased in shales or evaporites and contain oil and gas reservoirs hosted in the porous and permeable carbonate rocks.

Attached Carbonate Ramp in an Arid Tropical Environment

The southern coast of the Arabian Gulf offshore from the Gulf Coast States (Abu Dhabi, Dubai, and Qatar) is a fine example of a present-day carbonate ramp. The shelf slopes gradually from the low-relief desert of the coastal plain through the coastal waters down to a maximum depth of about 100 m over a distance of a couple of hundred kilometres (Figure 9). This gently sloping shelf morphology is the distinctive feature of a carbonate ramp, and there are no major reef systems or rimmed shelf margins. The prevailing winds ('Shamal') blow onshore from the north-west, which makes this a storm-wave dominated coastline (Figure 9). Owing to the restricted opening to the Indian Ocean through the Strait of Hormuz and the arid climate, salinities are elevated in the Gulf to 40–45‰ and are even higher in coastal areas, where evaporite minerals are precipitated from these waters.

The depth of the wave base, the water depth at which wave-generated currents affect the seafloor, has an important control on sediment texture in

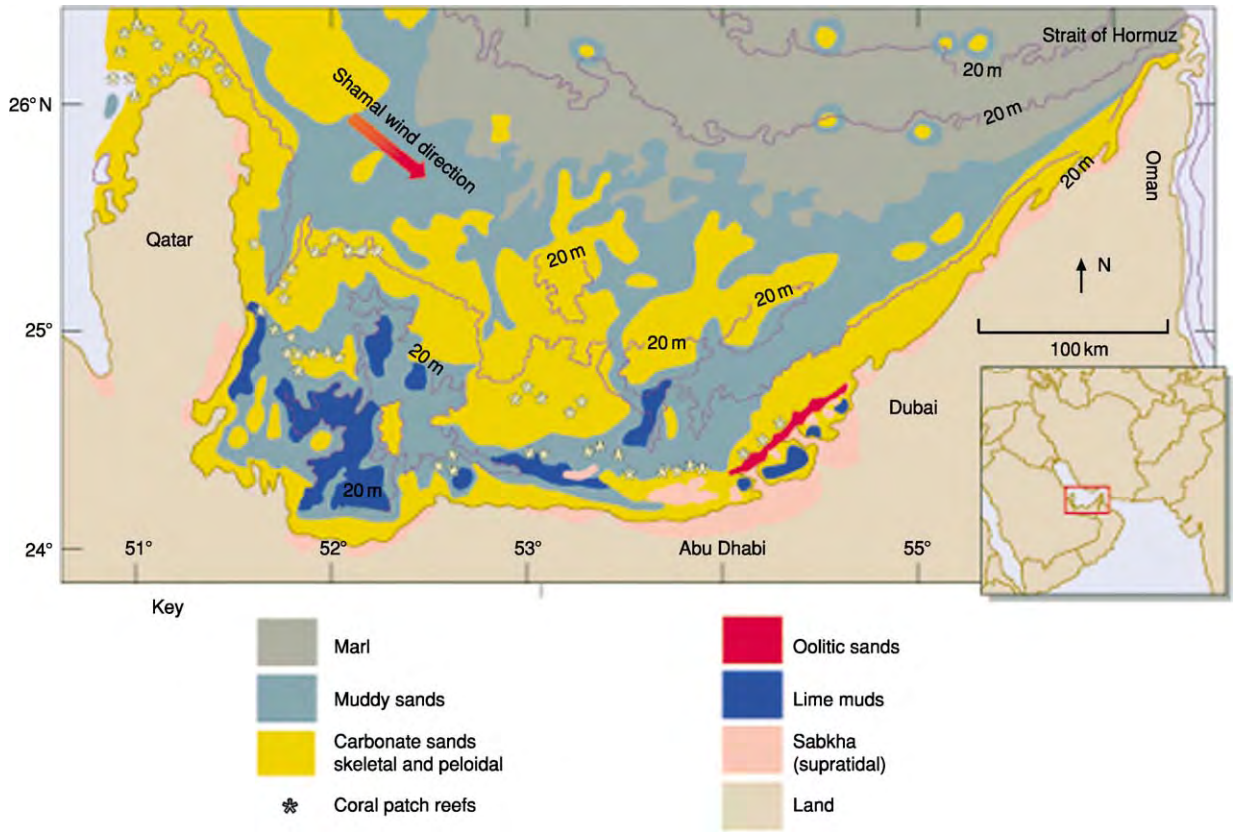

Figure 9 The south eastern region of the Arabian Gulf, showing bathymetry and the distributions of the main carbonate sediment types. (After Bosence DWJ and Wilson RCL (2003) Carbonate depositional systems. In: Coe A (ed.) *The Sedimentary Record of Sea level Change*, pp. 209 233. Milton Keynes and Cambridge: The Open University and Cambridge University Press.)

gently sloping ramps and is used to subdivide ramps into zones (Figure 10). Above the fair-weather wave base (the depth at which waves impinge on the seafloor during normal or fair-weather conditions) is known as the inner ramp (Figure 10). The zone between the fair-weather wave base and the storm wave base (wave base for storm-generated waves) is the mid-ramp, and the outer ramp is the deep-water zone below the effect of waves.

In the Gulf, the outer-ramp areas accumulate muds with a mixed composition (called marl), which are part carbonate of pelagic origin and part siliciclastic material brought into the Gulf by rivers. These marls grade up the gentle ramp slope into muddy and then clean skeletal and oolitic sands at the fair-weather wave base at around 10–20 m (Figures 9 and 10). Areas of clean skeletal sand are found in inner-ramp environments, and these are commonly cemented on the seafloor to produce extensive hardgrounds. Small patch reefs (Figure 10) occur but the coral fauna is of low diversity because of the elevated salinities and sometimes low winter temperatures.

The inner ramp is dominated by skeletal sand beaches or ooid barrier beaches in the Abu Dhabi area (Figure 9). Aragonitic ooids are precipitated in the relatively high-salinity marine waters with a moderate tidal and wave-energy regime. Ooid barrier islands are situated up to 20 km from the shoreline, and broad shallow lagoons have developed behind the barriers (Figure 9). The lagoons have elevated salinities of 40–50‰ and so have a reduced diversity of marine faunas comprising gastropods and ostracods that occur in peloidal muddy sands. The lagoons accumulate aragonitic lime muds, and both the

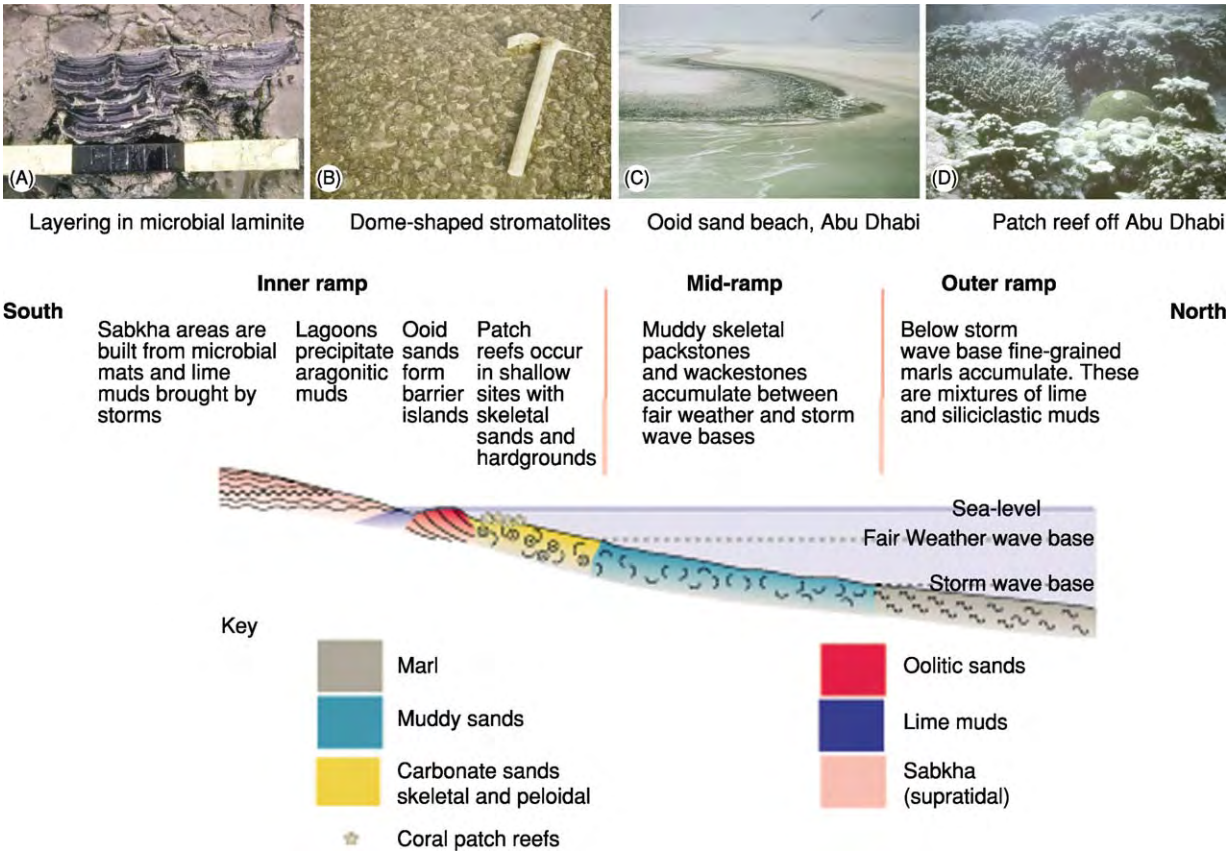

Figure 10 Cross section through the south eastern margin of the Arabian Gulf to illustrate depth related sediment types on a carbonate ramp. Note the changes in sediment type at the storm wave base and fair weather wave base. (Modified from Bosence DWJ and Wilson RCL (2003) Carbonate depositional systems. In: Coe A (ed.) *The Sedimentary Record of Sea level Change*, pp. 209 233. Milton Keynes and Cambridge: The Open University and Cambridge University Press.) The photographs (courtesy R. Till) illustrate the diversity of inner ramp sediment types in this arid climate. (A) Vertical slice though intertidal flats, showing alternating microbial (dark) and sediment (light) layers. White patches within the layering are precipitates of the calcium sulphate salt anhydrite (scale in inches). (B) Dome shaped stromatolites in the intertidal sabkha. These result from the upward growth of microbial mats and bound sediment, with lighter coloured sediment accumulating between the domes. (C) Light coloured beaches of ooid sand occur on a string of barrier islands off the coast of Abu Dhabi. The dark area by the water's edge is microbial mat. (D) Patch reefs offshore of the barrier islands have a low diversity compared with reefs of the nearby Indian Ocean because of the high salinity of the Gulf waters.

absence of calcified green algae (such as those present in South Florida and the Bahamas) and geochemical evidence from the lagoon waters and the deposited muds indicate that these muds were precipitated chemically within the lagoon rather than having an organic origin, as is the case in Florida Bay.

The sabkhas (Arabic for area of low-lying salty ground) are broad intertidal areas and coastal plains (Figures 9 and 10) that may be flooded by lagoon waters when storm winds blow landwards. Intertidal areas have extensive microbial populations on the tidal flats growing on and within sediment deposited on the sabkhas when they are flooded by storms. These processes give rise to sediments with alternating microbial-rich and sediment-rich layers, known as stromatolites (Figure 10). High aridity in the area leads to a net evaporation of floodwaters and the drawing up of saline groundwaters into the sabkha. This leads to the precipitation of evaporite minerals, such as dolomite, gypsum, and anhydrite, within the microbial mats, including the stromatolites.

With time all these depth-related sedimentary zones will build out or prograde into the Gulf, forming a sedimentary succession that has been recognized in many ancient limestones throughout the world. Ancient carbonate ramp successions are known from the Carboniferous of north-western Europe and the USA, where they build out carbonate shelves with facies similar to those described from the present-day Arabian Gulf. However, in addition, the deep-water areas are characterized by carbonate mud mounds that do not have an exact modern-day analogue. Very extensive Jurassic and Cretaceous carbonate ramps are known from the subsurface of the eastern part of the Arabian Plate. Here they host the rich oil and gas reserves of the Middle East in prograding units of inner ramp carbonate sand shoals and patch reefs. The oil and gas is preserved in these porous carbonate rocks and sealed by overlying evaporites, which formed in sabkha environments similar to those that occur today in the southern Arabian Gulf.

Attached Carbonate Ramp in a Cold Temperate Environment

The shelf regions of the north-eastern Atlantic form a large area of cold-water shelf carbonate sediments (Figures 2 and 11). These extend from the narrow Spanish shelf to broad shelf regions within the Arctic Circle near Spitzbergen. Similar extensive areas of cold-water carbonates are found in the southern hemisphere, particularly off the south coast of Australia (Figure 2). Cold-water carbonates differ from their warm-water counterparts in that they are formed only of skeletal material: there are no precipitated grains (ooids etc.) in these cooler waters. In the north Atlantic temperatures vary from an average of 7°C in winter to 15°C in the summer, and salinity levels are relatively constant at around 35‰. Within these waters skeletal sands and gravels are formed from a variety of different seafloor communities that contrast with those of the tropics.

The shelves of north-western Europe form what are termed distally steepened ramps in that they have very gentle gradients from the shoreline to a shelf margin at around 200 m water depth (Figure 11). Here, the seafloor drops away more steeply on what is known as the continental slope. The shelf environment is subject to a number of different currents that have an important effect on sediment types and their distribution. The North Atlantic Drift is an oceanic current that flows north-eastwards along the continental slope and is strong enough to transport sand along the upper slope in large seafloor sand dunes. The shelf is also affected by westerly winds that have blown across the Atlantic Ocean and generate significant storm waves (i.e. a maximum of 30 m during a 50 year period) that can rework the seafloor sediments

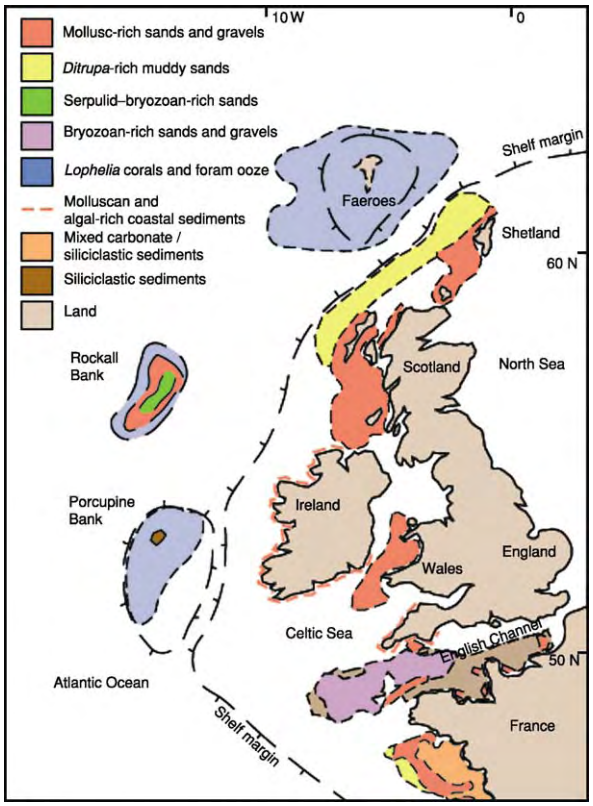

Figure 11 The north east Atlantic Ocean, showing the distribu tions of the main types of shelf and slope carbonate sediments. Note that carbonate sediments are abundant on the attached shelves of north western Europe and on the isolated platforms of the Faeroes, Rockall Bank, and Porcupine Bank. White areas of shelf region are those that have not been studied in detail.

right down to the shelf edge at 200 m depth. In addition, tidal currents are strong and can rework sediments and prevent mud deposition over much of the shelf. Therefore the entire shelf is above storm wave base and much of it is within the mid-ramp zone as the nearshore areas slope steeply off the coastal cliffs. Locally, for example in western Ireland and north-west Scotland, carbonate beaches are formed of skeletal sands and gravels (Figure 1C). By way of example, a shelf profile is shown across the shelf north of Scotland (Figure 12). Inner to mid parts of the shelf are swept by tidal currents that restrict any mud sedimentation, and these areas are characterized by mollusc-rich sands and gravels (Figure 12). Such facies are common throughout this carbonate province (Figure 11). Locally they are enriched in siliciclastic sand grains that have been reworked from nearby rocky cliffs and islands. These shell gravels not only represent the remains of a diverse molluscan-rich seafloor community but also form a substrate for encrusting calcareous organisms such as tube worms and bryozoans.

The outer part of the shelf and the shelf margin are inhabited by a quite different seafloor community dominated by an unusual free-living or non-encrusting tube worm known as *Ditrupa* (Figure 12). These conical tubes occur in great abundance (upto 1000 individuals per square metre) in the outer shelf, associated with minor contributions from molluscs, bryozoans, and solitary corals that use the *Ditrupa* tubes as a hard substrate to grow on. With increasing depth, pelagic foraminifera become more important and the sediments have a muddy texture below wave base and the shelf edge. Many areas of the deep shelf and continental slope are covered by a colonial coral known as *Lophelia* (Figure 12). Although not present on the selected transect, it is common around the unattached carbonate shelves of the Faeroes, Rockall, and Porcupine Banks of the north-east Atlantic (Figure 11) where it forms extensive thickets on the seafloor. On the Norwegian shelf it forms deep-water reefs tens of metres high and hundreds of kilometres long. Living at depths of 200–500 m, these coral thickets exist by suspension feeding. They are not

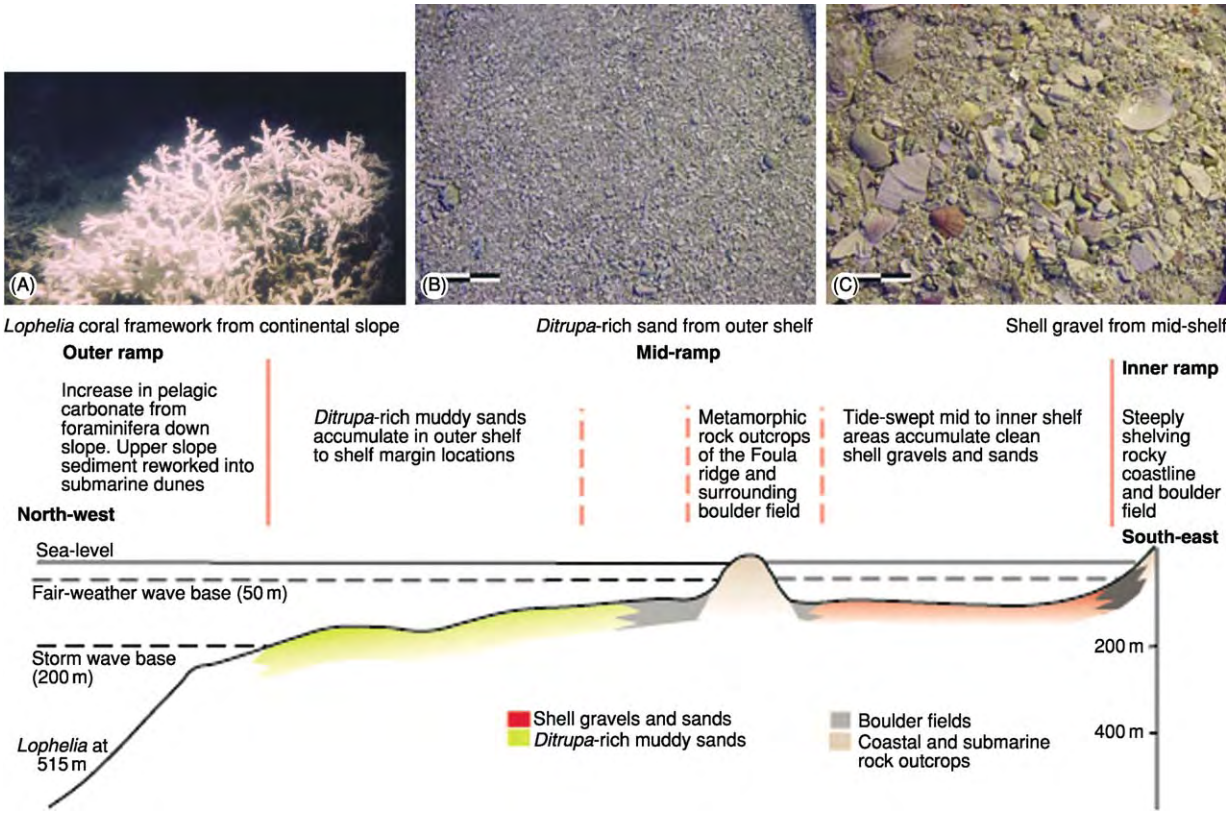

Figure 12 North west south east section across the shelf to the west of Shetland, illustrating the occurrence of the main carbonate facies with respect to shelf regions. Note the considerable depth of the fair weather and storm wave bases compared with the sheltered Gulf (Figure 10) and the importance of the rocky shoreline and islands (Foula) in this region. Photographs illustrate the skeletal nature of the shelf carbonates: (A) scale: foreground 50 cm across; (B, C) scale bars 2 cm. (After Light JL and Wilson JB (1998) Cool water carbonate deposition on the West Shetland Shelf: a modern distally steepened ramp. In: Wright VP and Burchette TP (eds.) *Carbonate Ramps*, pp. 73 105. Special Publication 149. London: Geological Society.

restricted to the photic zone like their warm shallow-water counterparts such as those from the Caribbean described above. However, they have an analogous complex associated fauna. The extent and thickness of these cold-water carbonates in the northern and southern hemispheres has become known only in the last 20 years or so, and the full geological impact of their discovery has yet to be established. Many Miocene limestones from southern Europe are now believed to be of temperate origin as are some Late Palaeozoic limestones of North America and southern Australia. Because of their more limited extent, cold-water carbonates have fewer economic uses than their tropical counterparts. In the coastal areas of north-western Europe the calcareous algae are dredged for use as agricultural and horticultural fertilizer and for liming the acidic soils of the region. However, because of the low growth rates of the carbonate producers, this is a non renewable resource.

Conclusions

From this review it can be seen that continental shelf seas have extensive areas of carbonate sediment accumulation. The nature and distribution of these areas are mainly controlled by climate and morphology. Although pelagic sediments forming in deep ocean waters are more abundant today, their usual geological fate is to disappear into subduction zones. This explains why limestones formed in shelf environments are the commonest type of limestone in the geological record. If we are to understand how limestones formed and what controls their distribution and composition, we must study their modern counterparts.

To conclude, carbonate shorelines and shelves are important features of the world's sedimentary and biological systems; they contain the biologically diverse and economically important habitat of tropical coral reefs, analogues for the interpretation of ancient limestones, and some of the most attractive coastlines of the world.

Contourites

M Rebesco, Istituto Nazionale di Oceanografia e di Geofisica Sperimentale (OGS), Italy

Introduction

Contourites are sediments deposited or substantially reworked by the powerful action of bottom currents.

The study of contourites is important in at least three main respects: palaeoclimatology, hydrocarbon exploration, and slope stability. The continuous and relatively high-resolution record included in these sediments is crucial for palaeoclimatology since it holds the key for priceless information on the variability in circulation pattern, current velocity, oceanographic history, and basin interconnectivity. Bottom currents are a crucial factor in oil and gas reservoir development since weak

flows may favour the accumulation of source rocks and robust flows may represent a viable mechanism capable of forming 'clean' sands in the deep sea. Low-permeability, fine-grained contourites have been found recently to play a critical role in slope stability by providing potential overpressured glide planes, either when their high-water-content is rapidly loaded or when their rigid biosiliceous microfabric is collapsed by diagenesis.

Despite its significance, little is still known about this group of sediments. There are three reasons for the long-lasting disregard: the inherent elusive nature of these complex deposits, the 50-year dominance of the turbidite paradigm, and the controversy that surrounds these sediments since they were first recognized. The elusive and very subtle characteristics of these slowly and continuously accumulated sediments and their occurrence within a spectrum of deep-water deposits (Figure 1) does not allow them to be easily recognized and decoded. The monumental efforts to promote the turbidite systems, the simplicity and predictability of turbidity current concepts, and the sense of confidence given by the routine use of widely applicable models has induced the geologic community to ignore alternative, more complex deep-water models. The never-ending disputes regarding the occurrence of sandy contourites versus reworked turbidites and the early errors in recognition of fossil examples have prevented the establishment of a widely shared consensus on valid diagnostic criteria for the identification of these deposits.

The growing level of interest and research in contourites is shown by the recent publication of several special volumes dealing with such systems, covering large parts of present ocean floors and continental margins. An increasing number of fossil occurrences in ancient sediments exposed on land have also been documented. Nevertheless, wide multidisciplinary approaches and the integrated work of different international specialists (e.g., deep-water sedimentologists, seismic interpreters, physical oceanographers, and palaeoclimatic modellers) are still needed to improve our knowledge of these systems and to help tackle the problems that remain.

History

The systematic study of deep-sea sediments began at the end of the nineteenth century. At that time the ocean floor was perceived as a tranquil realm receiving only pelagic clays. The possibility that thermohaline bottom currents may influence sedimentation in the deep oceans was suggested by the German oceanographer Wust in 1936. However, the contourite concept was not accepted in marine science until the second half of the 1960s after the American team of Heezen and Hollister had provided geological and oceanographic evidence of this process along the eastern North American continental margin. During the next two decades standard facies models for contourite sediments were developed from coring contourite accumulations. Other important steps forward were achieved by addressing the link between current strength and grain size and by confronting the problem of distinguishing contourites from other deep-sea facies like hemipelagites and fine-grained turbidites. Among the projects that have provided significant contributions to contourite research have been the HEBBLE

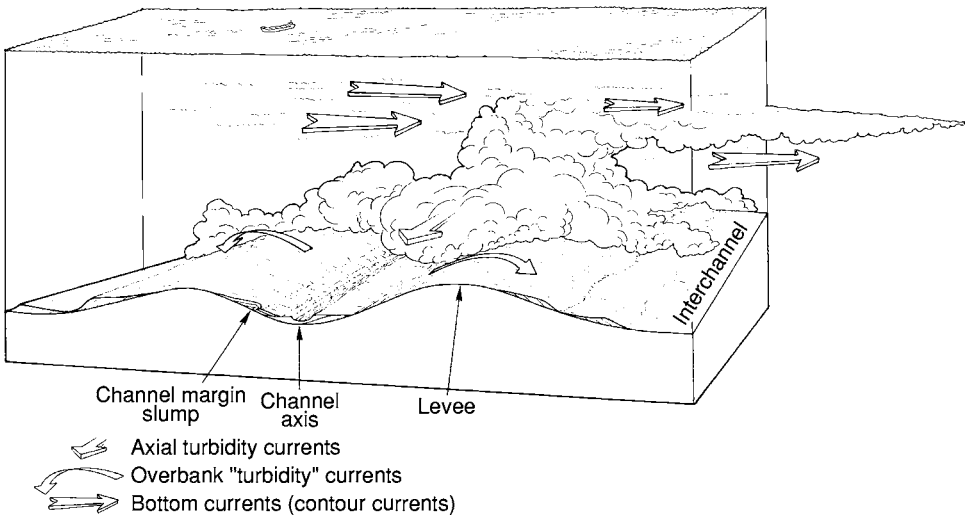

Figure 1 Schematic model of downslope gravity driven currents and alongslope bottom currents interacting within the continuous spectrum of deep water processes. Reprinted from Shanmugam (2000) 50 years of the turbidite paradigm (1950s 1990s): Deep water processes and facies models A critical perspective, *Marine and Petroleum Geology* 17: 285 342, with permission.

(High-Energy Benthic Boundary Layer Experiment) in the Nova Scotia Rise and the international drilling programs (ODP and predecessors) in most contourite deposits of the world's oceans (Figure 2). At the very end of the 1990s the International Geological Correlation Programme (IGCP) Project 432, named 'Contourite Watch', was launched to facilitate research on contourites and bottom currents. It included the establishment of a global network of contourite workers, the organization of international workshops, and the publication of selected special volumes, including an atlas of contourite systems.

Terminology

Most workers currently agree on very broad definitions and on the use of most terms related to contourite research. The need to maintain a certain degree of flexibility to allow for development in understanding has been acknowledged; nevertheless the present state of contourite terminology usage is possibly still too loose to allow for a clear description of the products (sediments) and consequently for a clear understanding of the depositional processes.

The term 'contourite' was originally introduced to define the sediments deposited in the deep sea by contour-parallel bottom currents. The term was subsequently widened to embrace a larger spectrum of sediments that at diverse depths are affected to various extents by different types of currents. Since both the depth and direction of the bottom currents that influenced nonrecent deposits are seldom precisely identifiable, a rigorous restriction of contourite to its original sense would severely limit its application. Such a long-established term should hence be maintained for nonspecific use, and the employment of modifying terms to qualify the deposit in terms of depth, current type and action, and interacting process is recommended (see Table 1).

The term 'contour current' refers to those thermohaline-driven, deep-water currents that flow approximately parallel to the bathymetric contours. It is widely used synonymously for 'bottom current', which in contrast includes all deep currents not driven by sediment suspension that are capable of eroding, transporting, and depositing sediment on the sea floor. Although bottom current is suitably applicable to different types of currents flowing alongslope as well as upslope and downslope (see below), the term contour current should be applied only to currents whose flow can be recognized as being parallel to contours.

Contourites were first described as being at great depths beneath deep-water bottom currents. Subsequently, contourites and bottom current-controlled deposits were recognized in several settings including shallow gateways, outer shelf and slopes, and even lakes. The depth ranges for a three-category subdivision was hence proposed: deep water ≥ 2000 m; mid-water = 300–2000 m; shallow water = 50–300 m. However, a rigid definition of the depth confine is of limited value, especially for nonrecent and fossil contourites for which the deposition depth is largely unknown. Nevertheless, the use of a modifying term to qualify the deposit in terms of depth is recommended when a distinction can be made.

'Sediment drift' is the generic term for a sediment accumulation that was appreciably controlled by the action of a bottom current. It is often used synonymously for 'contourite drift', which in contrast should be specifically used for sediment accumulations deposited principally (though not exclusively) by contour currents. Therefore, the most appropriate term for contourite accumulations is in most cases the wide-ranging designation 'sediment drift' or simply 'drift'. The occurrence of mixed system is the norm rather than the exception with sediment drifts. For this reason, a qualifying modifier like bottom current-controlled (modified, reworked, etc.) is recommended for turbidite systems and hemipelagic deposits that were significantly affected by interaction with bottom currents. Similarly, when mounds, levees, fans, lobes, channels, and other terms closely associated with downslope systems are applied to contourite systems, they must be preceded by the term contourite.

Bottom Currents

There is a wide spectrum of bottom currents that operate in deep water. The bottom currents sensu stricto (contour currents) are those that are part of either the thermohaline- or wind-driven major circulation patterns (Figure 3). They are usually persistent for long time intervals as testified by the thick drifts that took million of years to develop. Such currents generally have an overall alongslope flow, but in detail their velocity and direction are extremely variable in both time and space. In fact they are affected by seafloor morphology (obstacles, gateways, and changes in slope direction and steepness), Coriolis force, circular motions (gyres and eddies) unrelated to contours, and eddy kinetic energy changes (seasonal and at different scales). Substantial changes in kinetic energy at the seafloor may be produced by sea-surface topographic variations, resulting in episodic high bottom current velocities, referred to as 'benthic storms'. Such storms may resuspend large amount of sediment that nourish the bottom 'nepheloid layer' (several hundred metres thick, long-living, low-concentration (50 to 100 $\mu g\,l^{-1}$) clouds of sediment particles close to the seafloor).

Contourites, turbidites and process interaction, *Sedimentary Geology* 115: 3 31.

Table 1 Examples of qualifying terms for contourite related deposits

Depth	Deep water	Mid water	Shallow water	Shelf	Slope	Lacustrine
Type of current	Contour parallel	Thermohaline driven	Wind driven	Up and downwelling	Up and down canyon	Internal waves and tides
Type of action	Resuspended	Pirated	Far off transported	Condensed	Polished	Winnowed
Interacting process	Turbidite sourcing	Pelagic settling	Overbanking	Faulting	Creeping	Downslope resedimentation

N.B.: Not all kinds of terms are to be used concurrently (e.g., deep water turbidites winnowed by wind driven bottom currents, or mid water turbidite sourced contourites).

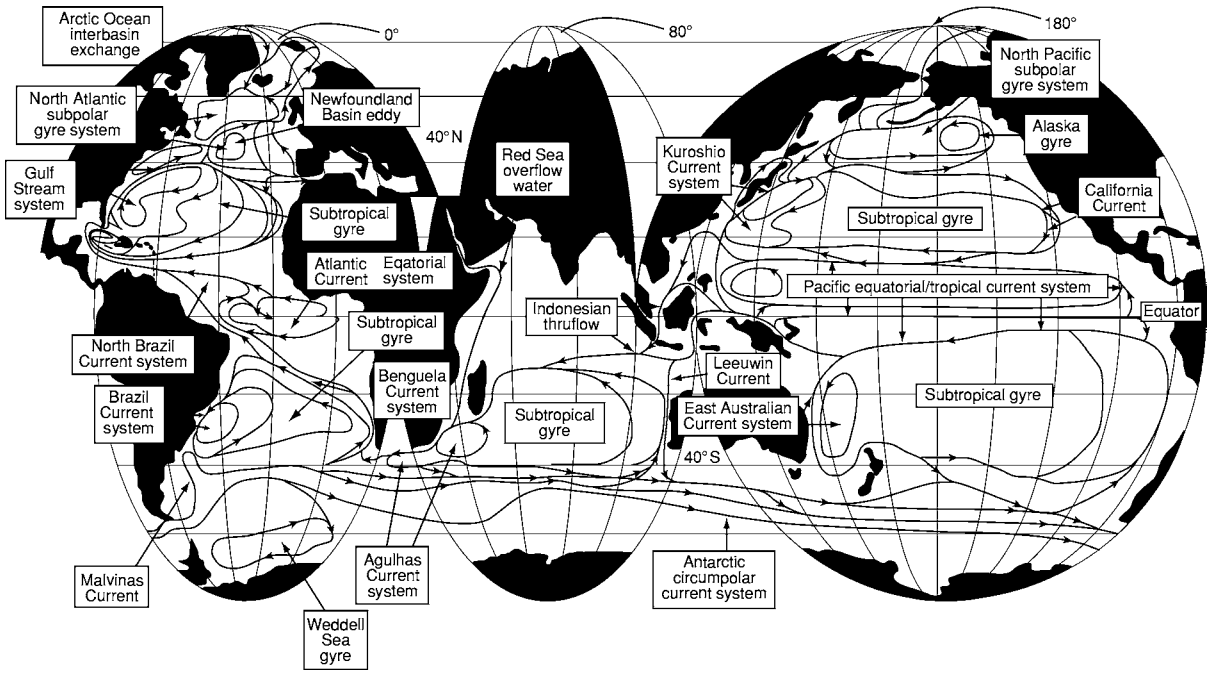

Figure 3 Global ocean circulation pattern. Reprinted from Steele JH, Turekian KK, and Thorpe SA (eds.) *Encyclopedia of Ocean Sciences*, Academic Press, London, with permission.

Additional types of deep (bottom) currents not driven by sediment suspension have been observed to flow mostly perpendicular to the slope. These include currents related to internal waves and tides (formed between subsurface water layers of varying density), canyon currents (frequently reversing flow of clear or very low-density turbid waters), and down- and upwelling flows (currents on the continental slopes that may be generated by density, wind, storms, or obstructions).

The present global thermohaline circulation of deep water is originated by the cooling and sinking of surface water masses in the polar areas. The Antarctic bottom water (AABW) forms beneath Antarctic floating ice shelves (especially in the Weddell Sea), descends the continental slope, and hence circulates clockwise in the Southern Ocean from which it escapes northwards into the world's oceans. The Arctic bottom water (ABW) forms in the Norwegian and Greenland Seas, flows intermittently south through basin gateways, and mixes with the North Atlantic bottom water and Labrador seawater. Subsequently, AABW and ABW gradually mix with other stratified water masses of their own density and circulation pattern (e.g., intermediate depth water produced by evaporation in semienclosed seas, like the Mediterranean overflow water—MOW).

The present global surface circulation is governed by dominant wind systems. In many cases the action of such currents affects the entire water column down to the seafloor. This is the case for the powerful Antarctic circumpolar current (ACC) and western boundary currents like the Gulf Stream, Brazil, and Agulhas and Kuroshio Currents.

All the above currents impinge upon the seafloor where they may erode, transport, and deposit sediment

in the form of contourites. The velocities of these bottom currents are generally very slow (few centimetres per second) and hence just able to slightly affect the action of other depositional processes (hemipelagic settling and low-density fine-grained turbidity currents). However, bottom currents accelerate when constrained by Coriolis force within western boundary undercurrents restricted against the continental slope (commonly with velocities ranging between 10 and 100 cm s $^{-1}$) or when constricted in narrow gateways (velocities may even exceed 200 cm s $^{-1}$). In many cases the bottom currents are strong enough to profoundly affect deep-water sedimentation by a number of processes including (in order of increasing current strength) the prevention of fine sediment deposition, the entrainment (pirating) and transport of suspended sediments within the nepheloid layer, the reworking of the coarse fraction introduced by episodic down-slope processes, the erosion and transport by traction of silt and fine sand, and sedimentary lag production by polishing and winnowing the seafloor. Such energetic processes take place chiefly beneath the core of the main bottom current flow. The velocity decreases away from the axis of the current, and deposition of various types of sediment drifts takes place in the relatively slack waters to the side of sediment-laden bottom currents. In most palaeocurrent reconstructions, the axis of the current is hence generally considered subparallel to the elongated direction of the drift and to its crest (if traceable). However, such a relationship between current and accumulation is in most case highly speculative since the associated time-scales are extremely dissimilar. In fact, the time required for a drift development is commonly one order of magnitude larger than the glacial–interglacial cyclicity, which is widely accepted to profoundly affect bottom-water circulation, and exceeds by over four orders the time length of our direct oceanographic observations.

Sediment Drifts

There is a large variety of contourites, ranging from those that occur closely interbedded with other deep-water facies to those that build up individually distinct bodies (mounded drifts). Due to their large dimensions, commonly ranging between a few tens and several hundred thousand square kilometres, drifts are essentially identifiable by means of seismic profiles. Although in some instances sediment drifts may be clearly recognized on the basis of seismic profiles alone according to a widely agreed-upon criteria, a rigorous identification generally requires independent supporting data. The large-scale features of the drifts (their morphology and overall geometry) are controlled by a number of interrelated factors including bathymetric setting (physiography, depth, morphology), current conditions (velocity, time length of activity, variability, frequency of changes), sediment availability (amount, type, source type, frequency, and variability of input), and the interaction with other depositional processes (in time and space, both collaboratively or antagonistically). Accumulation rates in sediment drifts are rather variable, from a few tens to hundreds metres per million years, depending on regional conditions, specific age, and evolutionary stage. However, for most drifts their average growth rate is commonly several tens of metres per million years.

Repeated attempts to categorize the essentially continuous spectrum of contourite accumulations into several types of drift have been made (Figure 4); however, the categorizations are not totally distinct such that some drifts may be classified as more than one type:

1. A ‘sheeted drift’ is characterized by a very broad low-mounded geometry. It has a very low relief (up to a few hundred metres) over a very large area (up to 1×10^6 km^2) and shows a slight decrease in thickness towards the margins. Two kinds of sheet drift may be identified:
   a. ‘abyssal sheet’, which fills basin plains whose margins trap the bottom currents within a complex gyratory circulation, and
   b. ‘slope plastered sheet’, which is coated (plastered) against continental margins where a gentle and smooth topography favours a broad nonfocussed current.
2. An ‘elongated, mounded drift’ is characterized by distinctly elongated and mounded geometry (Figure 5). This kind of drift is the most spectacular and was among the first to be identified. It may have a relief of several hundred metres above the surrounding seafloor (total thickness up to 2 km) and a very variable extent (10^3–10^5 km^2) with an elongation ratio of at least 2:1. Elongation is generally parallel to the margin, which means that the crest of the drift is parallel to the current axis. Nevertheless, elongation and progradation trends are variable, being controlled by at least three interacting factors: current system, bathymetry, and Coriolis force. Two types of mounded drift may be identified:
   a. A ‘separated drift’ is kept apart (separated) from the adjacent continental slope by a distinct moat in which the main core (axis) of the bottom current is flowing as testified by local nondeposition and/or erosion (Figure 6). Such drifts show an evident upslope progradation with a minor alongslope migration in the downstream direction.

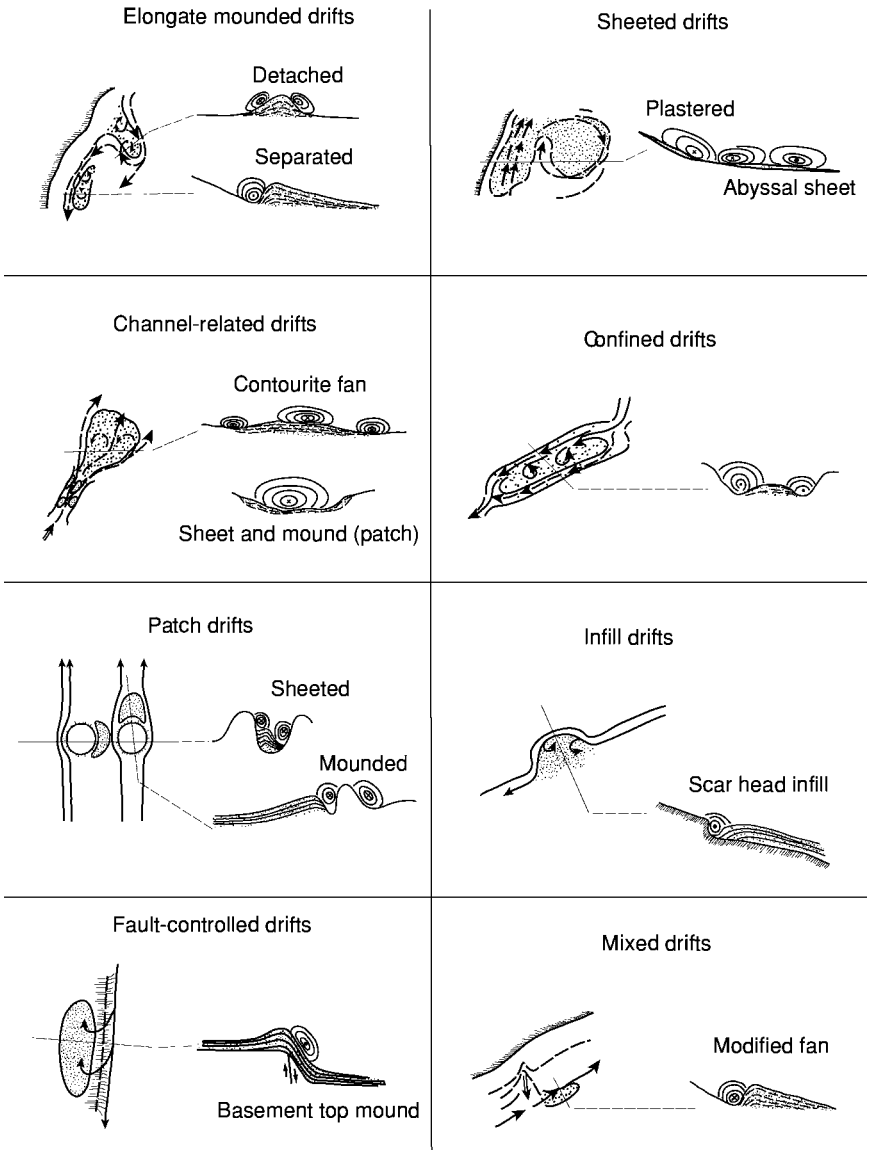

Figure 4 Sediment drift types and inferred bottom current paths. Adapted from Rebesco M and Stow DAV (2001) Seismic expression of contourites and related deposits: A preface, In: Rebesco M and Stow DAV (eds.) Seismic expression of contourites and related deposits, *Marine Geophysical Researches* 22: 303 308, with kind permission of Kluwer Academic Publishers; and: Stow DAV, Faugères JC, Howe J, Pudsey CJ, and Viana A (2002) Bottom currents, contourites and deep sea sediment drifts: Current state of the art, in: Stow DAV, Faugères JC, Howe J, Pudsey CJ, and Viana A (eds.) Deep Water Contourite Systems: Modern Drifts and Ancient Series, Seismic and Sedimentary Characteristics, *Geological Society, London, Memoir* 22: 7 20, with permission.

b. A 'detached drift' is removed (detached) from that part of the continental slope where it originally enucleated and has oppositely directed currents flowing along its two flanks. It is generated by the interaction of the bottom current with a distinct current system or with a prominent change in the slope orientation, and as a consequence in plain view it generally has an arched shape produced by the dominant downslope progradation.

3. A 'channel-related drifts' is characterized by its relationships with narrow conduits (deep channels, gateways, trenches, moats, etc.) where bottom currents are constricted and drastically accelerated. In addition to significant erosion/nondeposition, two quite distinct types of channel-related drift may develop:
   a. A drift deposited within the conduits, either as axial mounds on the floor or as lateral sheets on the flanks of the channel, is known as a 'patch drift' (though this name may cause confusion with patch drifts unrelated to channels) and 'subsidiary drift', where it occurs within the moat, separating a giant elongated drift

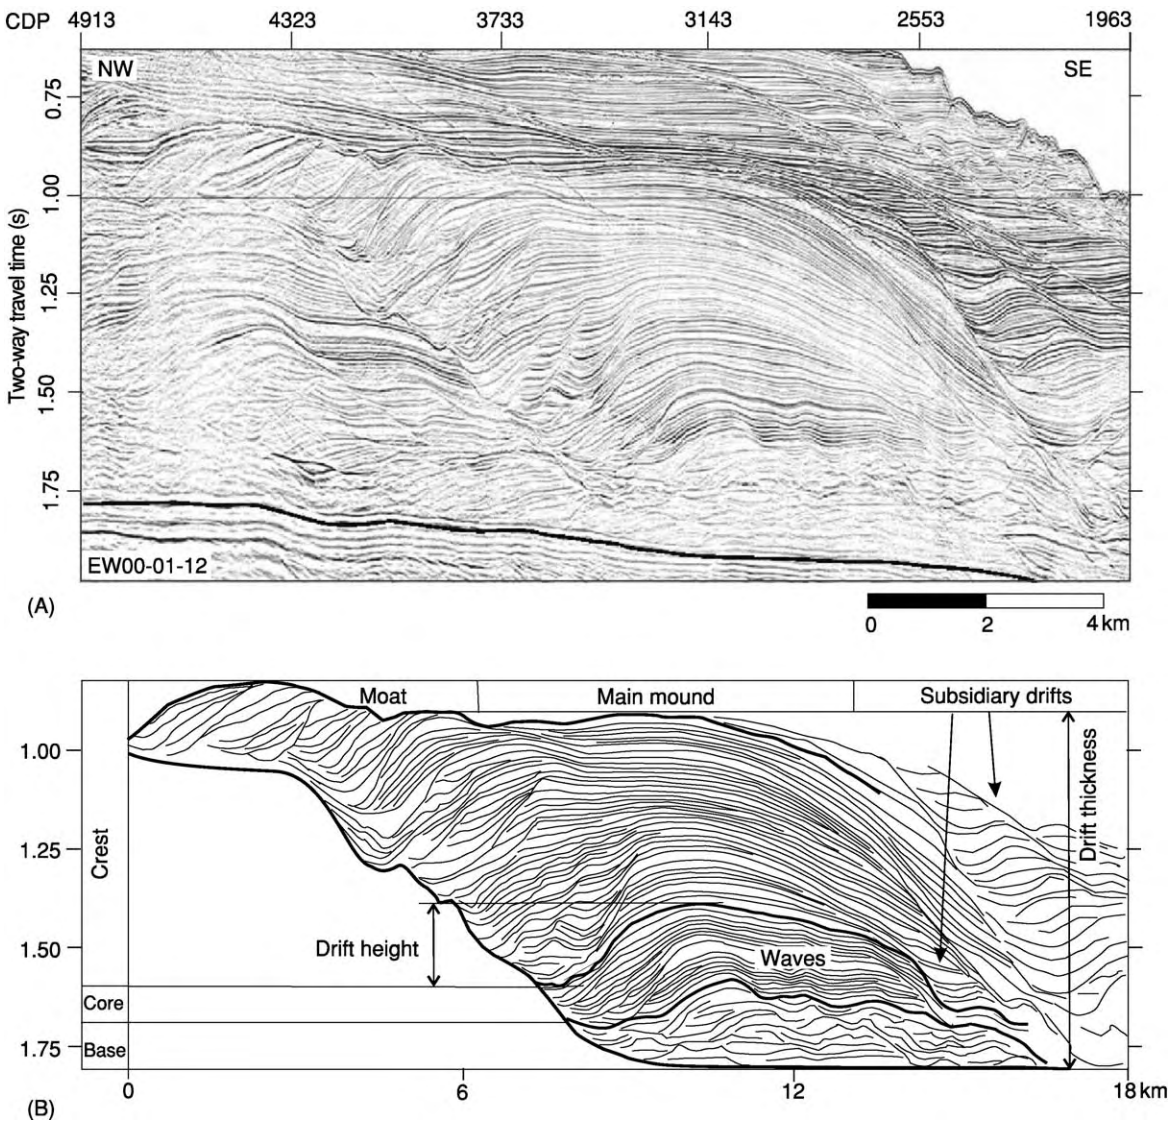

Figure 5 Seismic profile (A) and interpretation (B) showing an elongated, mounded drift in the north eastern Canterbury Bight. Adapted from Lu H, Fulthorpe CS, and Mann P (2003) Three dimensional architecture of shelf building sediment drifts in the offshore Canterbury Basin, New Zealand, *Marine Geology* 193: 19 47, with permission.

from the continental slope. This irregular, discontinuous channel-related drift generally elongates in the flow direction.

b. A 'contourite fan' is a much larger, cone-shaped deposit developed at the downcurrent exit of the conduits. It usually overlays major basal erosive disconformities, but for the most part shares many characteristics with medium-sized turbidite fans.

4. A 'patch drift' is characterized by a random (patchy) distribution controlled by the intricate interaction of the bottom current system with a complex seafloor morphology. Such a small-scale (a few tens of square kilometres), elongated, irregular drift may be either relatively mounded or thinly sheeted. It occurs plastered against reliefs or within a trough where the irregular topography may modify both direction and velocity of the local current flow.
5. A 'confined drift' is characterized by a mounded shape elongated parallel to the basin axis and distinct moats along both flanks. It occurs within relatively small enclosed basins, eventually actively subsiding, and generally shows a complex staking of upward-convex lenticular depositional units.
6. An 'infill drift' is characterized by a mounded geometry that progressively infills the topographic depression or irregularity in which it occurs. It typically forms at the head of the scar or at the

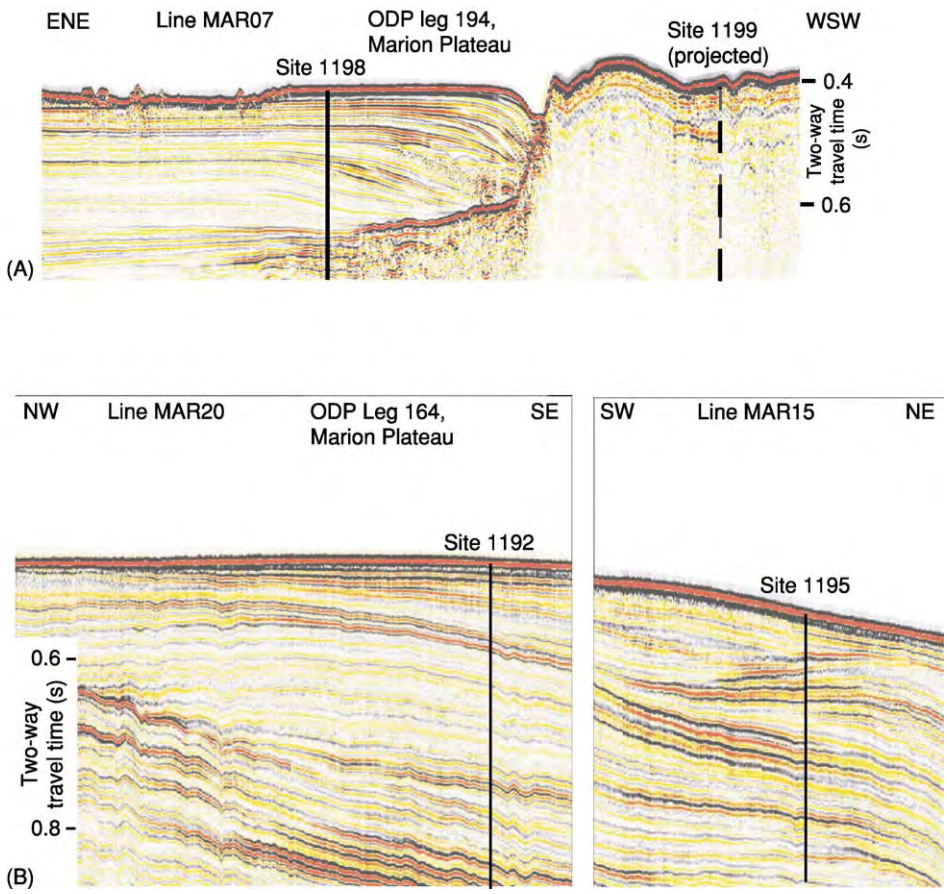

Figure 6 Seismic profiles showing a separated drift close to the Marion Platform margin (A) and a mounded drift complex, with location of some ODP leg 194 sites. Adapted from Shipboard Scientific Party (2002) Leg 194 summary, In: Isern AR, Anselmetti FS, Blum P, *et al.* (eds.), *Proc. ODP, Initial Reports*, Vol. 194. Available from: http://www odp.tamu.edu/publications/194_IR/chap_01/chap_01.htm.

margin of the toe of slumps developed beneath the path of a bottom current, and generally shows moderate relief and extent, variable shape, and downcurrent progradation.

7. A 'fault-controlled drift' is characterized by a certain influence in its development from faulting. This recent addition lacks many well-documented examples and is too little known to allow any generalization regarding deposit geometry and bottom current nature. However, it appears to develop either at the base or at the top of a fault-generated basement relief in response to perturbations in the bottom current flow pattern. A supplementary characteristic may be (subsequently reactivated) syndepositional faulting that affects the relatively steeper side of such drifts.
8. 'Mixed drift systems' are characterized by the interactions of alongslope currents with other depositional processes. The most effective interplay is between contourites and turbidites, but drift development may be variously affected by the association with debrite, hemipelagite, and glacigenic systems. On the basis of a large variety of different types of interactions (interfingering, intercalation, imbrication, incorporation, winnowing, entrainment, etc.), a wide assortment of terms has been adopted, including: companion drift-fan, fan-drift, levee-drift, composite slope-front fan, etc.

Seismic Characteristics

Although much progress has been made in determining the combination of criteria that best represent contourite deposits, seismic data without additional supporting evidence should not be used to make a firm identification of contourites. This is especially true when contourites are closely interbedded with other deep-water sediment facies (e.g., turbidites, hemipelagites, debrites, or glacigenic deposits). In addition, the vital information derived from detailed bathymetric images (either by multibeam or 3D

seismic surveys) of contourite deposits is still relatively rare (Figure 7). Nevertheless, there is a wide consensus on a three-scale set of seismic diagnostic criteria for confident contourite identification.

Large Scale (i.e., Sediment Body)

1. Drift geometry (one of those described in the previous section) beneath a bottom current system;
2. Large dimensions (up to $1 \times 10^6\,km^2$), larger on average than those of turbidite channel–levee systems;
3. Asymmetric mound-and-moat geometry in contrast to the symmetric gull-wing geometry typical of turbidite channel–levee systems (Figure 8);
4. Overall downcurrent elongation; and
5. Widespread regional discontinuities, especially at the base of the drift.

Medium Scale (i.e., Unit)

1. Overall downcurrent migration of the stacked lenticular, upward-convex, seismic units;

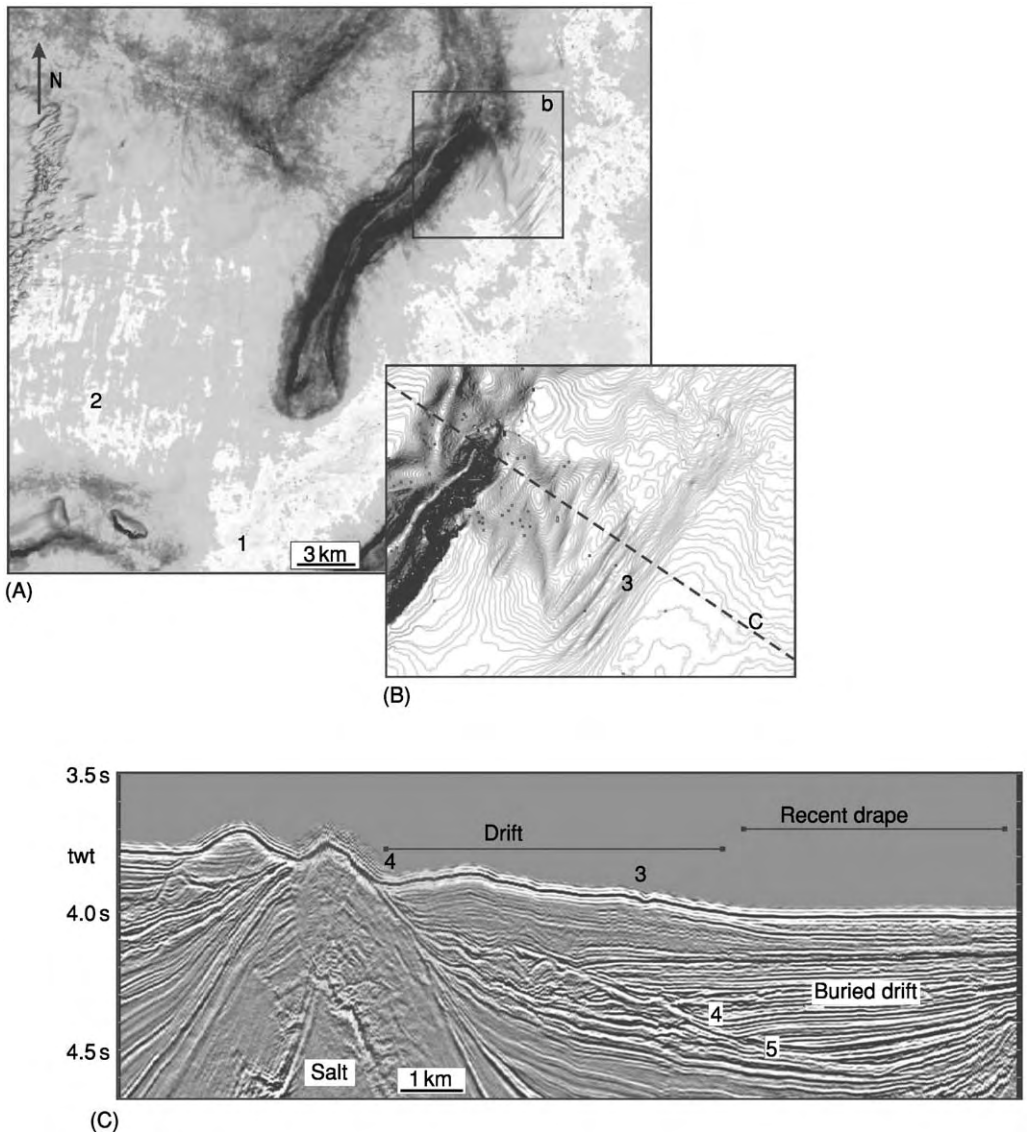

Figure 7 Grey scale seafloor map derived from 3D seismic amplitude (A), detail of the contour map (B), and seismic line (C) showing a mounded drift and bottom current related deposits adjacent to a NE SW trending topographic high. (1) Sheet like coarse grained deposit; (2) nonconfined, string like deposit; (3) erosional furrows; (4) moat between upslope migrating separated drift and topographic high; (5) basal erosional discontinuity. Reprinted from Viana A (2001) Seismic expression of shallow to deep water contourites along the south eastern Brazilian margin, In: Rebesco M and Stow DAV (eds.) Seismic expression of contourites and related deposits, *Marine Geophysical Researches* 22: 509 521, with kind permission of Kluwer Academic Publishers.

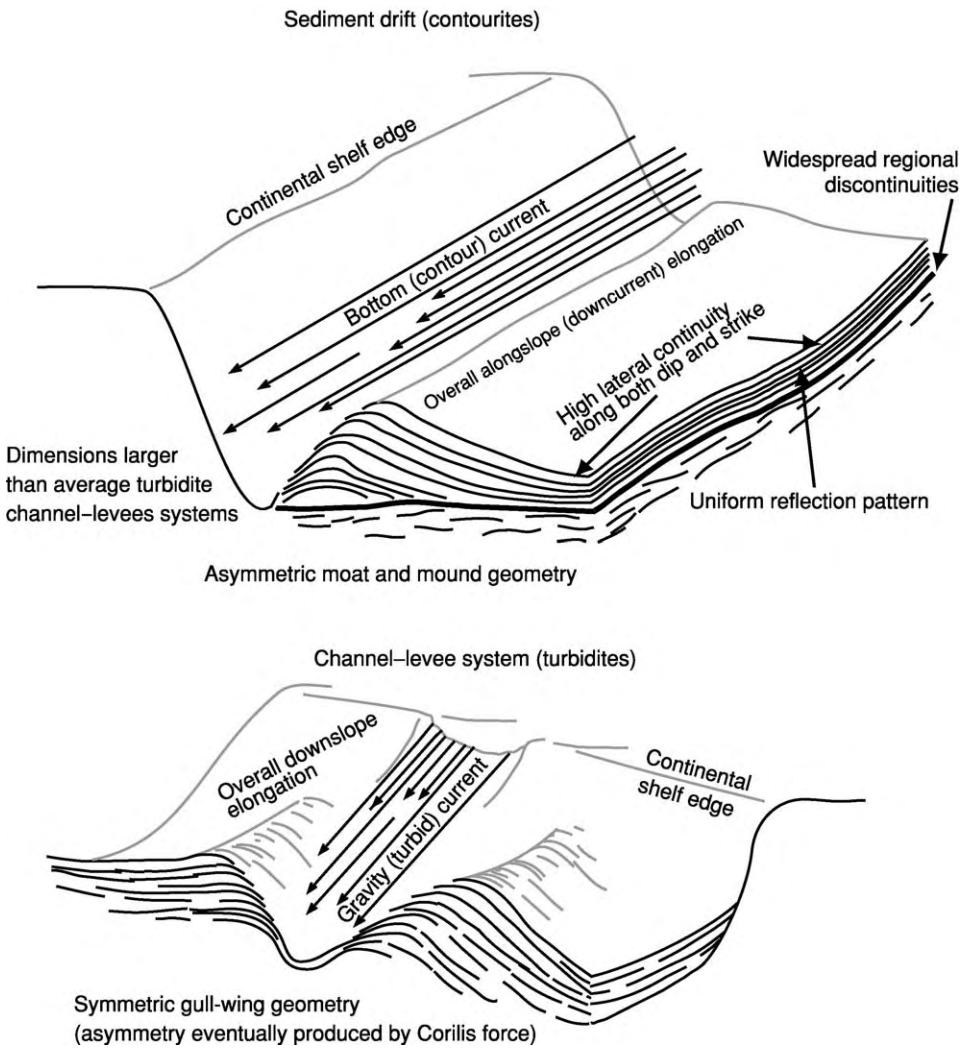

Figure 8 Schematic model showing some typical seismic characteristics of the sediment drifts and the ideal difference with a channel levee system.

2. Downlapping (onlapping on steep slopes) and sigmoidal progradational reflector patterns where downstream and upslope migration occurred;
3. Uniform reflection pattern, commonly found with extensive subparallel moderate to low amplitude reflectors;
4. Well-layered units with high lateral continuity along both strike and dip; and
5. Distribution of the depositional/erosional areas and lateral migration influenced (significantly at high latitudes) by the Coriolis force.

Small Scale (i.e., Facies)

1. Transparent layers and low-amplitude parallel reflectors, though seismic characteristics are very dependent on acquisition and processing methods;
2. Continuous, discontinuous, chaotic, and wavy reflectors in contourites and in turbidites, though seismic facies exclusively associated with contourites have not been defined yet;
3. Sediment waves, in both contourite and turbidite systems, though initially considered diagnostic of contourites; and
4. Bedforms, including longitudinal furrows, depositional tails in the lee of obstacles, and dunes.

Facies Model

Most typically, contourites are composed of fine-grained, structureless, highly bioturbated mud. However, they show a wide range of grain-sizes, composition, and preserved sedimentary structures (Figures 9 and 10).

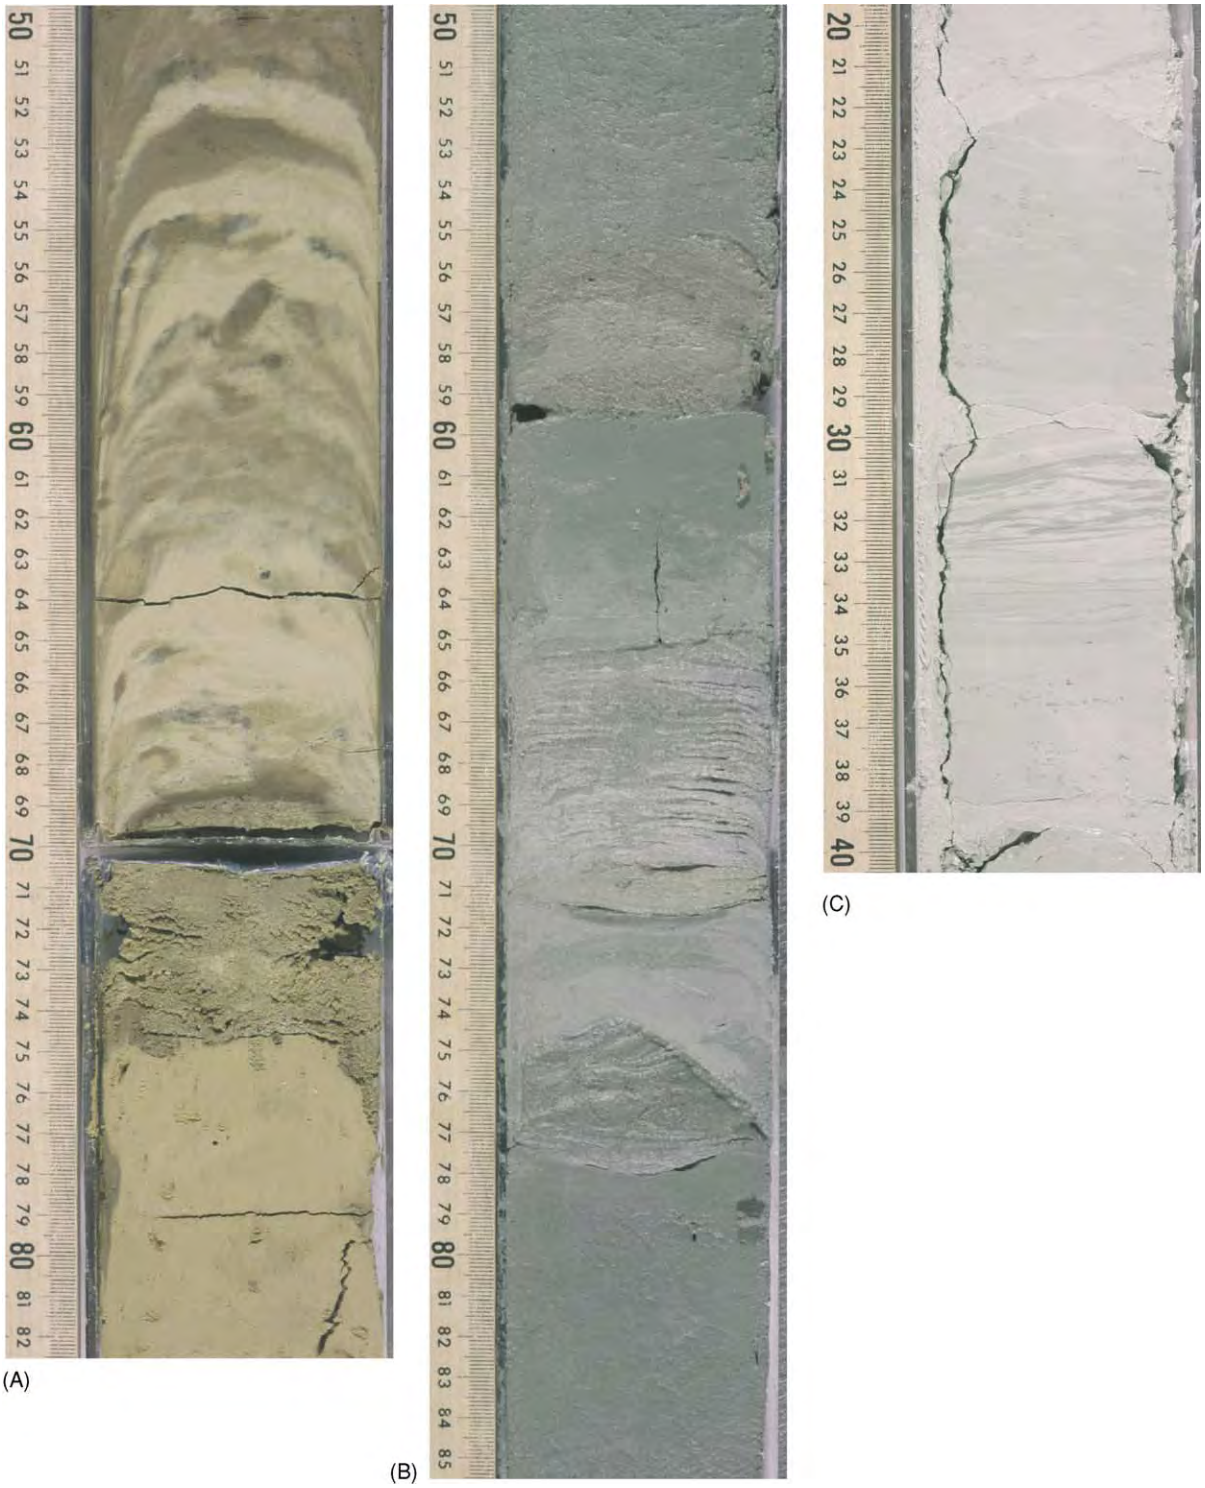

Figure 9 Core photos from ODP Leg 181 in the SW Pacific Gateway. From Carter RM, McCave IN, Richter C, *et al.* (eds.) (1999) *Proc. ODP, Initial Reports*, Vol. 181. Available from: http://www odp.tamu.edu/publications/181_IR/181ir.htm. (A) Core 181 1121B 1H CC, 50 82 cm from the Campbell Drift showing brownish yellow sand with extremely sharp bottom contact (75 cm) with the underlying yellow clay. This sand bed exhibits no grading and is interpreted as a contourite deposite left behind after that an intense winnowing removed the fine material. (B) Core181 1122C 44X 2, 50 85 cm in the left (north) bank levee of the abyssal Bounty Fan showing greenish grey fine sand and silt beds that commonly exhibit sharp scoured top and bottom contacts with the interbedded mottled, dark greenish grey pelagic/hemipelagic bioturbated silty clay. The conspicuous planar and cross laminations, representing concen trations of foraminifera and carbonate debris, suggest a stronger, episodic benthic flow regime, in contrast to that of the decelerating turbidity currents. (C) Core 181 1124C 37X 2, 20 40 cm from the Rekohu Drift showing light greenish grey clay bearing nannofossil chalk with flaser like interbeds and laminae suggesting the presence of sediment moving bottom currents.

They normally occur as thick (tens to hundreds of metres), uniform, fine-grained sequences (including thin to medium coarser-grained beds), or interbedded with hemipelagites, turbidites, and other resedimented facies, or as coarse lags within gateways. They are dominantly homogeneous (Figure 9A), poorly bedded (Figure 10A), and mostly bioturbated (Figure 10B) and mottled throughout, with little primary structures preserved. Bioturbation is generally considered an essential characteristic of contourites based on the belief that an active bottom current would increase oxygen concentration in the water and in turn increase organic activity, thus allowing contourites to be distinguished from episodic turbidites. However, bioturbation potential is also inferred to be a function of current intensity and other life-favourable environmental conditions. As a matter of fact, nonbioturbated contourites have been described as well (Figure 10C). Well-developed but somewhat irregular, fine lamination with indistinct bioturbation may be evident both in shallow-water and in high-latitude facies (Figure 10C), possibly as a result of a hybrid turbidite–contourite deposition. Although cyclicity is common, primary silty parallel and cross lamination (Figures 9B, 10C), where present, shows no regular sequence of facies as in turbidites. Contourites may show reverse grading, with coarse lag concentrations and sharp or erosive contacts (Figures 9A and

9B, 10A and 10B). Grain size may vary from (silty) mud to sand. Gravel-rich contourites are common in glacigenic environments due to the presence of ice-rafted debris. Bottom current winnowing and erosion in narrow gateways may also produce gravel lags or shale-chip layers. Sorting is generally medium to poor, but some sandy contourites may be well sorted and relatively free of mud, showing low or negative skewness values. No offshore textural trend may be observed. Composition is generally mixed with a combination of biogenic and terrigenous material. High sand-sized content in muddy hemipelagic contourites is often formed by bioclasts (Figures 9B, 10B). The terrigenous component largely reflects the nearby local sources, but alongslope mixing and far-off contributions also occur. In contrast the composition is essentially pelagic in biogenic contourites developed in open oceans or in upwelling areas. Manganese dioxides or iron oxides may occur as micronodules, stains, coating, and metal-enriched crusts within the manganiferous contourites. Fabric (when not exceedingly altered by bioturbation) is indicative of alongslope grain orientation, parallel to the bottom current flow. Contourites (Figure 11) are normally arranged in few decimetre-thick sequences showing gradual grain size and/or compositional changes. Five divisions may be eventually identified: (C1) lower mud, (C2) lower mottled silt, (C3) middle sand, (C4) upper mottled silt, and (C5) upper mud. A complete C1–5 sequence is interpreted to represent a gradual long-term current velocity variation and/or sediment supply change. Partial base-only or top-only sequences are also common.

Facies Continuum and Distinguishing Criteria

Deep-sea sediments may be interpreted as the product of three main processes: gravity-driven downslope resedimentation, alongslope bottom current activity, and slow pelagic settling through the water column. However, such processes are in fact end members belonging to a continuum spectrum. Deep-sea sedimentary facies are often hybrids resulting from interactions within such process continuum (Figure 1) rather than a mere stacking of interstratified deposits produced by discrete processes. Imaginably, the distal part of very-low-concentration (0.025 to 2.5 g l ^{1}), low-velocity (10–50 cm s ^{1}), fine-grained (silt and clay) turbidity currents may be easily deflected by Coriolis force from its natural downslope path to an alongslope direction and then entrained in the indigenous contour current. Concurrently, the tests of calcareous and siliceous planktonic organisms and the associated organic matter biosynthesized in the surface layers of the ocean may be significantly contributed by slow vertical

settling through the water column. The current originally driven by the gravitational effect of its terrigenous sedimentary load would hence imperceptibly grade into a thermohaline- or wind-driven, contour-parallel bottom current capable of depositing a hemipelagic, 'resedimented' contourite.

Although the traction effects of the bottom currents within an otherwise tranquil pelagic realm are fairly visible and may easily lead to the interpretation of the resulting deposits as contourites, a much more difficult and disputable work is required in trying to distinguish contourites from turbidites. Different sets of criteria have been proposed to characterize bottom current-reworked sandy sediments that occur where strong, permanent bottom currents have been active within a turbidite setting. In general, reworked turbidites are constituted by predominantly fine-grained sand and silt and are specially characterized by thin-bedded to laminated sand (usually less than 5 cm) in deep-water mud. Rhythmic occurrences of sand and mud layers are common (Figure 10C), with numerous sand layers (50 or more per 1 m of core). In many cases, the lower divisions of turbidites may be preserved and the upper ones entirely removed or partially modified by bottom current reworking. Reworked tops may show common bioturbation and burrowing, reverse grading, and lag concentrations. Horizontal and bidirectional low-angle cross-laminations and sharp erosive contacts may occur within the turbidite sequence. Cross-bedding is believed to be produced by steady and equlibrium flow conditions due to the bottom current action and, in contrast, is, envisaged with difficulty in episodic turbidity current events (Figure 9B). With respect to the adjoining turbidites, they may be cleaner, better sorted, more negatively skewed, and with a more bimodal fabric. In addition, the following diagnostic sedimentary structures have been proposed, although not universally agreed upon: lenticular bedding and starved ripples; mud offshoots; flaser bedding (Figure 9C); and the occurrence of sand layers with traction structures in discrete units, but not as part of a vertical sequence of structures, such as the Bouma sequence with basal graded division.

Deltas

T Elliott, University of Liverpool, Liverpool, UK

Introduction

Deltas form where sediment-laden rivers enter oceans, enclosed seas, lakes, or lagoons and supply more sediment than can be distributed by processes that operate within the receiving basin. They produce a protrusion of the shoreline and typically advance, or prograde, into the basin. Major deltas such as the Amazon, Ganges-Brahmaputra, Nile, and Mississippi are served by well-defined, often long-lived, continent-scale drainage basins that result in an alluvial trunk stream (Figure 1). Deltas are important sites of sediment deposition in their own right and they also create basin-scale depocentres, in that deltas in turn supply sediment to shelves, slopes, and deep-basin submarine fans. It is no accident that many present-day submarine fans occur basinwards of major deltas.

The social, cultural, and economic importance of deltas is considerable. They account for a significant proportion of the world's wetlands and are important in terms of habitation, agriculture, fishing, and navigation. They are extraordinarily sensitive to fluctuations in sea-level, whether caused by subsidence or eustatic sea-level change, and therefore feature prominently in studies of land loss, water management, and coastal stability. For example, in the United States, wetlands in Louisiana have been experiencing compaction-induced rates of sea-level rise in excess of $1\,\mathrm{cm\,year^{-1}}$ for several decades, causing land loss rates to exceed $100\,\mathrm{km^2\,year^{-1}}$. Current measurements and predictions of the rate at which eustatic sea-level is presently rising will have a major impact not only in Louisiana, but also on deltas globally. In view of their links to continent-scale drainage basins, deltas are also important when considering pollutant dispersal to the margins of oceans. Finally, the deposits of former deltas host significant fossil fuel reserves, providing both source and reservoir rocks in many oil- and gas-bearing basins.

Controls on the Variability of Deltas

Deltas are extremely diverse in appearance and behaviour. The formation and ultimate character of a delta are determined by variables that stem from the hinterland that is responsible for creating the sediment supply and from the fluvial system that serves the delta, and from the basin that receives the sediment. Major controls, such as climate and tectonics, act on both the hinterland and the receiving basin, and sea-level is critical at the interface between them. The means by which the variability of deltas is presently summarized involves a classification scheme based on the sediment calibre delivered to the delta and the interaction between fluvial, wave, and tidal processes that takes place in the shoreline or delta front sector (Figure 2). This allows interpretation of the Mississippi delta as a fine-grained, fluvial-dominated delta and the Ganges-Brahmaputra delta as a more sand-rich, tide-dominated delta. Despite their complexity and variability, deltas comprise two major components: the delta front, which includes the river mouth, adjacent shoreline, and seaward-dipping profile, and the delta plain, which is the low-lying, largely subareal part of the delta behind the delta front; the delta plain is dominated by

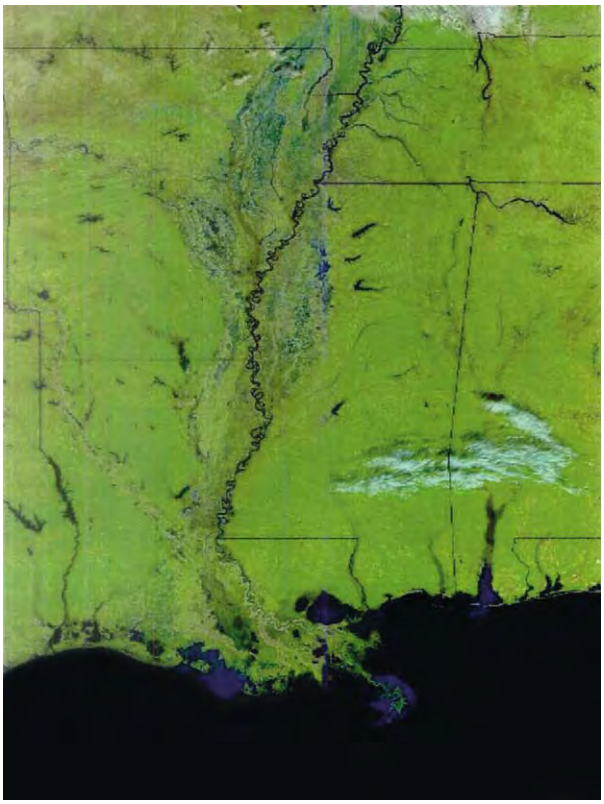

Figure 1 The Mississippi River and delta complex; the Mississippi River drainage basin extends over two thirds of the United States and is the alluvial trunk stream of the delta. The modern birdsfoot delta is flanked by the now abandoned, premodern shoal water deltas. The light blue sediment rich embayment west of the modern delta is where the new Atchafalaya and Wax river deltas are located.

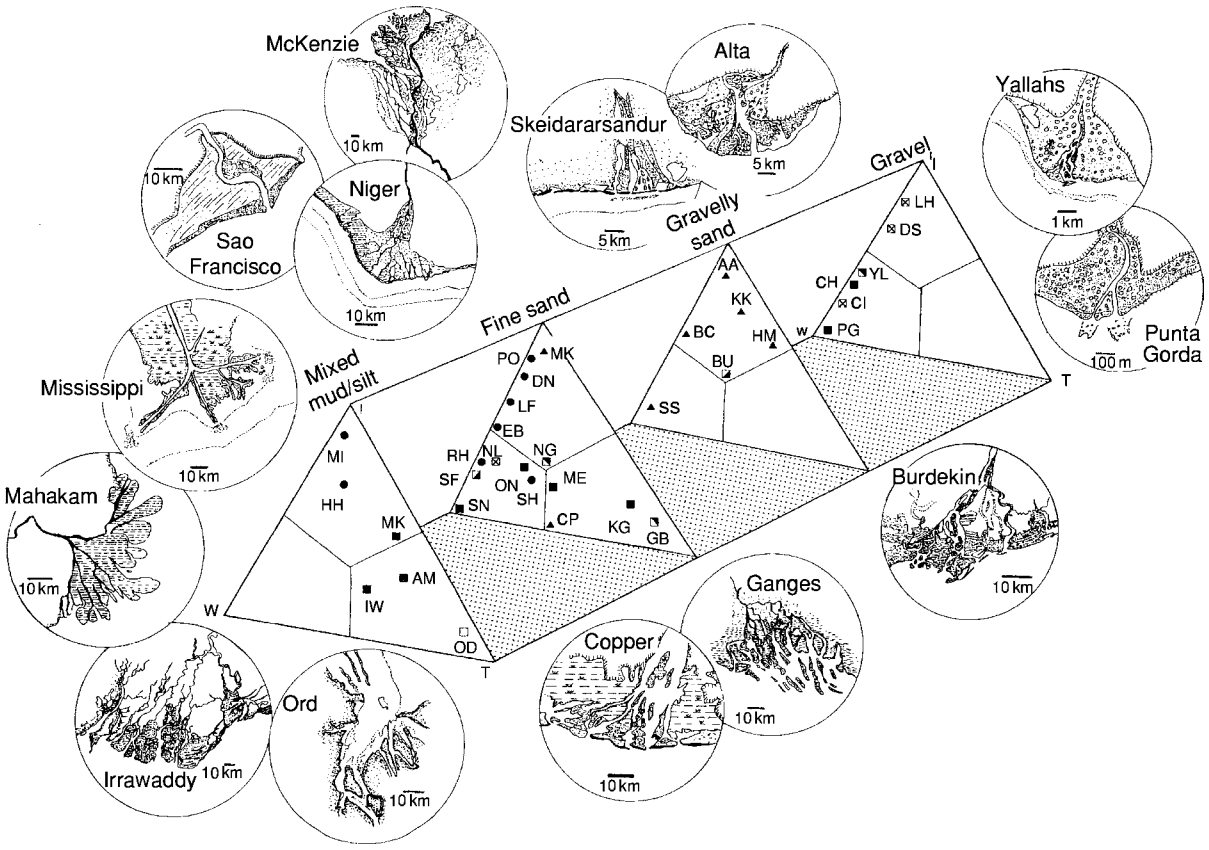

Figure 2 A classification scheme for deltas based on sediment calibre and the process regime of the delta front. In each triangular cross section, the top portion represents an input dominated (I) process, the left bottom portion represents a wave dominated (W) process, and the right bottom portion represents a tide dominated (T) process. distributary and crevasse channels, levees, bays, lakes, and tidal flats in tide-influenced deltas.

River Mouth Processes and Plumes in Deltas

The most important subenvironment of deltas is the mouth of the river, or the distributaries of the river, because this is where the interaction takes place between the sediment-laden river waters derived from the hinterland and the receiving basin. When river discharge reaches the mouth of a channel, it decelerates due to loss of gradient, expands due to loss of confinement by the channel margins, is required to mix with the waters of the receiving basin, and comes under the influence of basinal processes such as waves and tides. The outcome of this complex interaction will determine, first, whether a delta forms, and, if so, the characteristics the delta. The first-order control is the relative density of the incoming sediment-laden river waters and the waters of the receiving basin (Figure 3). Where the water masses are equal density (homopycnal flow), immediate mixing occurs at the river mouth and the sediment load is deposited locally at the river mouth. This can lead to the formation of localized, steep-fronted deltas referred to as 'Gilbert-type' deltas, which form commonly where bedload-rich rivers enter lakes. They can also form where gravel-grade rivers or alluvial fans enter the margins of marine basins, creating fan deltas. In this case, deposition results from the loss of competence to transport the gravel-grade material beyond the river mouth, rather than the density contrast of the water masses.

Where sediment-laden river waters are less dense than the basin waters (hypopycnal flow), then the outflow from the river is buoyantly supported and extends into the basin as a surface jet or plume (Figure 3). This process operates in major marine deltas because salt water is denser than fresh water is, and suspended sediment concentrations in river waters are typically insufficient to overcome this difference. Satellite images of major deltas invariably show murky, sediment-laden

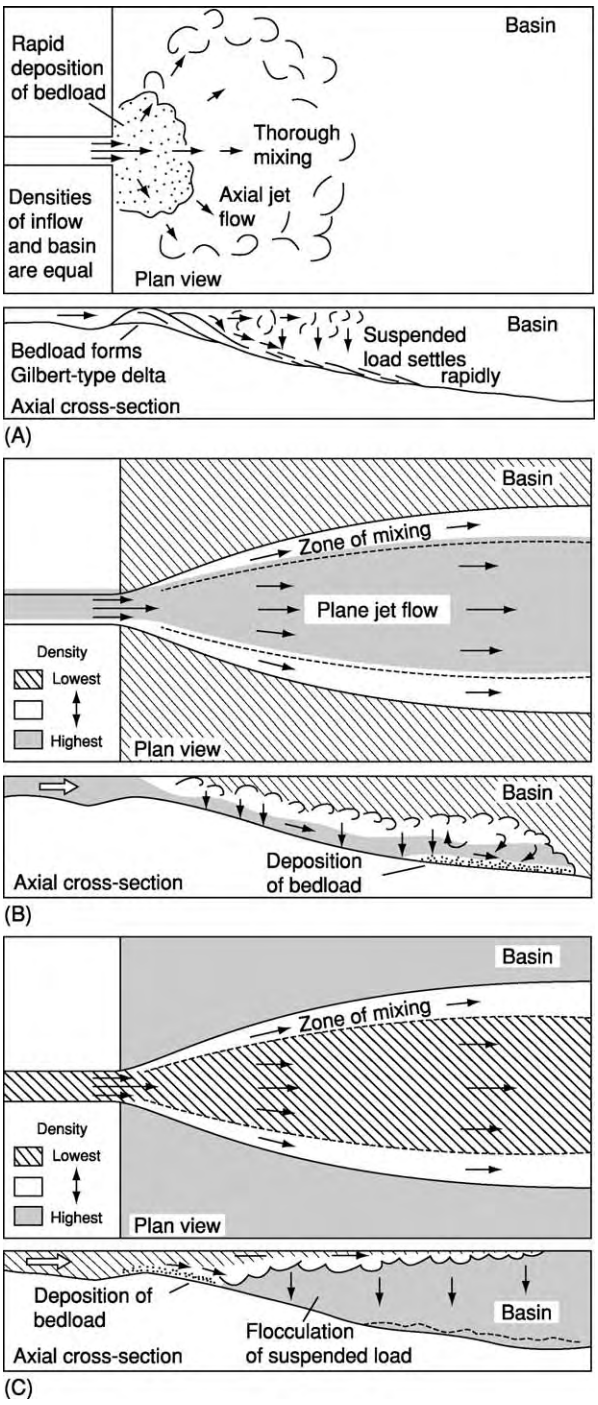

Figure 3 Fundamental processes that operate at the mouths of rivers or distributary channels based on the relative densities of the sediment laden fluvial discharge and the water of the receiving basin, distinguish ng homopycnal (A), hypopycnal (B), and hyper pycnal (C) flow. Reproduced with permission from Bates (1953).

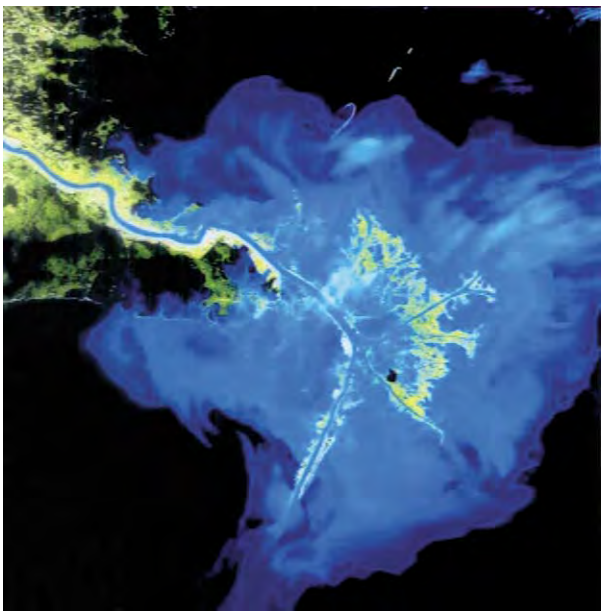

Figure 4 Plumes of sediment laden water (light blue) issuing from the Mississippi delta during a high discharge, river flood period. The plumes are buoyantly supported because the saline basin water is denser than the river water, despite the presence of suspended sediment in the latter.

plumes issuing from river and distributary mouths across the darker, sediment-free waters of the basin (Figure 4). In this situation, relatively coarse, sand-grade sediment is often deposited close to the channel mouth, either as bedload or from suspension, whereas finer material is transported further offshore in suspension. Turbulent mixing gradually reduces the density contrast between the water masses, causing the suspended load of the plume to be deposited with a trend of decreasing grain size offshore.

Where the sediment-laden river waters are more dense than the receiving basin (hyperpycnal flow), an underflow occurs, causing the sediment-laden flow to move discretely beneath the basin waters down the gradient of the basin margin (Figure 3). The extent to which this process operates in deltas is debatable. Clearly, if it operated exclusively, then a delta would not form, because all of the sediment load of the river would bypass the shoreline to be deposited subaqueously. However, the process may operate intermittently during major river floods. In a freshwater lake, suspended sediment concentrations of $\sim 1\,\mathrm{kg\,m^{-3}}$ can produce a hyperpycnal flow, but in marine settings, concentrations of $35–45\,\mathrm{kg\,m^{-3}}$ are required due to the greater density of salt water. The Huanghe River delta (China) regularly exceeds the critical value and produces hyperpycnal flows. Predictive modelling indicates that numerous small rivers entering marine basins also have the potential to produce hyperpycnal flows, because their catchments produce high sediment yields but limited water discharge. However, the modelling also argues that major river deltas cannot produce hyperpycnal flows,

Figure 5 The delta plain and upper delta front of the strongly tidally influenced Ganges Brahmaputra delta. The distributaries are tidal estuaries, the lower delta plain comprises tidal flats and creeks, and tidal processes contribute to the seaward dispersal of the plumes of suspended sediment at the distributary mouths.

because their ratio of sediment yield to water discharge is too low, even during extreme floods. A residual question is the extent to which these arguments apply during periods of sea-level lowstand, when the physiography of the fluvial systems is different (see later, Shelf-Edge Deltas in Quaternary Lowstand Periods).

The dispersal of sediment at the river mouth is also influenced by processes within the receiving basin. Moderate to high levels of wave or tidal processes promote mixing of the two water masses and also influence the orientation of the resultant plume. Wave processes limit the offshore extent of the plume and extend shore-parallel transport. Continuous beach sands rim the delta front, connecting the distributary mouths. In contrast, tidal currents extend the offshore component of sediment transport and elongate the plume into the basin (Figure 5). The tidal currents produce a network of tide-dominated channels separated by long, linear sand ridges.

The Initiation and Abandonment of Deltas

Deltas have a natural life cycle of initiation, growth, and abandonment. As deltas prograde into the receiving basin, the length of the lower part of the river feeding the delta is increased and the gradient is reduced. Shorter, steeper gradients therefore develop adjacent to stretches of the coastal plain. During major floods, the banks of a river can be breached and a new channel can branch, or avulse, off the main channel. If the breach is deep and is reused during subsequent floods, the new channel, with its steeper gradient, develops at the expense of original channel by diverting increasing amounts of the river discharge into the new channel. On reaching the margin of the receiving basin, the new channel initiates a delta, providing that it supplies more sediment than the receiving basin can redistribute. The delta at the mouth of the original river subsides because it no longer receives sufficient sediment to counter compaction of previously deposited sediments. The waters of the receiving basin progressively drown the former delta. The original delta dies and new delta is born.

This life cycle is particularly pronounced where fluvial-dominated deltas form on broad, unconfined coastal plains, such as the Gulf of Mexico. During the past 6000 years, the site of the Mississippi delta has varied along the margin of the Gulf of Mexico. Lobes and major delta complexes have switched across the margin of the Gulf of Mexico to the west and, to a lesser extent, to the east of the modern delta (Figure 6). These lobes and complexes that have been abandoned sequentially during the past 6000 years are now in differing states of abandonment. The present-day birdsfoot delta was established 600–800 years ago and new deltas are presently forming at the mouth of the Atchafalaya River and the Wax River, west of the modern delta (Figure 7). The Atchafalaya River branches off the Mississippi River and has a course to the Gulf of Mexico that is more than 300 km shorter than that of the Mississippi River. The tendency for sediment to be diverted along the Atchafalaya River has been stemmed for several decades by man-made controls because of the dire consequences for land loss in Louisiana if the avulsion is allowed to proceed unabated. The continued progradation of the modern delta towards the shelf edge is therefore artificially maintained.

The Abandonment of Deltas

What happens when a delta is abandoned? In view of current concerns of rising global sea-level, this question is germane. Rising sea-level not only inundates low-lying delta plains but also reduces gradients in the lowest parts of the river course and promotes avulsion. Abandonment of a delta therefore involves a reduction in sediment supply, whether via a lowering of river gradients or diversion of the river. Compaction of previously deposited sediments and related subsidence continues and land loss results because the supply can no longer maintain the delta plain.

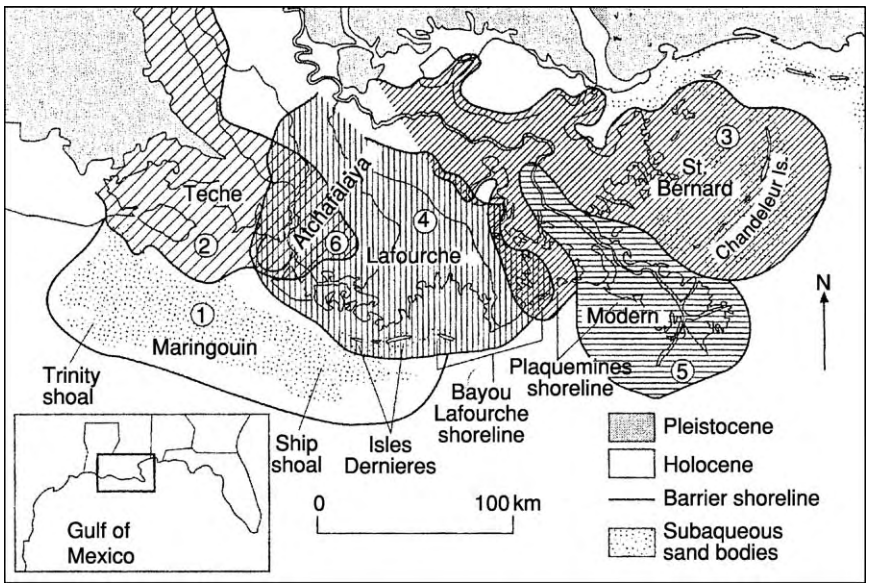

Figure 6 The major lobe complexes of the Mississippi delta system. The lower numbers indicate progressively older lobes that were active during the past 6000 years but are now in varying stages of abandonment (compare with **Figure 1**).

Figure 7 The Atchafalaya (right) and Wax River (left) deltas, forming in the Atchafalaya basin, are the new deltas of the Mississippi complex, west of the modern birdsfoot delta (see **Figure 1** for location of the Atchafalaya basin).

Additionally, with a reduction in sediment supply to the delta, the effectiveness of basinal processes is enhanced and these processes begin to rework the abandoned delta, particularly the former delta front. New shorelines are created and migrate landwards over the former delta plain as sea-level continues to rise. Precisely what happens during abandonment is therefore determined by the rate and magnitude of relative sea-level rise, the physical regime of the receiving basin, and the nature of the delta being abandoned.

In the Mississippi delta, the premodern, more lobate deltas experienced moderately high rates of relative sea-level rise related to compactional subsidence (**Figure 8**). Delta front areas are partially reworked initially into land-attached beaches (**Figure 9**) and subsequently into detached, arcuate barrier islands (**Figure 10**) that migrate landwards and are ultimately submerged as subsidence continues. The lower part of the former delta plain is converted into a shallow lagoon that progressively inundates the former delta plain (**Figure 11**), and the upper part becomes an extensive peat-forming swamp that blankets the underlying delta plain deposits. Offshore, the lower parts of the delta front accumulate slowly deposited, faunally rich muds or even carbonates as a consequence of the reduced sediment supply. In overall terms, the abandoned delta is draped by a suite of facies that record slow sedimentation rates by comparison with the facies that accumulate during active delta progradation. These slowly deposited abandonment facies produce distinctive marker horizons that are invaluable aids to identifying abandonment events and mapping the extent of former lobes and delta complexes.

Syn-Sedimentary Deformation in Deltas

Deltas are inherently unstable. This tendency has been known for some time in deltas worldwide, but as hydrocarbon exploration in the Gulf of Mexico extended onto the delta front area in the 1960s, the extent of these processes suddenly became clear. As soon as drilling rigs were placed on the delta front, they encountered problems. In 1969, as Hurricane

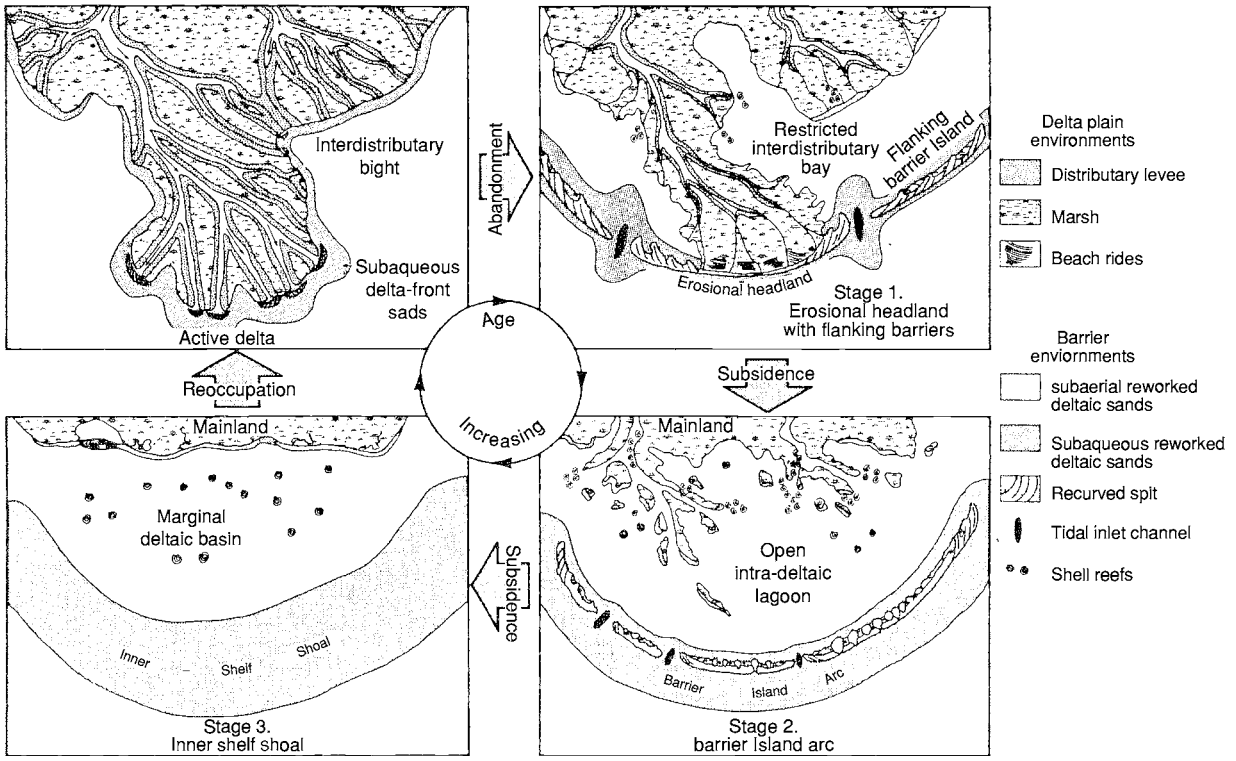

Figure 8 The evolution of the premodern lobe complexes as they are abandoned. In Stage 1 of abandonment, the former delta is reworked into a beach and barrier island complex as the effectiveness of the waves is enhanced and sediment supply diminishes. In Stage 2, transgression causes the initial beach to detach and migrate landwards and the former delta plain to be converted into a lagoon. In Stage 3, continuing transgression causes the barrier island to drown. At this stage, the only exposed part of the former delta is the upper delta plain, which is now blanketed beneath an extensive peat blanket (see **Figures 9** **11** for illustrations of Stages 2 and 3).

Figure 9 Formation of land attached, transgressive beaches during the early stages of abandonment of the Lafourche delta complex, Mississippi delta. Note the sealing of a former distributary channel by the beach sands and the storm induced wash over lobes that project onto the former delta plain (compare with Stage 1 of **Figure 8**).

Camille passed west of the delta, one rig was lost and another moved downslope. This prompted a thorough re-evaluation of the delta front, including seafloor mapping and renewed geotechnical investigations. During the 1970s, the diversity and areal density of deformational processes operating on the delta front were appreciated for the first time Figure 12). The Mississippi delta is still the most well-understood delta in this regard, but the processes are known to occur on many other deltas, and syn-sedimentary deformation should be regarded as an integral part of delta systems, particularly if the deltas have a significant fine-grained component to their sediment calibre. These processes are important in understanding patterns and rates of subsidence in deltas and also because they can have a profound effect on the final facies patterns that are preserved in deltaic deposits. The latter point is confirmed in studies showing that ancient deltaic successions commonly exhibit these features.

Aside from the possibility of seismic activity where deltas are located in tectonically active basins, there are three main mechanisms for syn-sedimentary deformation:

1. Oversteepening of the front of the delta related to high sediment accumulation rates can cause the delta to collapse, releasing large volumes of sediment as slides and slumps to deeper waters areas offshore and leaving a large detachment scar that is repaired by later sedimentation.

Figure 10 Chandeleur Island, a transgressive barrier island associated with abandonment of the St Bernard lobe, Mississippi delta complex. The lagoon on the landward side is established on the former delta plain; note the irregular margin on the barrier island on the lagoonal side due to multiple washover fans that are associated with the landward migration of the island across the lagoon (compare with Stage 2 of **Figure 8**; see also **Figure 1**, in which Chandeleur Island can be seen in an apparent NNE direction from the modern delta).

Figure 11 Levees bordering a former distributary channel in the delta plain of an abandoned delta, Mississippi delta complex. The remainder of the delta plain has been transgressed and is submerged, leaving only the highest former levee exposed.

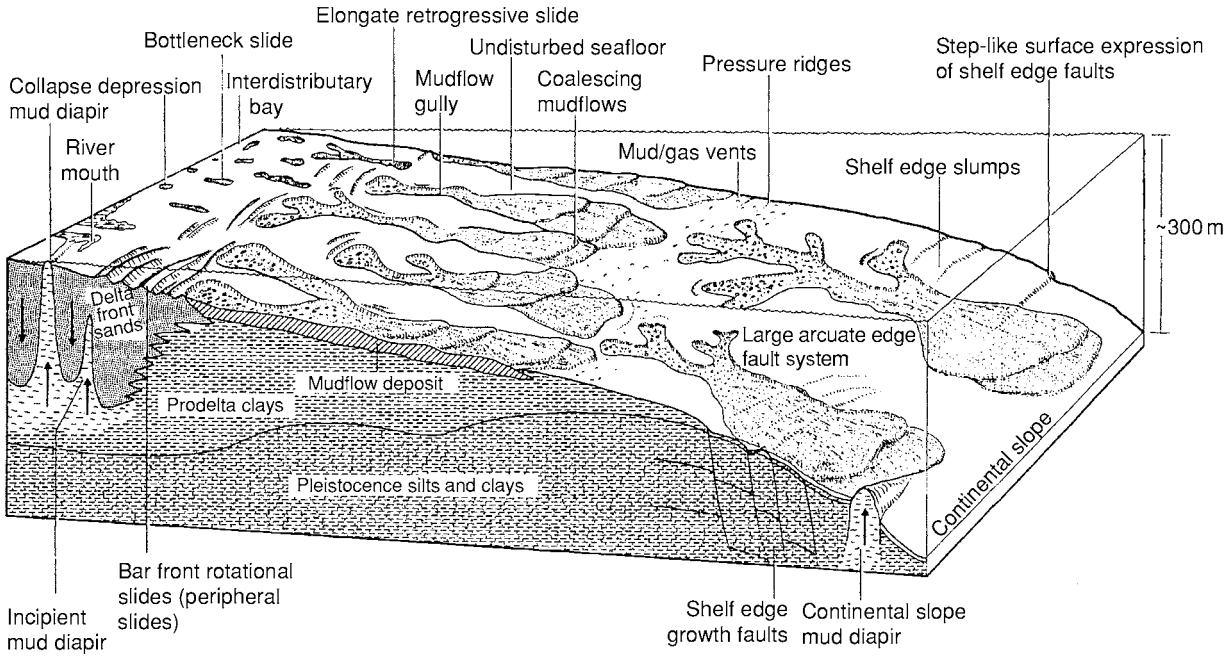

Figure 12 Summary of syn sedimentary deformational features in the delta front of the modern Mississippi delta; note the distinction between superficial and deeper seated features. Reproduced with permission from Coleman JM, Suhayda JN, Whelan T, and Wright LD (1974) Mass movement of Mississippi River delta sediments. *Transactions of the Gulf Coast Association of Geological Societies* 24: 49 68.

2. Repetitive pounding of the delta front by storm or hurricane waves can reduce the shear strength of near-surface sediments, leading to a coupling between surface waves and bottom and to sediment surface waves that can penetrate up to 20 m below the sediment surface.
3. High rates of sediment accumulation lead to thick piles of sediment that are water rich and in some cases also include early methane and carbon dioxide gases. During early burial of these sediments, pore pressures often increase as the sediments begin to compact and permeability is reduced.

Eventually, pore pressures begin to support part of the sediment load, thereby slowing compaction and leading to the sediments being overpressured and undercompacted for their depth. These sediments are unstable in relation to further sediment loading, and they creep basinwards, creating a wide range of deep-seated deformational features.

Superficial Deformational Features

Superficial deformational features include circular collapse depressions, linear gullies and mudflows, and rotational slides (Figure 13). It is estimated that 50–60% of the front of the Mississippi delta has failed via these mechanisms and has been transferred basinwards in recent times. Collapse depressions are created by wave pounding of shallow upper delta front areas between distributary mouths during storm or hurricane periods. As waves cyclically pound the sediment surface, they cause sediments to expel water and early methane gas, to re-pack, and to locally collapse, creating depressions 100–200 m across and 1–3 m deep. The downslope margins of the depressions often fail and viscous sediment/water mixes flow downslope as mudflows. The mudflows shear a linear pathway that is enlarged by rotational failures of the margins after the mudflow has passed. This creates delta front gullies 1000 m wide and 3–20 m deep, at the mouths of which are lobate mudflows that can be 10–15 m thick and can include outsized blocks of sediment that were rafted in the viscous flows.

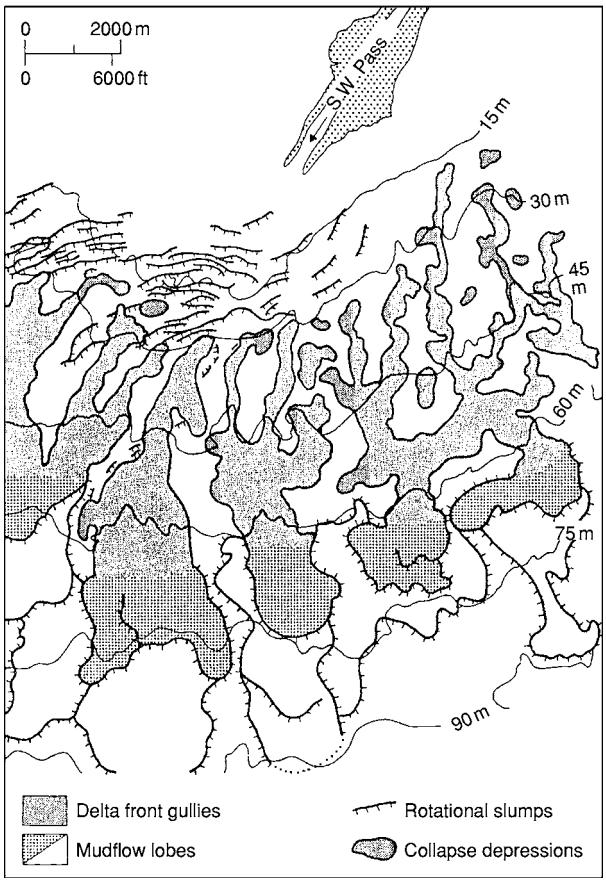

Figure 13 Map of collapse depressions, gullies, mudflow lobes, and rotational slumps in the delta front of the modern Mississippi delta. Reproduced with permission from Suhayda and Prior (1978).

Low-angle rotational slides, analogous to subareal landslides, are also common features, and it is this process that led to the loss of the drilling rig in 1969 (see earlier). Detachment surfaces dip at 1–4° in the headward regions then flatten into slope parallel surfaces. Blocks of sediment slide basinwards and may be preserved either as coherent, undeformed slides or as slumps that are deformed internally, particularly as they come to rest.

Deeper Seated Deformational Features

Basinward creep and gravitational sliding of overpressured/undecompacted fine-grained facies create an extensional regime along the basin margin and can lead to the formation of growth faults. Farther offshore in the toe regions of these structures, shale ridges and diapirs can occur (e.g., the Niger delta; Figure 14). The faults are listric extensional faults that mainly downthrow towards the basin, though counter-regional, landward-dipping faults also occur. Displacement varies from zero at the upper fault tip, to a maximum value in the middle part of the fault, decreasing again as the fault flattens with depth. In plan view, faults have curved traces that are concave to the basin and are of limited lateral persistence, though they may coalesce to form more extensive linked faults. The faults intersect the sediment surface and the hangingwall sides form preferred sites of deposition for delta front sediments. Thick, expanded, often sand-rich sections accumulate in the hangingwall of the faults and cause the faults to become self-perpetuating, because loading by the hangingwall section promotes further displacement. Anticlines offset by minor synthetic and antithetic faults form in the hangingwall succession. Through time, the site of active faulting migrates basinwards in concert with the overall migration of the delta system. Earlier faults experience a reduction in displacement and are eventually overlain by unfaulted strata. The vertical scale of the faults can vary from several tens of metres to kilometres. Sand-rich hangingwall anticlines are prime reservoirs in many deltaic hydrocarbon provinces (e.g., Niger delta).

Shale ridges and diapirs are compressional structures that form in the distal, offshore parts of deltas or the upper continental slope. They form where the toes

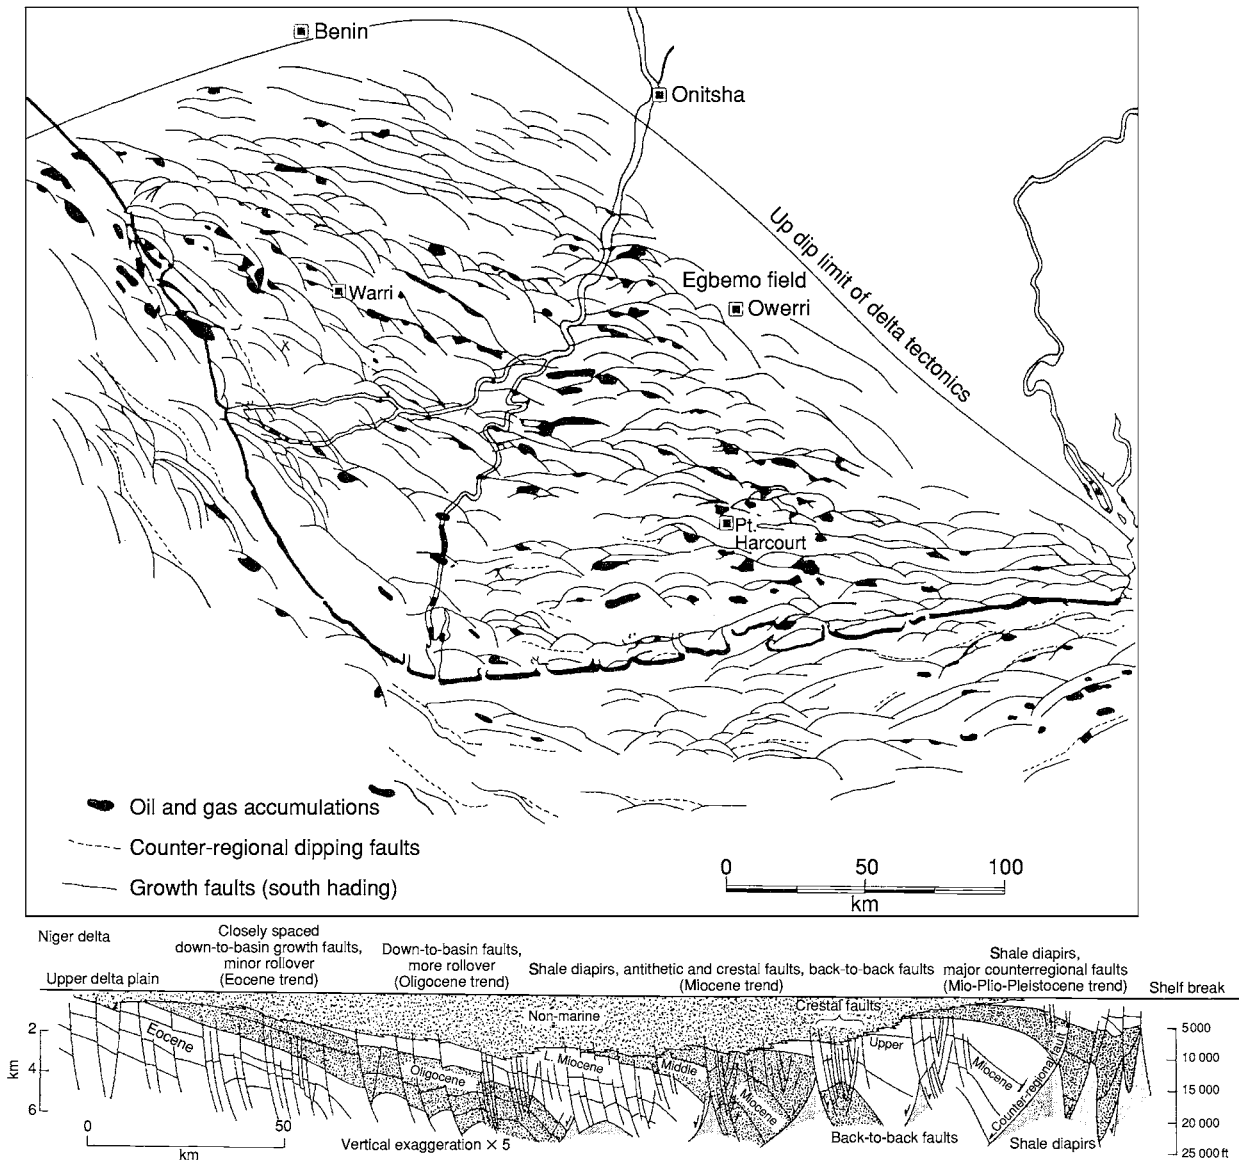

Figure 14 Map view of (top) extensional growth faults in the Niger delta and (bottom) a cross section through the delta from the upper delta plain (left) to the shelf break (right). Note the lateral impersistence of the faults, their curved traces, and general parallelism to the delta front in the map. In the cross section, note the down to basin displacement on most of the faults and the shale diapir province in the toe region of the deformation zone. Reproduced with permission from (top) Weber and Daukoru (1975) and (bottom) Winker CD and Edwards MB (1983) Unstable progradational clastic shelf margins. In: Stanley DJ and Moore GT (eds.). *The Shelfbreak: Critical Interface on Continental Margins. Special Publication the Society of Economic Paleontologists and Mineralogists*, Vol. 33, pp. 139 157. Tulsa, OK: Society of Economic Paleontologists and Mineralogists.

of listric faults cut up-section as they intersect the sediment surface, or where basinward-creeping overpressured shales intersect the surface. In the Mississippi delta, mud diapirs occur, somewhat unusually, in the delta front area, due probably to earlier shale ridges being point-loaded by distributary mouth bar sands. The diapirs appear as mudlump islands that project above sea-level by several metres. They are elevated shortly after major flood periods in response to high sediment accumulation rates and related sediment loading in the distributary mouth area and are eroded slowly by wave processes between flood periods. Mudlumps often survive between flood periods and are reactivated by the major flood, therefore becoming semipermanent features of the delta front. Sediment uplift of several hundred metres can be demonstrated and uplift rates of 100 m in 20 years have been documented. Subsurface investigations

Figure 15 A delta front gully (lower left) filled by mudflow deposits in an Upper Carboniferous deltaic succession in the Clare Basin, western Ireland. One margin of the gully is exposed on the right side, truncating earlier strata; the gully is 3 4 m deep and extends over at least 20 25 m laterally to the edge of the cliff.

Figure 16 A mud diapir in an Upper Carboniferous deltaic succession in the Clare Basin, western Ireland. Note that the bedded sandstones that overlie the diapir are thin above the crest and thicker on the flank of the diapir, indicating that the diapir grew during deposition of the sandstones. Cliff height is 25 m.

reveal that the mudlumps are growth anticlines related to reverse faults. The growth nature of the structures is depicted by thickness variations in the overlying mouth bar deposits that are thin above the diapir crest and thick in areas between diapers. Syn-sedimentary deformational features can also be observed in exposed, ancient deltaic successions (Figures 15 and 16).

Shelf-Edge Deltas in Quaternary Lowstand Periods

Presently, because of the Holocene transgression and the current highstand of sea-level, most major, ocean-facing deltas are located at the inner margin of a broad continental shelf. In contrast, during periods of sea-level lowstand associated with peak glacial in the Quaternary, these deltas were located at the outer edge of the continental shelf where they border on the continental slope. Falling sea-level forced the deltas into this position and they remained there until they retreated back across the shelf during sea-level rise associated with the onset of interglacial conditions. These shelf-edge deltas have been examined extensively in recent years using shallow, high-resolution seismic data that have demonstrated several distinctive features. The deltas are fed by widespread fluvial systems that are often incised into the former shelf (incised valleys). These systems supply large volumes of sediment to the shelf-edge deltas at a time when the accommodation space available for sediment accumulation is limited. As a result, the delta front slopes of lowstand deltas, seen as dipping clinoforms in seismic data, are typically steep (~2–4°) and frequently display evidence of large gravitational failures. Slump scars can cut 200–300 m of strata and extend laterally for several kilometres. Instantaneous bathymetric relief associated with the scars can be as great as 30 m and the scars may grow further by subsequent faulting. Slump scars therefore have the potential to release significant volumes of sediment to the deep basin as slides, slumps, debris flow, or turbidity currents, and to define minibasins that are repaired by subsequent deltaic sedimentation. Seismic data from these slump scar minibasins indicates that the repair of the scars is rarely simple. Healing by sediment accumulation alternates with renewed sediment failure, and the evolution of the scar fill can be critical in understanding the delivery of sediment to the deeper water setting during lowstand periods.

Economic Aspects

Deltaic deposits are commonly preserved in the geological record as thick, expanded sections of predominantly clastic sedimentary facies. As already mentioned, these deposits are of great economical importance. They contain vast reserves of hydrocarbons, both solid, in the form of coal, and fluid, as gas and oil (*see* **Petroleum Geology:** Overview). Because deltaic sediments are commonly rapidly deposited, with little reworking, organic matter is preserved in them. When buried and heated, this organic matter may generate oil and gas. In humid climates, the waterlogged surfaces of deltas are colonized by lush vegetation that is preserved in anaerobic marshes and swamps. These environments are sites of formations of peat that can accumulate to significant

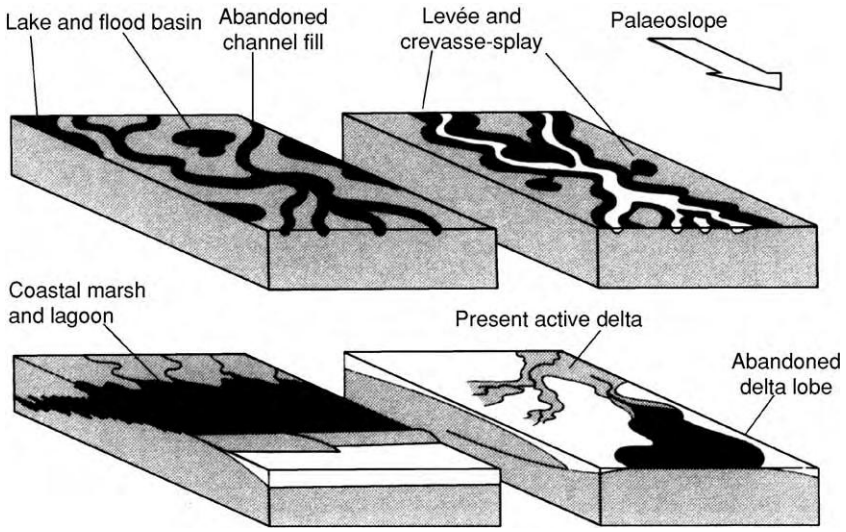

Figure 17 Sketches illustrating the common occurrence of beds of coal in deltaic settings. Note that to predict the geometry of an individual coal bed it is important to diagnose the subenvironment, rather than the overall depositional environment of the associated sediments. Channel abandonment coals, for example, occurs in fluvial, deltaic, and intertidal settings. Note also that coal geometry is controlled not only by its depositional environment, but also by subsequent erosion. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. thicknesses due to the high subsidence rates that prevail in deltas. When beds of peat are buried and heated, they metamorphose into lignite (brown coal), then bituminous coal, and finally anthracite. The conversion of peat into moderate- to high-grade coal involves a compaction ratio of ~10:1. Most coal beds are laterally continuous and relate to episodes of delta abandonment. In plan view, the geometry of coal beds may be irregular and is closely controlled by the depositional environment of the parent marsh (Figure 17). However, major coal beds in deltaic successions often relate to episodes of delta abandonment and are therefore laterally continuous coal beds that blanket underlying deposits. Most of the coal deposits of the world occur in deltaic deposits of Carboniferous age, and most of the lignite (brown coal) deposits of the world occur in Tertiary deltas. Deltas are often major petroleum systems (*see* **Petroleum Geology:** The Petroleum System). This is because a delta is a natural mechanism for depositing large volumes of sand (potential petroleum reservoirs) that prograde out over organic-rich muds (potential source rocks). Furthermore, deltas generate their own petroleum traps. These include the diapiric mud lumps, growth faults, and roll-over anticlinal structures. Deltas also contain a wide range of potential stratigraphic traps, such as sand-filled channels and delta front bars (Figure 18). The Tertiary–Holocene Niger and Mississippi deltas are major petroleum systems that illustrate these juxtapositions of source and reservoir rocks, and this range of trapping styles.

Deserts

N P Mountney, Keele University, Keele, UK

Introduction

Deserts are arid regions in which the annual precipitation is less than half of the annual potential evapotranspiration (a measure of moisture loss). Approximately 30% of the present-day land surface of the Earth is characterized by desert conditions, with hyper-arid regions restricted primarily to parts of the Saharan, Arabian, Atacama, and Namib Deserts (**Figure 1**). The world's largest deserts, including the Saharan, Arabian, and Australian, are located in tropical tradewind belts that are characterized by the atmospheric circulation of relatively moisture-free air. Other deserts, for example the Sonoran of the

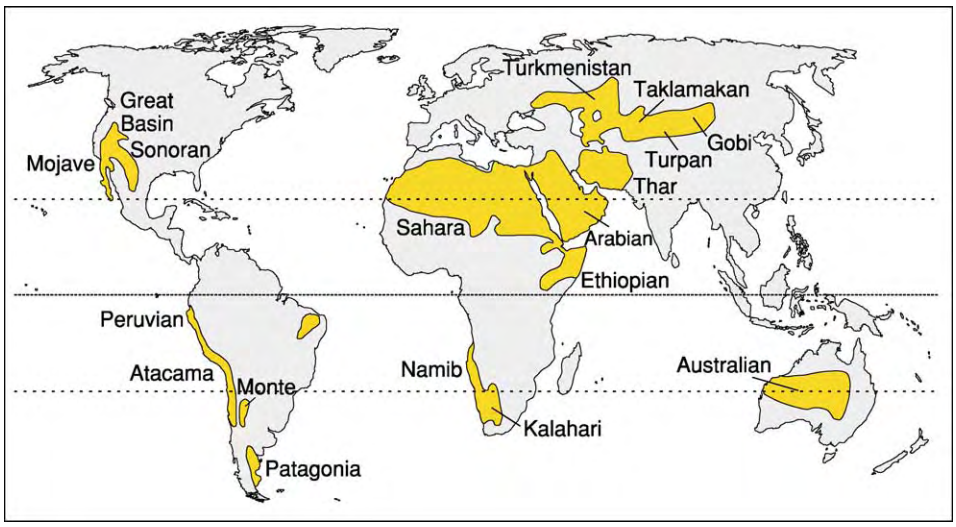

Figure 1 Distribution of the world's major climatic deserts.

south-western USA, are located in continental interiors away from humid maritime climates. The Namib and Atacama are coastal deserts in which aridity is promoted by cold offshore currents, whilst rain-shadow deserts, such as the Turpan of China, occur in the lee of mountain ranges. Deserts are not necessarily characterized by high temperatures; high-atitude polar deserts cover significant parts of Antarctica.

Deserts are composed of a variety of erosional and depositional geomorphic elements (Figure 2). Predominantly erosional mountainous and badland regions cover in excess of one-third of desert areas, whilst predominantly depositional regions composed of sand dunes, interdunes, sandsheets, playa lakes, sabkhas (salt flats), ephemeral and occasionally perennial rivers, and alluvial fans cover the remaining area. Where actively migrating sand dunes occur collectively, they form 'sand seas' or 'ergs', which cover approximately 20–30% of the surface area of the world's major deserts. The erosion, transport, and deposition of sediment in deserts are dominated by aeolian and fluvial processes, although chemical processes, such as salt precipitation, may be important locally.

The morphology and sedimentary characteristics of modern and recent desert environments, together with an understanding of the mechanisms by which these systems accumulate and become preserved, provide the basis for the recognition and interpretation of ancient outcrop examples. The architecture of ancient desert sedimentary systems can be summarized in the form of a depositional model.

Modern and Recent Desert Systems

Dunes and Sand Seas

Aeolian (wind-blown) dune bedforms are common in deserts in which the airflow is saturated with sediment. Dunes adopt a variety of morphologies (Figure 2) depending on factors such as the strength and directional variability of the wind, the size of sediment grains in transport, and whether the airflow undergoes downwind deceleration. Dune flanks and stoss (windward) slopes are characterized by wind-ripple strata, whilst steeper lee slope 'slipfaces', which are subject to periodic gravitational collapse, are characterized by grainflow (avalanche) and grainfall strata. Dunes occur either as individual, spatially isolated sand bodies, or they form collections ('trains') of bedforms that are arranged into sand sea accumulations, the morphologies of which are determined by the migration of hierarchies of bedforms of differing sizes and shapes, moving at varying rates and in varying directions relative to one another. Sand seas range in size from a few square kilometres to 560 000 km^2 in the case of the Rub al Khali erg in Arabia. Downwind changes in dune type across sand seas are common. For example, the Great Sand Dunes of Colorado are characterized by a zone of small, spatially isolated, partly cemented dunes at their upwind margin, a central zone of undulating barchan, parabolic, and transverse dunes with intervening interdunes, and a zone of large, actively accumulating transverse and star dunes separated by

only minor interdune depressions at their downwind margin.

Interdunes

Interdune flats and hollows occur between aeolian dunes (Figure 2) and are classified as dry, damp, or wet. 'Dry interdunes' occur where the depositional surface exhibits no evidence of sedimentation that is influenced by moisture. Dry interdunes are dominated by wind-ripple strata, aeolian plane-beds, and granule and pebble lags left behind after aeolian 'deflation'. 'Damp interdunes' occur where the depositional surface is in contact with the capillary fringe of the water table and sedimentation is influenced by the presence of moisture. Damp interdunes are dominated by a range of adhesion structures where sand sticks to the damp surface and by minor salt precipitation structures. 'Wet interdunes' occur where the depositional surface is continuously or periodically inundated by water due to elevation of the water table, flash flooding within the dune-field, or overbank flooding from beyond the margins of the dune-field. Mud-, silt-, and sand-grade sediment may be supplied to these interdunes via a combination of aeolian and fluvial processes. Sedimentary structures associated with such settings include subaqueous current and wave ripples, wavy and contorted bedding, desiccation cracks, raindrop impressions, hardpan crusts, and mud flakes. Carbonate sediments are known to accumulate in some long-lived ponds. Near-surface moisture in damp and wet interdunes encourages plant and animal colonization, and a variety of bioturbation structures, including roots, burrows, and trackways, are common in these settings. The geometry of interdune elements is determined by the spacing and plan-view shape (morphology) of adjoining dunes, and varies from spatially isolated hollows that are completely surrounded by dunes, to narrow but elongate corridors that extend for several kilometres between rows of transverse or linear dunes, to extensive interdune flats completely surrounding isolated bedforms. Interdunes typically decrease in

size and degree of interconnectedness from the margin to the centre of a sand sea as surrounding dunes increase in size.

Sandsheets

'Sandsheets' are areas of wind-blown sand that lack high-relief bedforms, but are instead characterized by wind ripples, plane-beds, and sometimes by low-relief ridge- and dome-like features called 'zibar'. Sandsheets develop where aeolian sand supply and its availability for transport are restricted to the extent that dunes do not develop. Additionally, the presence of stabilizing factors, such as vegetation or a shallow water table, can act to restrict sand movement and promote accumulation. Sandsheets subject to erosion are often characterized by an armoured lag of granules and pebbles left behind following aeolian deflation of finer sand-grade sediment. Individual sandsheets vary in extent from localized sand patches ($<1\,km^2$) to major geomorphic features, such as the $>100\,000\,km^2$ Salima Sandsheet of the eastern Sahara.

Sabkhas, Playa Lakes, and Salt Flats

'Sabkhas' are low-relief flats in which accumulation occurs wholly or partly as a result of evaporite precipitation (and in some cases carbonate sedimentation). The term 'sabkha' was originally used exclusively for the description of salt flats in coastal desert settings, but is now also widely used for the description of inland salt flats (Figure 2), which often border evaporitic 'playa lake' basins. Sabkha sedimentation usually involves interactions between chemical (precipitate) and aeolian processes, and results in the generation of a variety of wavy and crinkly laminae that are often disturbed by salt growth structures such as 'teepees'. Salt precipitation in sabkhas requires periodic wetting and subsequent desiccation of the surface, and is often controlled by subtle water table changes which, in coastal settings, may be driven by sea-level change, as is the case in the Dhahran Sabkha of Saudi Arabia.

Desert Fluvial Systems

Ephemeral rivers that typically flow for no more than a few days each year are common in many desert systems and are usually fed by high-intensity but short-duration and low-frequency rainfall events. Flash flood events mean that the infiltration capacity of the substrate is rapidly exceeded, resulting in overland flow. Desert stream flood hydrographs are markedly peaked, exhibiting a rapid rise to peak discharge, followed by a rapid fall. High peak discharge rates, together with a lack of vegetation cover and a substrate that is often covered with loose sediment, mean that fluvial transport and the deposition of sediment in desert regions are important geological processes. A lack of vegetation and a high proportion of non-cohesive sandy sediment result in a low degree of bank stability, which, when coupled with high rates of bedload transport, tends to favour the development of unconfined, braid-plain fluvial systems, such as those encountered in Namibia (Figure 2). Many desert rivers exhibit a downstream reduction in discharge due to transmission losses through a porous, sandy substrate. 'Endogenic' desert streams have catchment areas within the boundaries of the desert region, whilst the catchment area of 'allogenic' streams lies beyond the confines of the desert region, and such rivers may therefore be perennial in nature and provide a valuable water resource in an otherwise arid environment.

Alluvial Fans

'Alluvial fans' are depositional landforms that occur where confined streams fed by mountain catchments emerge, often via a narrow feeder canyon, onto a low-relief plain. A decrease in gradient causes an abrupt reduction in stream power at the mountain front, which promotes deposition and the build-up of a radial fan or cone of sediment. Desert alluvial fans are ephemeral systems with sediment transport only occurring during and in the immediate aftermath of flash flood events. Sediment transport may occur either as a sheetflood or as channellized flow, in which case channels on the fan surface often develop a distributary (downstream splitting) architecture. Alluvial fan sediments are generally coarse grained and exhibit a proximal to distal fining that reflects a downstream loss of stream power and resultant transport capacity. Proximal fan deposits are typically chaotic and structureless, often being the product of debris flows, whilst more distal fan deposits usually form more organized cross-bedded units that reflect a stream flow origin. At any given time, alluvial fan sedimentation is typically restricted to one particular part of the fan surface called a 'depositional lobe'. However, over time, lobes become choked with sediment, and eventually it becomes more efficient for the sedimentation process to 'avulse' (jump) to a new lobe. Alluvial fans often develop adjacent to active normal faults, the movement of which provides the mechanism that maintains the high gradient necessary for fan development. Where faults control fan activity, as is the case in Death Valley, California, a line of overlapping fans develops into a linear apron or 'bajada'.

Accumulation and Preservation of Aeolian Strata

The preservation of desert aeolian systems in the rock record is a three-stage process that requires: (1) the construction of a sand sea, (2) its accumulation to form a succession, and (3) its long-term burial.

Sand Sea Construction

Aeolian sand sea construction is a function of sediment supply, sediment availability, and the transport capacity of the wind. The 'sediment supply' is the volume of sediment of a suitable grain size for aeolian transport generated per unit time. This sediment may form either a contemporaneous or time-lagged source of material with which to construct an aeolian system, and may be derived from a variety of pre-existing aeolian or non-aeolian sources. 'Sediment availability' is the susceptibility of surface grains to aeolian entrainment, and is influenced by stabilizing factors, such as the presence of vegetation, mud drapes, coarse-grained lags, an elevated water table, or surface binding and cementing agents. The 'transport capacity of the wind' is a measure of the potential sand-carrying capability of the wind, which increases with wind power. Where sediment availability is limited, the airflow will be undersaturated with respect to its potential sediment load, and the wind will be potentially erosional. Conversely, an airflow that is fully saturated with sediment and undergoes deceleration must drop some of its load, thereby encouraging aeolian bedform growth.

Accumulation

'Accumulation' to generate a body of strata occurs when an aeolian system experiences a positive 'net sediment budget', such that upstream sediment 'influx' exceeds downstream 'outflux' and the accumulation surface rises over time. Accumulation of migrating bedforms occurs as a consequence of 'bedform climb' with respect to the accumulation surface. The 'angle of climb' is determined by the ratio between the rate of downwind bedform migration and the rate of rise of the accumulation surface (Figure 3). For most aeolian dune systems, the accumulation rate is small compared with the migration rate and the resultant angle of climb is low, such that, as bedforms move through space, they truncate the upper parts of the preceding bedforms in a train, and only the basal parts of the bedforms accumulate to form sets of cross-strata, a process called 'subcritical climbing'.

Bounding Surfaces in Aeolian Strata

'Bounding surfaces' are erosional surfaces that are generated as an intrinsic product of aeolian dune migration and climb, such that bedforms (or parts thereof) scour into pre-existing deposits as they move through space. Three broad types of aeolian bounding surface are recognized to occur as a product of 'autocyclic' (intrinsic) migratory bedform behaviour. 'Reactivation surfaces' result from periodic erosion of a dune lee slope, followed by renewed sedimentation as a consequence of a change in bedform migration direction, migration speed, asymmetry, or steepness (Figure 4). These changes are common because the airflow on lee slopes is often subject to modification and is rarely steady. In some cases, the period of the flow fluctuation is regular and generates cyclic reactivation surfaces, for example due to diurnal or seasonal wind reversals. Nested reactivation surfaces on two or more scales occur when cyclic sets of cross-bedding separated by reactivation surfaces are generated by the interaction of two or more forcing parameters operating with different periodicities. 'Superimposition surfaces' result from either the migration of superimposed dunes over a larger parent bedform, or the

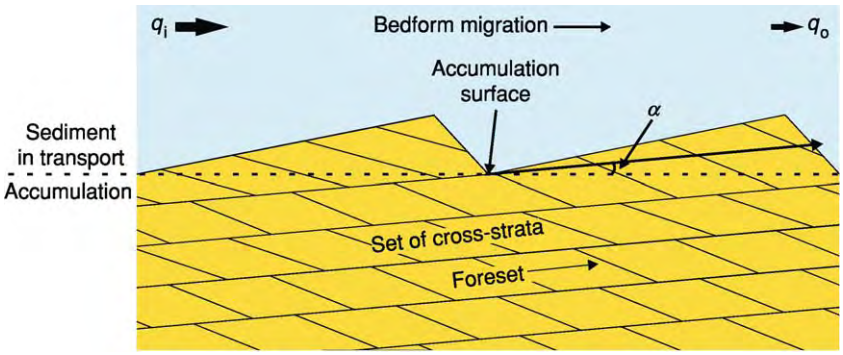

Figure 3 Generation and accumulation of sets of cross strata by migrating and climbing bedforms. Accumulation requires a positive net sediment budget, whereby the influx (q_i) exceeds the outflux (q_o) and the accumulation surface rises through time. The ratio between the rate of rise of the accumulation surface and the rate of downwind migration of the bedforms determines the angle of climb (α) of the accumulated sets of cross strata.

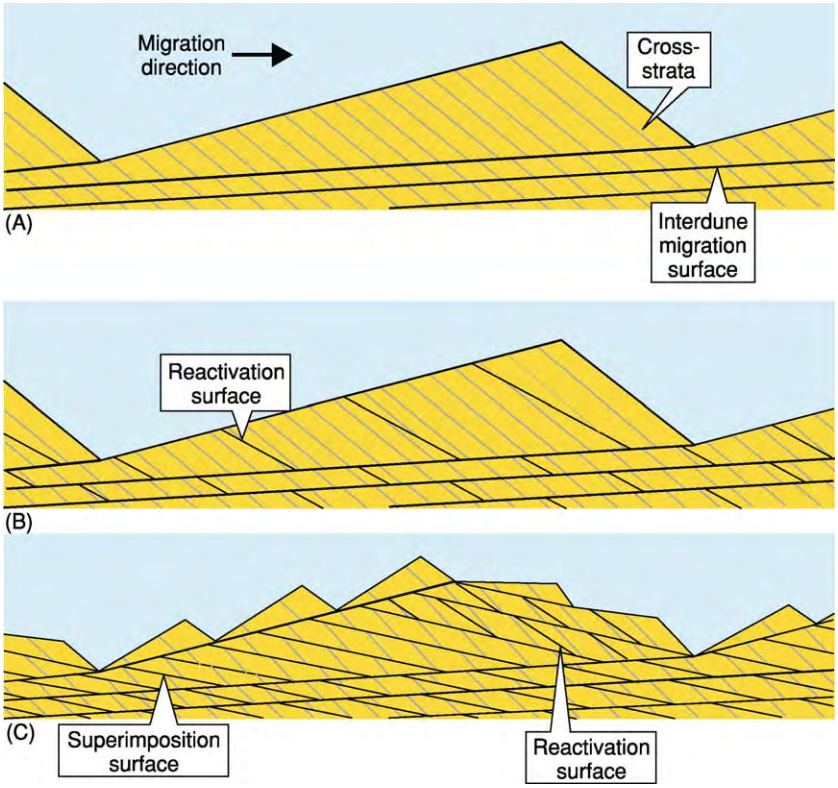

Figure 4 Generation of bounding surfaces in aeolian strata as a consequence of bedform migration. (A) Interdune migration surfaces. (B) Reactivation surfaces. (C) Superimposition surfaces arising from the migration of small bedforms over more slowly migrating parent bedforms. Reactivation surfaces may be nested within sets bounded by superimposition surfaces.

migration of scour troughs on the lee slope of a bedform (Figure 4). Although superimposed dunes and scour troughs can theoretically migrate directly up or down the lee slope of a parent bedform, oblique migration is more common because of secondary airflow along the lee slope of the parent bedform. Where both reactivation and superimposition surfaces are developed, the latter always truncate the former. 'Interdune migration surfaces' result from the migration of bedforms separated by interdunes (Figure 4). The surfaces are carved by the passage of an erosive scour that defines the interdune trough between successive bedforms. The depth to which the interdune trough scours as it migrates influences the extent to which deposits of the preceding bedform are eroded. Interdune surfaces, which truncate both superimposition and reactivation surfaces, typically extend continuously downwind for distances of hundreds of metres to several kilometres.

Types of Desert Aeolian System

In 'dry aeolian systems', the water table lies substantially below the accumulation surface, such that moisture plays no role in influencing sedimentation, and deposition occurs as a result of aerodynamic configuration alone. Bedforms in dry systems only commence climbing (i.e. accumulating) once they have grown to the point at which interdune flats have been reduced to isolated interdune depressions. In 'wet aeolian systems', the water table or its capillary fringe is in contact with the accumulation surface, such that moisture influences sedimentation, and deposition occurs as a result of both aerodynamic configuration and moisture content determined by the level of the water table. The angle of climb in wet aeolian systems is determined by the ratio between the rate of water table rise and the rate of downwind bedform migration, and such accumulations tend to be characterized by downwind climbing dune strata separated by climbing damp interdune units. In 'stabilizing aeolian systems', factors such as vegetation and surface cementation influence sedimentation, and deposition occurs as a result of both aerodynamic configuration and the degree and type of surface stabilization. For example, vegetation acts to disrupt the primary airflow, leading to a reduction in sand transport capacity and thereby a promotion of accumulation.

Supersurfaces and the Preservation of Aeolian Sequences

Aeolian accumulation ceases when the net sediment budget switches from positive to neutral or negative. Under such circumstances, a positive angle of bedform climb is replaced either by a zero angle of climb ('bypass'), when the accumulation remains static over time, or by a negative angle of climb ('deflation'), when an undersaturated airflow cannibalizes the dunes and the accumulation surface falls over time (Figure 5). Both bypass and deflation result in the generation of a 'supersurface', a fourth type of bounding surface that caps the underlying accumulation. The accumulation defines a 'sequence' and its bounding supersurface defines a 'sequence boundary'. Distinguishing supersurfaces in aeolian strata from other types of bounding surfaces is often difficult. Sedimentary features associated with supersurfaces include desiccation cracks, polygonal fractures, bioturbation, rhizoliths (calcified roots), and salt structures, all of which yield important palaeoenvironmental information regarding the nature of the desert surface at the time of supersurface formation. Supersurfaces often have great lateral extent and continuity and may bound entire sand sea successions. Thus, supersurfaces, which often result from changes in 'allogenic' (external) controlling factors, such as climate or tectonic setting, are considered to be of a higher order than the autogenically generated bounding surfaces that they truncate.

Long-term preservation of an aeolian succession requires that the body of strata is placed below some regional 'baseline of erosion', beneath which erosion does not occur, the principal agents promoting preservation being subsidence, water table rise, sea-level rise, and surface stabilization.

Ancient Desert Systems

Ancient aeolian desert systems exposed in outcrop are widely recognized from all seven continents, and a sizeable database of case examples now exists. In particular, the extensive Permian to Jurassic outcrops of the Colorado Plateau in the western USA (Figure 6) have been the focus of intensive study in recent years.

Dry Aeolian Systems

Dry aeolian systems, in which accumulation is controlled solely by aerodynamic configuration, are widely documented in the rock record. Accumulation in such systems occurs once dunes have grown to cover former interdune flats. The angle of climb of the system is determined by the ratio between the rate of accumulation (i.e. rise of the accumulation surface) and the rate of bedform migration. Steep angles of climb enable larger proportions of the original bedforms to be preserved, although climb angles rarely exceed 1° and typically only the basal 10–15% of a climbing bedform is preserved as a dune set (Figure 3). Thus, the facies preserved within aeolian dune sets record the processes that operated on the lower part of the dune lee slope at the time of accumulation, and are dominated by wind-ripple, grainflow, and grainfall strata. Additionally, superimposition and/or reactivation bounding surfaces may be present within climbing dune sets bounded by interdune migration surfaces. Supersurfaces within dry aeolian systems develop as a consequence of changed aerodynamic conditions, with deflation usually occurring when the airflow passing over a dune-field is not fully laden with sediment. The Page Sandstone of Utah and northern Arizona is a dry aeolian system represented by separate supersurface-bounded sequences, each composed of climbing dune strata and an

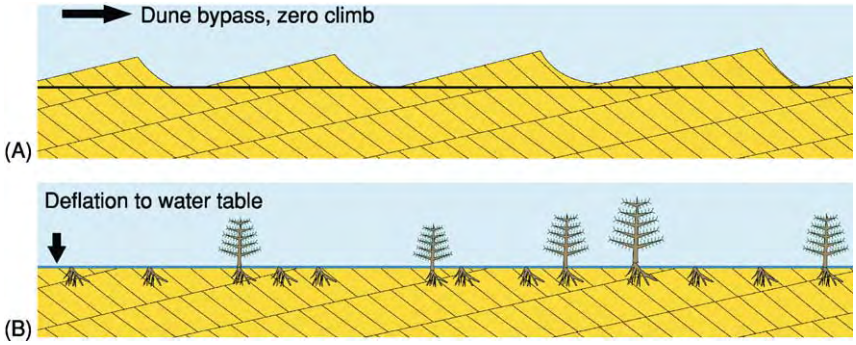

Figure 5 Models for the generation of supersurfaces in aeolian systems. (A) Bypass supersurfaces occur where the angle of dune climb reduces to zero, although dune migration may continue. (B) Deflationary supersurfaces occur as a result of erosion, often to the level of the water table. Such surfaces may exhibit evidence of widespread plant and/or animal colonization.

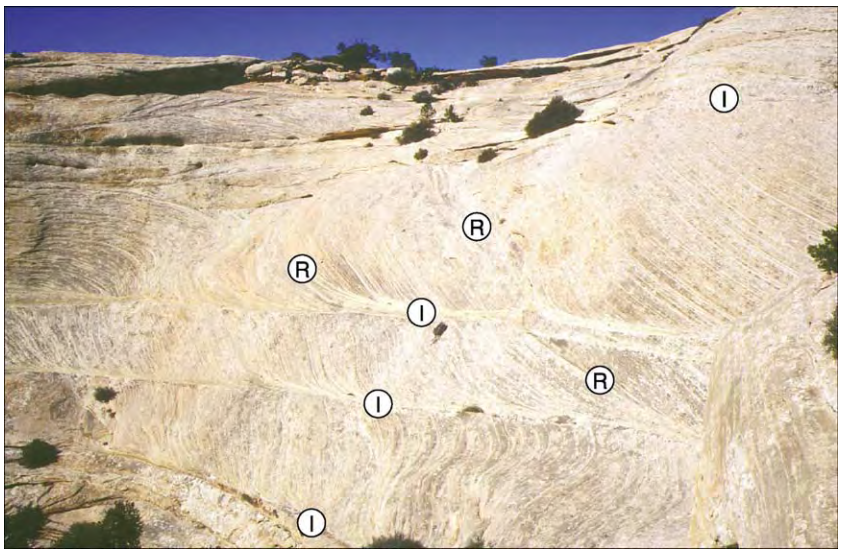

Figure 6 Sets of climbing aeolian dune strata bounded by interdune migration surfaces (I). Sets are composed of grainflow and grainfall strata that pass down into low angle inclined wind ripple strata at the set base. Numerous reactivation surfaces (R) are evident. Permian Cedar Mesa Sandstone, south east Utah, USA. Rucksack is 0.8 m.

absence of extensive interdune flat strata. The aeolian succession interfingers with transgressive marine units of the neighbouring Carmel Formation, indicating a coastal dune setting. In many cases, the supersurfaces are overlain by sabkha and subaqueous strata and exhibit great lateral extent. They are characterized by polygonal fractures and a corrugated, erosional relief. The aeolian-dominated sequences record episodic, punctuated accumulation and, rather than being stacked vertically, occupy laterally variable palaeo-depocentres. Episodes of accumulation of dry aeolian strata occurred because of a plentiful sand supply during periods of marine regression when the exposed coastal shelf acted as the sand source. Deflation to the water table and supersurface generation occurred because of reduced aeolian sand supply during marine transgression.

Wet Aeolian Systems

Wet aeolian systems, in which accumulation is controlled by a progressive water table rise coinciding with ongoing aeolian activity, are less widely recognized in the rock record than dry systems. Ancient wet aeolian systems are characterized by cross-stratified aeolian dune sets that are separated by interdune units exhibiting evidence of accumulation at or close to the water table. A progressive water table rise that occurred synchronously with dune migration in such systems is indicated by intertonguing of the toesets of advancing dune strata and strata that accumulated in the adjacent interdune. Accumulation controlled by a water table rise is indicated by a downwind rise (climb) through the stratigraphy of both dune sets and intervening interdune units, as seen, for example, in the Jurassic Entrada Sandstone, Utah, USA (Figure 7). Changes in either the rate of water table rise or the rate of dune migration cause the angle of climb to vary. The relative level of the water table is determined by both absolute water table changes, as governed by the climatic regime, and by subsidence, whereby the accumulation can subside through a static water table. Increases and decreases in the rate of relative water table rise cause interdunes to expand, and contract, respectively, at the expense of dunes. Where climatic regimes fluctuate on a cyclical basis, interdune units preserved in wet aeolian successions reflect this change (Figure 7), as observed, for example, in the Triassic Helsby Sandstone of north-west England. As interdune units expand and contract through time, so conditions at the depositional surface vary from dry, through damp, to wet and back in response to subtle variations in the level of the water table relative to the accumulation surface. Bypass supersurfaces are generated in wet aeolian systems when the relative water table remains static, whilst deflationary supersurfaces may occur as a consequence of relative water table fall.

Stabilizing Aeolian Systems

Stabilizing aeolian systems, in which accumulation occurs because agents such as vegetation or cementation act to restrict the availability of sediment for

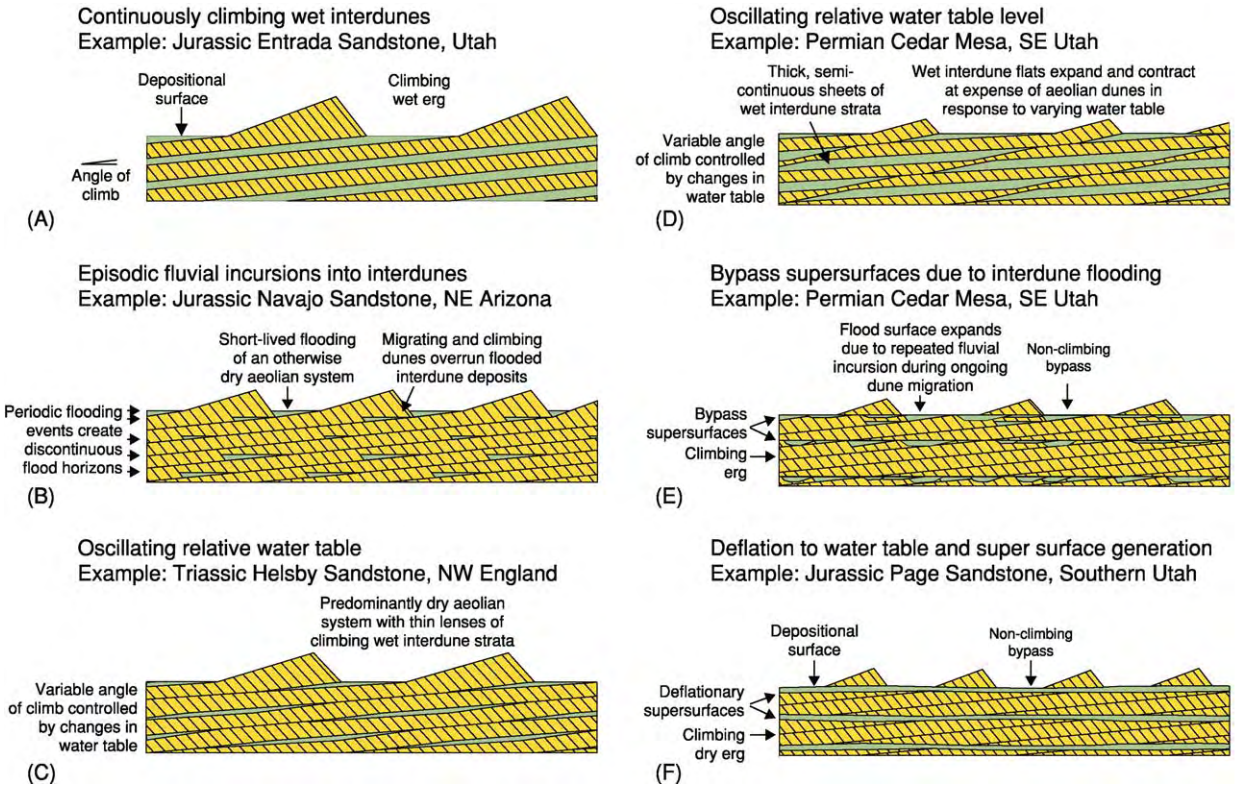

Figure 7 Common styles of dune interdune architecture in preserved aeolian desert successions. Interactions can potentially occur on a variety of scales. Adapted with permission from Mountney NP and Thompson DB (2002) Stratigraphic evolution and preservation of aeolian dune and damp/wet interdune strata: an example from the Helsby Sandstone Formation, Cheshire Basin, UK. *Sedimentology* 49: 805 833.

transport, are not widely recognized in the rock record. Accumulation of such systems is determined by the rate of emplacement of the agent responsible for stabilization. Colonization of dunes by vegetation is the most common modern stabilizing agent and is also considered to be responsible for enabling the accumulation of some ancient successions. Part of the Tertiary Tsondab Sandstone that underlies much of the modern Namib Desert is characterized by sets of cross-stratified dune strata that contain abundant plant root structures, which are considered to have both decreased near-surface wind speed (thereby promoting sediment accumulation) and acted as a sand-binding agent (thereby preventing deflation). Prior to the development of widespread land-based vegetation in the Devonian, chemical and physical factors, rather than biogenic factors, were the main stabilizing agents. Surface and near-surface cementation by chemical precipitates, a high water table, periodic flooding, and the presence of coarse-grained lags all encourage accumulation in warm-climate stabilizing aeolian desert systems, whilst permafrost may play an important role in enabling accumulation in cold-climate systems.

Depositional Models for Desert Systems

Preserved desert accumulations exhibit complex transitions on a variety of scales between the various subenvironments that comprise the arid climate depositional system for two main reasons (Figure 8). Firstly, at a relatively small scale, the various neighbouring depositional elements present within desert systems often undergo contemporaneous accumulation, resulting in the generation of complex interfingering architectures. These types of interactions are examples of 'autocyclic' (intrinsic) behaviour within the sedimentary system, reflecting episodic switching of sedimentary processes. For example, aeolian erg margin systems often interfinger with ephemeral fluvial and alluvial fan systems, such that aeolian and fluvial processes are in direct interaction. Interdune corridors periodically act as conduits for flood waters and, in turn, dry river beds provide a source of sand for the construction of aeolian dunes. Secondly, at a larger scale, sedimentary architecture is governed by shifts in key controlling factors that influence

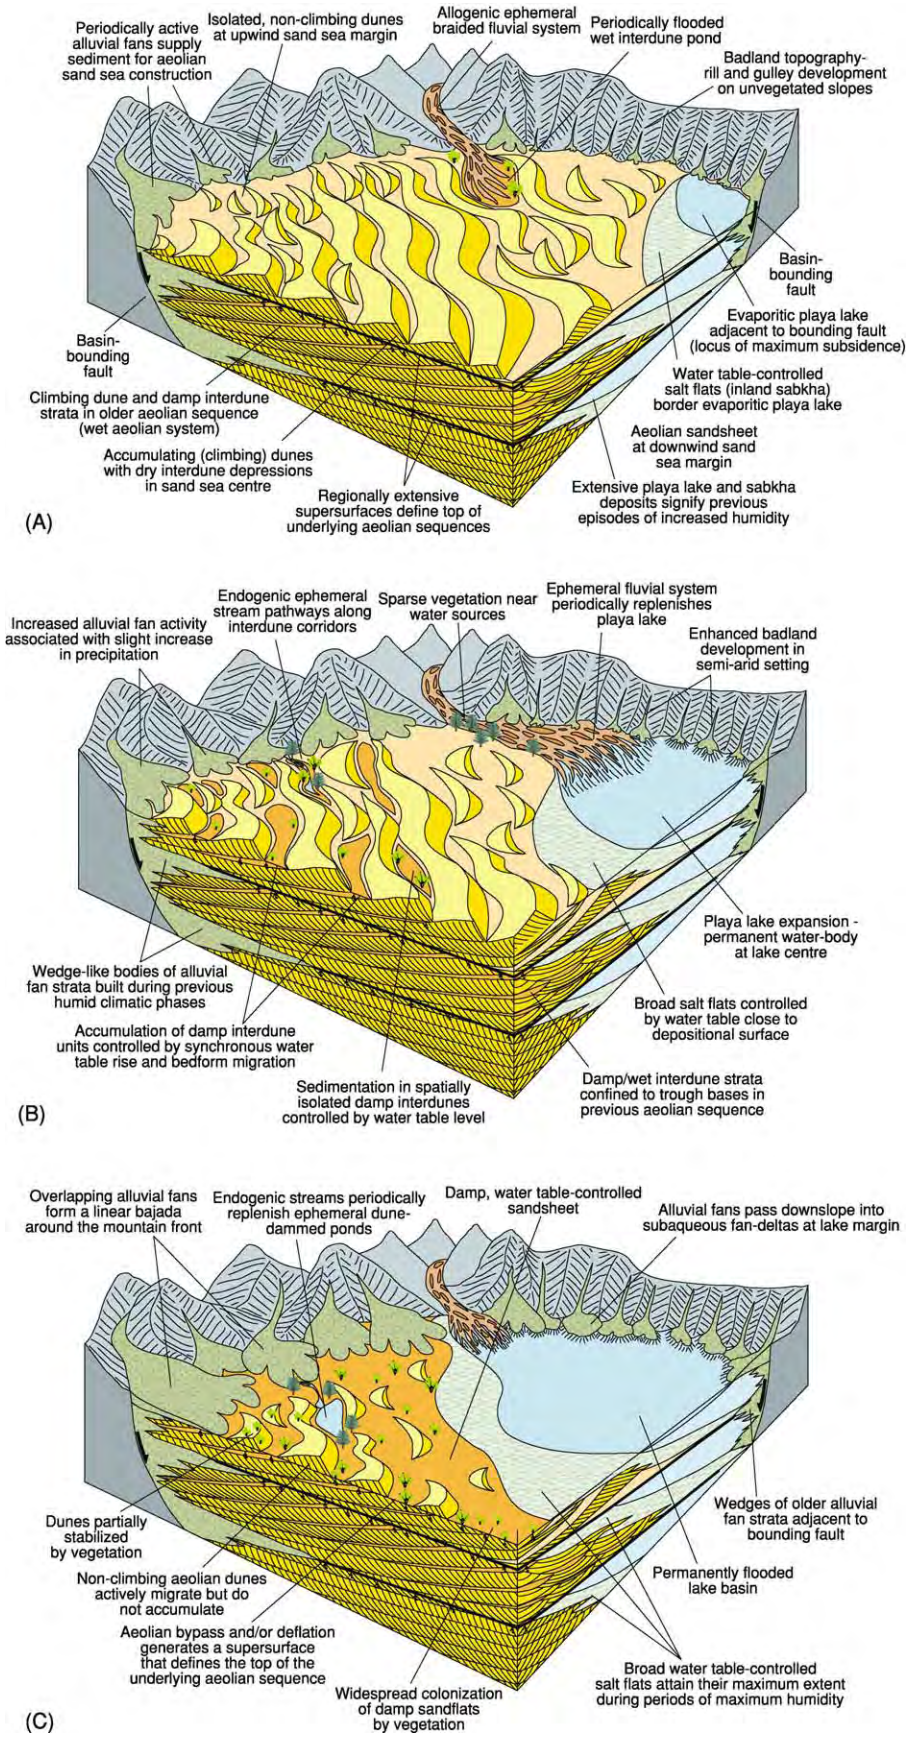

Figure 8 Depositional models for a conceptual desert system.

the gross-scale preserved architecture of the system. These 'allocyclic' (extrinsic) controls impose widespread change on the behaviour of the system. The major external controls on sedimentary architecture in desert systems are climate and tectonic basin setting. Together, these also determine the generation, supply, and availability of sediment for transport. Temporal changes in these factors will have different effects on different parts of the desert system (Figure 8). For example, a switch to a more humid climate may result in playa lake expansion due to a rise in water table. At the same time, elevation of the water table may restrict the availability of sediment for aeolian transport, causing dunes within an erg setting to stop accumulating and interdunes to expand or become flooded. Thus, various subenvironments within the desert system expand or contract, and accumulate or become eroded, over time as external controls vary. This is reflected in the preserved sedimentary architecture by large-scale shifts in the position of facies belts and the generation of surfaces of non-deposition and/or erosion (supersurfaces). In attempting to understand the complexity present within desert successions and to be able to differentiate between the extrinsic and intrinsic controls, preserved sedimentary architecture needs to be investigated on a variety of scales.

Lake Processes and Deposits

M R Talbot, University of Bergen, Bergen, Norway

Introduction

Lakes range in area from less than 1 km^2 to the *ca.* 374 000 km^2 of the modern Caspian Sea and in depth from less than 1 m to 1741 m in Lake Baikal. The salinity of lake waters ranges from fresh to salt concentrations several times that of seawater. Today, about 75% of large lakes (areas of over 500 km^2) are fresh; the rest are brackish to hypersaline. In view of this variety, it is not surprising that lakes share several sedimentary processes with the oceans but are also subject to other processes that, although not unique to lakes, are of much greater significance here than in marine environments. We can recognize a number of fundamental processes that directly or indirectly influence the types and distributions of deposits found in lakes.

- Physical processes are related to currents and waves generated by inflowing water or within the lake itself. Of particular importance are processes associated with rivers and with vertical and horizontal lake currents, and the physical structure of the water column. Physical processes, in particular the processes associated with slope failure and turbidity flows, are responsible for sediment mass movement and deposition.
- Biological processes may be directly responsible for the production of sediment or may play an important role in sediment accumulation and stabilization.
- Chemical processes: chemical sediments are common in some sorts of lakes, the most important being calcareous deposits and the evaporite accumulations characteristic of saline lakes.
- Hydrothermal processes: many lakes in tectonically active or volcanic regions are influenced by hydrothermal springs, which may affect the water chemistry or precipitate mineral deposits.
- Tectonic processes: most large long-lived lakes occur in basins of tectonic origin. In such basins tectonic effects may have a significant impact on patterns of sediment distribution and accumulation.

Although each process is listed separately, it should be borne in mind that some are closely interrelated. The production of biogenic sediments, for example, may depend on the presence of an essential nutrient, the supply of which is controlled by a lake's mixing regime. The inorganic precipitation of calcium carbonate often occurs during periods of high biological production and in some settings is probably controlled by it (see below).

Water-Column Structure, Currents, and Waves

Vertical Mixing

The degree to which surface and deeper waters mix is of fundamental importance to several aspects of lake sedimentation and biological production. Mixing is largely controlled by the turbulence associated with wind-driven surface waves and by the density contrasts between different parts of the water column. In shallow lakes wind stress may be sufficient to keep the water column more-or-less permanently well mixed, but in deeper lakes the degree of mixing between surface and bottom waters is largely determined by density differences. Although sediment and salt content influence the density of lake water, the primary control in freshwater lakes is temperature. Water becomes denser as it cools, achieving its maximum density at 4°C, so many temperate and high-latitude or high-altitude lakes go through an annual mixing cycle. In summer, when insolation is strongest, the surface water is warm and has a lower density than the deeper cooler waters. The water column is density stratified, with a warmer epilimnion and a cooler hypolimnion. These are separated by a relatively thin zone, the metalimnion, where there is typically a marked temperature gradient, the thermocline (Figure 1). During autumn and winter, surface waters cool until they become denser than the deep water, at which time the density stratification breaks down and vertical mixing occurs (Figure 1). In warm climates, particularly the subtropics and tropics, where temperatures are always high, surface waters may never cool sufficiently to become denser than the deep waters, so complete vertical mixing cannot occur. Such lakes are permanently stratified and are said to be meromictic. The role of climate in controlling mixing regime is clearly illustrated by the contrast between Lake Baikal and the deep East African rift lakes. The former is subject to a mid-latitude continental climate, with hot summers and frigid winters. Despite its great depth, Lake Baikal is well mixed. Lakes Tanganyika and Malawi, on the other hand, are meromictic tropical lakes, with an anoxic hypolimnion that constitutes a significant proportion of the total water mass.

Density stratification has several important sedimentological consequences. It determines the depth

at which inflowing water enters the lake (see below), determines the degree of oxygen renewal to the hypolimnion, and has a major influence on the nutrient supply to the surface waters, where most primary production takes place. A prolonged or permanent absence of complete vertical mixing may result in oxygen deficiency in the hypolimnion. This anoxia is inimical to higher forms of life (*see* **Sedimentary Environments:** Anoxic Environments). The hypolimnion can also become a sink for nutrients. Primary production is limited to the photic zone, which typically has a maximum depth of *ca*. 40 m and is often much less, depending on the clarity of the water. Dead organic matter produced in the epilimnion sinks into the hypolimnion where it is broken down by microbes; the nutrients released by this decomposition will be unavailable for new production unless they are returned to the surface waters. Recycling of nutrients in this way is of major significance to primary production and, ultimately, to economically important fisheries in many large lakes. Under anoxic conditions, some of the dead organic matter may survive decomposition to become incorporated into the bottom sediments. The deep-water deposits of stratified lakes are commonly notably rich in organic matter. The absence of higher organisms also means that the sediments can accumulate undisturbed by bioturbation. As well as having a high organic-matter content, sediments that accumulate in the hypolimnions of meromictic lakes are often characterized by a very regular fine lamination.

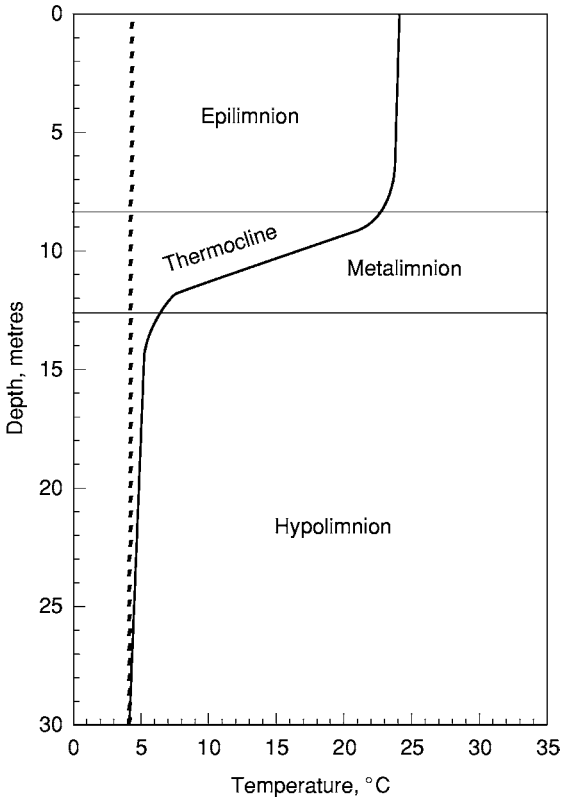

Figure 1 Temperature profiles through a typical temperate lake in summer (solid line) and winter (dashed line). Note how the thermocline separates the lake into two distinct water masses in summer. Isolation of the hypolimnion at this time can lead to severe oxygen deficiency or even anoxia. The winter profile shows the lake in an isothermal condition when it can mix to the bottom.

In addition to turbulent and density-related effects, other processes may enhance the mixing between deep and surface waters, even in lakes with permanent stratification. If a strong wind blows continuously from one direction, the surface waters can be pushed downwind, leading to the development of an epilimnetic wedge, which is separated from the hypolimnion by a tilted thermocline (Figure 2A). At the upwind end of this wedge, surface waters may eventually be completely displaced, to be replaced by upwelled water from the hypolimnion (Figure 2A). When the wind drops or changes direction, the thermocline tends to return to the horizontal; typically this does not occur in a single simple motion, but instead the thermocline oscillates in a seesaw fashion, setting up an internal wave or seiche (Figure 2B) along the length of the lake. The seiche will eventually decay, but, before doing so, may repeatedly bring cool nutrient-rich waters into the photic zone. Upwelling related to the development of an epilimnetic wedge and seiching is an important aspect of nutrient cycling in large tropical water bodies such as Lakes Malawi and

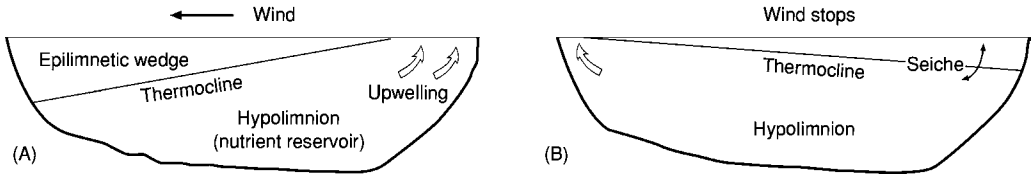

Figure 2 (A) Development of an epilimnetic wedge due to a strong unidirectional wind. Downwind displacement of the epilimnion causes the thermocline to tilt in an upwind direction and can eventually lead to the upwelling of cooler nutrient rich water from the hypolimnion. (B) When the wind stops, the thermocline rebounds, setting up an oscillatory motion or internal wave, known as a seiche. The seiche eventually decays because of frictional effects, but while it persists it may cause periodic upwelling at both ends of the lake.

Tanganyika. The upwelling zones are typically areas of very high primary production and may be characterized by the accumulation of sediments that are notably rich in biogenic material (see below).

River Inflow

Virtually all lakes, apart from those in areas of karst, are maintained by surface inflow from rivers and streams, which are also the principal suppliers of detrital sediment. How the inflowing water interacts with the lake water depends on the relative densities of the two water masses. It is not uncommon for river water to be significantly cooler than the water at the lake surface, such that the inflow tends to sink, forming either an interflow or an underflow (Figure 3). High sediment loads or salt contents can also produce dense river water. When such waters enter a lake they will plunge below the surface until they reach a depth where the lake water has a similar density. Interflows and underflows can be very efficient distributors of detrital sediment to offshore areas of lakes (Figure 3). One of the best-known examples occurs in Lake Mead (USA), which was formed by the damming of the Colorado River. Relatively salty sediment-laden river water enters the head of Lake Mead as an underflow current, which persists until it reaches the dam *ca.* 150 km downstream.

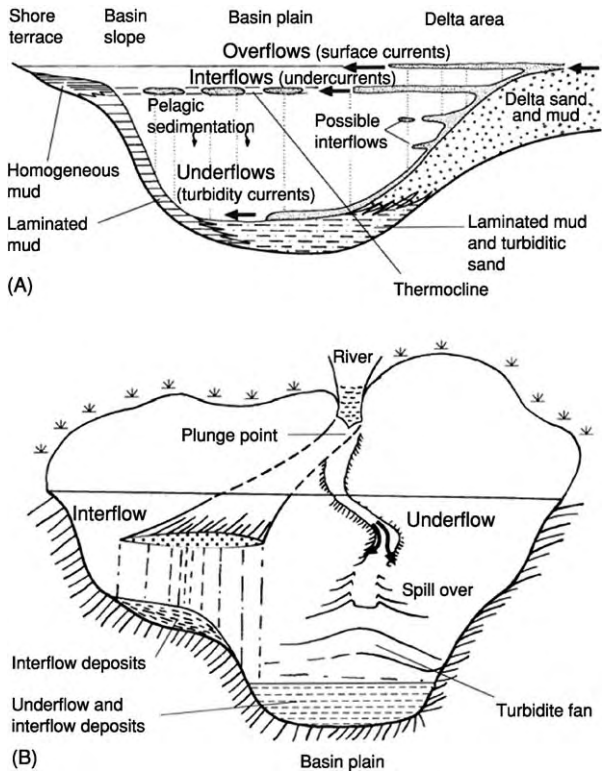

Figure 3 (A) Various types of density driven currents and their characteristic deposits as they relate to the flow of water into a lake. Overflows occur when the inflowing water has a lower density than the lake water; interflows have a density similar to that of a particular level in the water column, and underflows have a density that is at least as great as that of the deepest water in the lake. (B) Sediment distribution as it relates to interflows and underflows. The former can transport sediment to areas of the lake floor that would otherwise be starved of sediment. Persistent underflows can lead to the development of turbidite fans with well developed levées. Reproduced with permission from Talbot MR and Allen PA (1996) Lakes. In: Reading HG (ed.) *Sedimentary Environments: Processes, Facies and Stratigraphy*, pp. 83 124. Oxford: Blackwell.

The most characteristic deposits associated with river inflow are those that accumulate in deltas and fan deltas, which are a typical feature of many lake shorelines. Lacustrine deltas share many features with marine deltas, but the absence of tidal and, in many lakes, longshore currents means that sediment may not be as rapidly dispersed from the river mouth as it is in the ocean. These are some of the reasons why there is a tendency for lacustrine deltas to develop foresets with a large angle of repose, particularly where they build into relatively deep water (Figure 4). Such deltas are commonly referred to as Gilbert-type deltas after G K Gilbert, who first described these features in the abandoned shorelines of Lake Bonneville, a giant Pleistocene lake that formerly occupied the Great Salt Lake basin in Utah. The deposits of lacustrine deltas vary from coarse gravels to fine sands and silts, depending on flow conditions and the nature of the available sediment (Figure 5A). The relatively steep slopes of Gilbert-delta foresets can make them prone to collapse (see below), and, if underflows are frequent, the foresets can be reworked by them to produce ripples and imbricated clasts. Delta topsets merge with river-channel and floodplain deposits, and the bottomsets merge with the lake's deeper-water offshore deposits.

Waves

In addition to their role in the turbulent mixing of surface waters (see above), waves can be important sedimentological agents. In small or sheltered lakes where the wind's fetch is restricted, wave action may be limited. Indeed, shorelines that are little affected by waves may be marked by beds of reeds or other macrophytes, which act as very effective baffles, further reducing the potential impact of waves. On exposed shorelines, however, wave action can be significant, producing beaches and berms of well-sorted sand or gravel (Figures 5B and 6). In the absence of tides, lacustrine beaches may be relatively narrow in comparison with their marine counterparts and may show a rapid transition into offshore deposits. Nevertheless, seasonal or longer-term variations in lake level due to changes in water balance can cause large areas of the shoreline to be affected by wave action. In

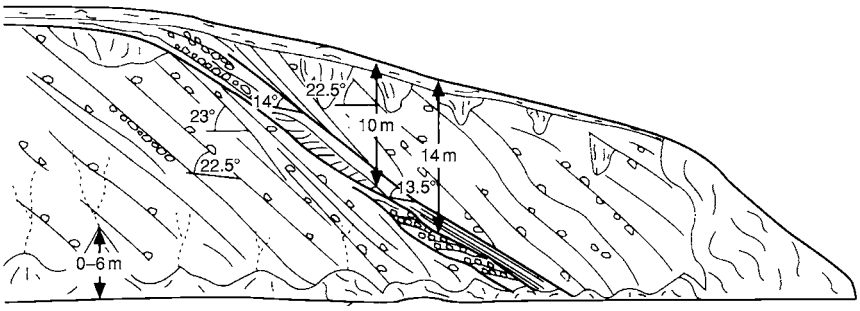

Figure 4 Cross section through a Gilbert delta from the type area along the eastern shore of the Great Salt Lake. The unit with low angle cross bedding in the middle of the section is due to wave reworking of the delta foresets, possibly related to a fall in lake level. The length of the section is *ca*. 150 m. See **Figure 5A** for a close up of the foresets showing the typical deposits. Reproduced with permission from Talbot MR and Allen PA (1996) Lakes. In: Reading HG (ed.) *Sedimentary Environments: Processes, Facies and Stratigraphy*, pp. 83 124. Oxford: Blackwell.

some lake basins, stranded beach ridges provide important evidence of major changes in lake level related to regional climate change.

Surface Currents

Horizontal currents occur in all lakes, and in large lakes they can be a major feature of the water's circulation. Wind stress is the commonest cause of surface currents, but they can also occur in association with river inflow. Strong persistent winds can set in motion longshore currents of sufficient strength to transport significant volumes of sediment, leading to the formation of spits (Figure 6). Where surface flow is restricted by topographical obstacles such as islands, the resulting intensification of the current can also affect deeper waters – sandy current-reworked deposits have been observed at depths in excess of 200 m in Lake Superior, for example.

Subsurface Currents

As indicated above, cooler or sediment-laden river water may plunge beneath the surface of a lake to become an interflow or underflow; in this way river-derived sediment can be spread over large areas of a lake. It is also not uncommon for significant quantities of suspended sediment to be temporarily trapped at the equilibrium depth of the interflow (which is often the thermocline), to be released gradually through simple settling or rapidly as a result of a breakdown in thermal stratification. In both cases, large areas of the lake floor can be blanketed with silt- and mud-rich sediment (Figure 3). Persistent sediment-laden underflows can lead to the development of sublacustrine canyons and deep-water fans with well-developed channels and levees (Figures 3 and 7) and can deposit beds of graded sand over large areas of the deep lake floor. The accumulation of subaqueous fans from underflows and turbidity currents is a characteristic feature of deep-water sedimentation in lakes at high and low latitudes.

Underflows can also play an important role in the formation of one of the most characteristic lacustrine deposits, varves (Figure 8). These are composed of sand rhythmically interbedded with clay or silt and, as originally defined, preserve one annual cycle of sediment accumulation on a lake floor. Each sand lamina represents summer deposition, when abundant sediment is transported into the lake, and the cold sediment-laden river water forms an underflow that transports the sand to the lake floor. The clay or silt lamina accumulates in winter, when rivers are frozen and the lake is covered by ice. However, detailed studies of rhythmically laminated sand and clay or silt deposits have shown that by no means all such couplets are the product of an annual cycle of deposition. Some may be graded beds produced by turbidity currents during minutes to hours of sedimentation; others are the product of an individual flood event (the sand) and its waning flow (the clay or silt) with a duration of hours to days. Given that varve counting is widely used for chronological purposes, it is clearly essential to exercise care in the interpretation of varve or varve-like deposits. Ideally, the inferred annual cyclicity should be confirmed by an independent dating method.

A variety of rhythmically interlaminated deposits reflecting annual climatic variations other than those related to a freeze–thaw cycle are known from lakes. Some of these are described below.

Mass Failure

As indicated above, the foreset slopes of lacustrine deltas may be prone to collapse. In addition, many lake

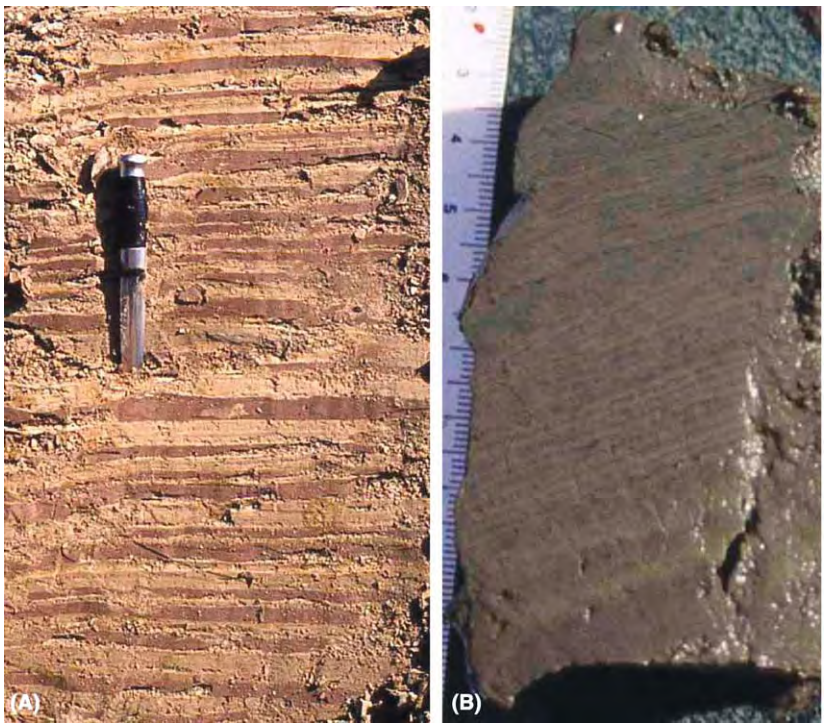

Figure 8 (A) Varves from a glacial lake. The darker brown layers are clay and silt (winter); the lighter layers are sand (spring summer). Note that, in detail, some of the sand layers are distinctly laminated, suggesting that they accumulated during a number of discrete depositional events. Late Pleistocene, Bredåkra, Sweden. Photograph by Jan Mangerud. (B) Recent varves from Lake Malawi. The lighter laminae are rich in diatoms and accumulated during the dry windy season. The darker laminae contain abundant terrigenous plant and mineral material and were deposited from the abundant runoff generated during the rainy season. The thicker more homogeneous layers are thin turbidites.

basins have steep margins adjacent to high mountains. Both settings favour mass failure and the generation of slumps, slides, and turbidity currents (Figure 7). Such events can result in the redistribution of large volumes of sediment and leave extensive slump scars on delta tops (*see* **Sedimentary Processes:** Particle-Driven Subaqueous Gravity Processes). In addition to producing characteristic deposits, such slumps can have catastrophic consequences for lakeside communities. Sediment cores and historical records document the occurrence of damaging surges (tsunamis) associated with major slumps in some Swiss lakes. Slumps may be triggered by earthquakes or major floods. Typically, they produce turbidite beds that are exceptionally thick in relation to the normal deepwater sediments and may be characterized by a relatively homogeneous texture due to the mixing and rapid deposition of sediment from a number of sources. Seismic shock may also deform lacustrine deposits through liquefaction, without causing mass movement. Zones of seismically induced deformation in the cores of lake sediments have been used to date prehistoric earthquakes and determine earthquake recurrence intervals.

Mass-flow processes are also of major importance in glacial lakes, where glaciers deposit large volumes of unconsolidated till and other sediment at the ice margin. Slumping of this material into deep water can be widespread. In addition, large masses of sediment can be dumped in the lake by the calving and overturning of icebergs.

Biological Processes

Organic remains can make a significant contribution to lake sediments; the most important types are calcium carbonate in the form of shells, opaline silica predominantly produced by diatoms, and organic matter.

Calcium Carbonate

In lakes there are no planktonic organisms equivalent to the calcium carbonate-secreting foraminifera and green algae (coccoliths) responsible for producing the extensive chalk deposits of Mesozoic to modern oceans. However, there are many species of freshwater mollusc, and, under suitable conditions, these can be important sediment producers. In Lake Tanganyika, for example, some shallow marginal areas are characterized by very extensive accumulations of gastropod shells, which are concentrated by the winnowing action of waves in this large and windy lake. Ostracod carapaces can also contribute significant amounts of biogenic calcium carbonate to lake sediments, but it is rare for them to be the dominant component of a sediment.

Some macrophytes actively precipitate calcium carbonate. Of particular significance are the charophytes (stoneworts), which can form dense 'meadows' in the shallows of hard-water lakes. Charophytes produce calcified reproductive bodies, and the plants themselves are often encrusted with calcite. Both forms of calcium carbonate can make important contributions to the sediments of shallow lakes.

Stromatolites are another type of calcium-carbonate accumulation that is widespread in modern and ancient lacustrine deposits. Stromatolites are formed through the development of mats and films of algae, bacteria (particularly cyanobacteria), and other microbes. In some situations the role of these micro-organisms has been primarily to trap and bind sediment particles, but many lacustrine stromatolites are calcified, giving the structures considerable rigidity and resistance to erosion. These calcified stromatolites are often referred to as lake tufa. Internally, the stromatolites typically show a fine wavy lamination, and in many the laminae are convex-up or hemispherical, reflecting the generally upward and outward growth of the structure. Some stromatolites reach spectacular proportions, and examples several metres high and tens of metres in diameter are known from the fossil record; in some cases they form reef-like accumulations around the margins of former lakes (*see* **Biosediments and Biofilms**).

Silica

During the Tertiary, diatoms emerged as important nonmarine algae, and from the Miocene onwards they have been major producers of lacustrine sediment. Diatoms secrete a porous skeleton (frustule) of amorphous opaline silica, the majority of which are between 5 μm and 200 μm in diameter. Where supplies of dissolved silica and other nutrients are abundant, diatoms often play a major role in primary production, even in offshore pelagic zones, thereby supplying abundant opal to the sediment. During the spring warming of temperate lakes, and at times of upwelling in stratified lakes, diatoms can occur in huge numbers, producing blooms that turn the surface waters cloudy. Deposits rich in diatoms are called diatomites and are characterized by a chalky appearance and very low density (some float when dry). Because of their low bulk density, it may seem surprising that so many diatoms sink to the bottom. It is likely that another biological process – grazing by zooplankton and the subsequent excretion of diatom-rich faecal pellets, which sink relatively quickly – plays an important part in the sedimentation of diatom remains. Variation in the rate of accumulation of biogenic silica has proved to be a useful proxy indicator of palaeoproductivity and thus palaeoclimate.

Where diatom blooms are a seasonal event, the resulting diatom-rich sediment layer may contribute to the development of varves, as is the case in some areas of Lake Malawi. Diatom production here is highest in the dry windy season, when turbulent mixing and upwelling recycle nutrients from the anoxic hypolimnion. At this time of the year runoff from the land is at a minimum, so a relatively pure diatomaceous lamina accumulates. In the rainy season, on the other hand, winds are slacker and productivity declines, but runoff is at a maximum, bringing abundant mineral and organic debris into the lake. Thus, the two seasons are represented by a light diatom-rich lamina and a dark detrital-rich layer (Figure 8B).

Organic Matter

Many lake sediments contain notable quantities of organic matter. This material has two principal sources.

1. It may consist of the remains of higher plants that populate the lake shallows, shore, and surrounding landscape. Accumulation of large quantities of such plant remains leads to the formation of freshwater peats and coals.
2. It may consist of the remains of planktonic organisms. In addition to diatoms, a number of planktonic algae and cyanobacteria can be major primary producers in lakes. Under some conditions these can make a major contribution to the sediment. In oxygenated environments, dead algal and bacterial-cell material quickly breaks down, but its chances of preservation are much greater if it accumulates in an anoxic environment, such as the hypolimnion of a stratified lake. This environment, allied with high primary production in the epilimnion, can result in the deposition of offshore muds with organic-matter contents in excess of 10%. Ancient organic-rich lacustrine shales are of major economic importance as hydrocarbon source rocks; in countries such as China, Brazil, and Angola a large proportion of the oil has been generated from such sources.

Chemical Processes

A number of important lacustrine sediments are of chemical origin, formed by direct precipitation from the lake water. The most important in terms of sediment production are calcium carbonate and evaporite minerals.

Calcium Carbonate

Lakes fed by rivers draining areas of limestone or other rocks rich in calcium, such as some basic lavas, can have high concentrations of dissolved calcium carbonate, which may precipitate as calcite, or, less commonly, aragonite. In temperate lakes, precipitation occurs during the warm season, but it may be a year-round phenomenon at lower latitudes. Although the precipitates typically comprise simple crystals, 10–100 μm long, of clearly inorganic origin, it is now recognized that their formation is often closely tied to organic processes. At times of high primary production, the photosynthetic consumption of dissolved carbon dioxide may greatly exceed the rate at which it can be replenished. Under these conditions, surface waters can rapidly become supersaturated with calcium carbonate, leading to widespread calcite or aragonite precipitation. Recently, it has also become clear that micron-sized plankton (picoplankton) may play a crucial role in the initial nucleation of the calcite crystals. During phytoplankton blooms precipitation can occur over large areas, resulting in events known as whitings (Figure 9). In Europe, deposits rich in calcium carbonate of this sort are sometimes referred to as lake marl. Seasonal precipitation of significant amounts of calcium carbonate can result in the formation of varved sediments, the light carbonate-rich lamina representing spring and summer seasons, while a darker detrital-rich layer is deposited in autumn and winter. A number of Swiss lakes have accumulated such deposits through much of the Holocene.

Another form of inorganic calcium carbonate can occur along the shores and in the shallows of wave-agitated carbonate-precipitating lakes. Here characteristic concentrically laminated sand-sized grains known as ooids may develop and, under favourable conditions, produce extensive deposits. They are, for example, widespread in the modern Great Salt Lake and on some of the beaches of Lake Tanganyika. Calcite cement may also precipitate in the pores of these deposits to produce beach-rock.

Evaporites

Evaporite minerals are deposited from saline lakes, where they form as a result of the evaporative concentration of lake water (*see* **Sedimentary Rocks:** Evaporites). Definitions of what constitutes a saline lake vary, depending on the criteria used. The most practical definition is a biological one, based on the observation that typical freshwater organisms are generally absent from waters whose salinity exceeds 5‰. A bewildering number of different salts have been recorded from saline lake basins, including some, such as borates, nitrates, and sodium carbonate minerals, that are of major economic importance. The commonest lacustrine evaporites are gypsum ($CaSO_4 \cdot 2H_2O$), halite (NaCl), and a variety of sulphates, carbonates, and bicarbonates of sodium.

Figure 9 Satellite image of Lake Michigan taken on 20 August 1999. The surface waters over much of the southern half of the lake have a milky appearance ('whiting') due to the extensive development of phytoplankton blooms and the accompanying precipitation of calcite (Part of NASA Visible Earth image #ev4338_S1999254181550.png).

Which minerals are precipitated is determined by the chemistry of the inflowing water. This is in marked contrast to the formation of marine evaporites, where the uniform composition of seawater ensures that only a limited suite of minerals can occur.

Because the precipitation of salts requires the evaporation of large volumes of lake water, their formation and accumulation tend to occur in lakes that are hydrologically closed (i.e. they have no outflow) and in regions with a dry or arid climate. In these settings, water loss due to evaporation can exceed inflow. Such lakes tend to alternate between brief periods of flooding, following rainfall, and longer periods of saline or even completely desiccated conditions. Because of their large variations in volume, many saline lakes are surrounded by extensive salt flats, where salt precipitation may continue owing to groundwater seepage and loss through capillary effects (Figure 10).

Hydrothermal Processes

Lake Baikal and many lakes in the East African rift system, the western USA, and the Andes receive a portion of their inflow from the subsurface. These springs may enter the lake from above or below the lake surface, and their temperature may be anywhere between ambient and boiling. The water may be rich in dissolved ions, which can have a measurable influence on the chemistry of the lake water and, in saline lakes, the nature of any evaporite minerals that may precipitate. In addition, effects induced by changes in physicochemical conditions at the point where a spring vents into a lake may trigger mineral precipitation and the accumulation of hydrothermal deposits. Silica and carbonates are the commonest precipitates; the latter may form spectacular deposits (Figure 11). Sulphide mineralization has also been recorded in some of the East African rift lakes.

The spring deposits typically take the form of irregular masses of travertine and sinter, which in many cases are rather porous and show complex growth patterns. One reason for these features is that many springs, even those that emerge at close to boiling point, have dense growths of filamentous and encrusting microbial communities associated with them. These colonies clearly influence the manner in which the minerals accrete. The larger voids represent conduits through which fluids passed; some of the sublacustrine springs in Lake Tanganyika are marked by chimney-like structures of aragonite, many of them carrying fronds of milky white filamentous bacteria, swaying in the stream of hot water exiting the conduit.

Tectonic Processes

Although lake basins have a variety of origins, outside areas of glaciation most large long-lived lakes occupy basins formed by tectonic processes. The morphology of such a basin is to a large degree determined by its tectonic setting. The Lake Baikal and East African rifts, and many of the basins in the western USA, for example, are the result of crustal extension, which typically produces half-graben structures characterized by marked topographical asymmetry (Figure 12) (*see* **Tectonics:** Rift Valleys). The form of the basin determines the position of the lake, which will occur at the topographically lowest point of the basin; typically, this means that the deepest water is close to a border fault. Sediment accumulation is also greatest here, where maximum subsidence rates produce the space needed to accommodate new deposits. Continuous Miocene–Holocene subsidence has resulted in the accumulation of several kilometres of lacustrine sediment beneath Lake Baikal and in parts of the East

Figure 10 (A) Surface of desiccated salt lake, Death Valley, California. (B) Close up view showing upturned edges of desiccation cracks with salt efflorescence precipitated from seeping groundwater. The salt is mainly halite (NaCl).

Figure 11 Mounds of calcium carbonate ('The Pinnacles') formed by the discharge of carbonate rich water through the floor of a Late Pleistocene lake. The mounds are aligned along a fault zone. Searles Lake, California.

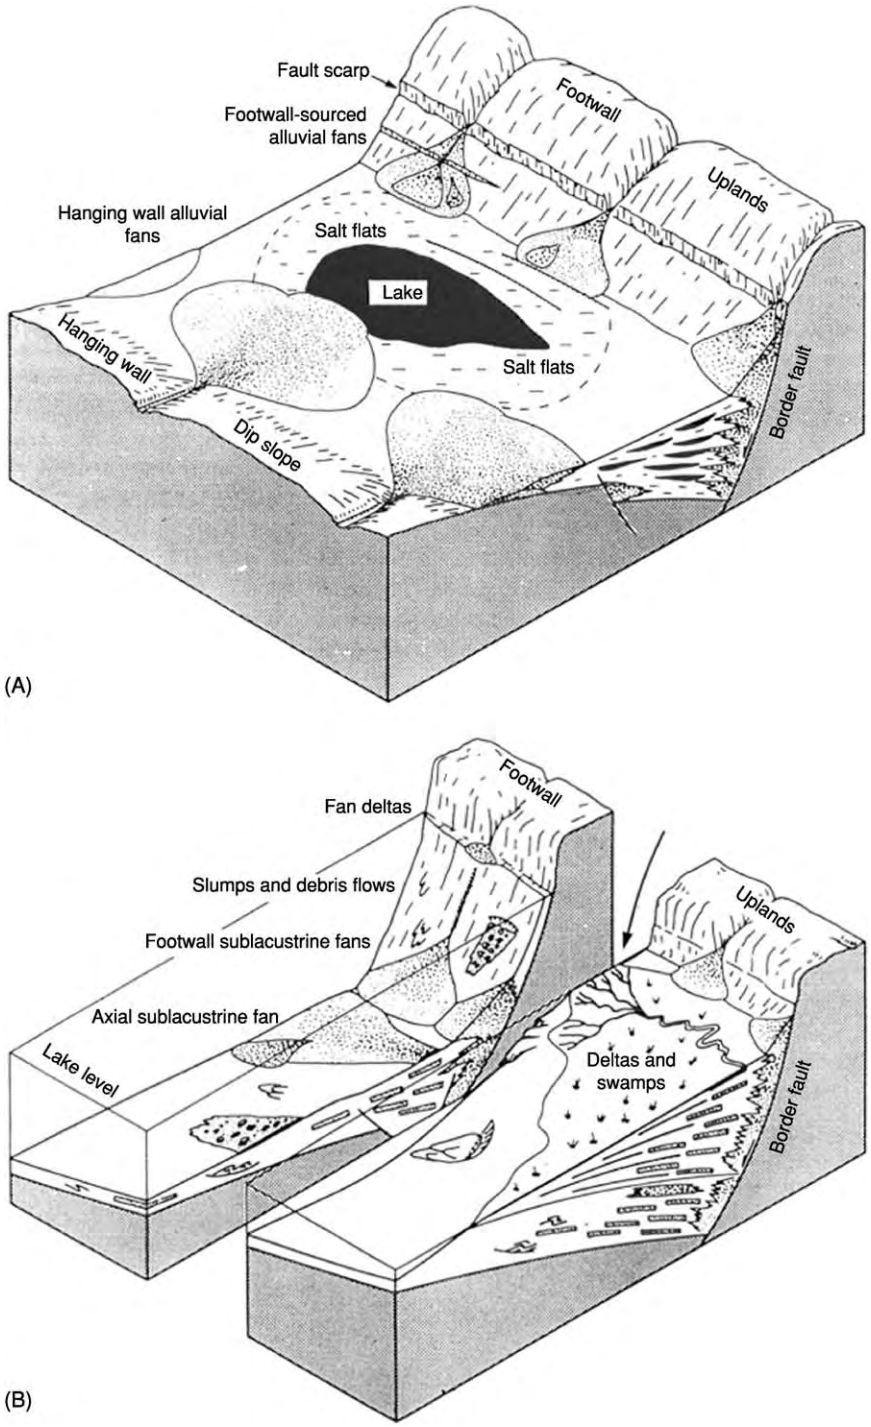

Figure 12 Schematic distributions of deposits in and around lakes developed in a half graben (rift) basin under (A) dry to arid and (B) humid climatic conditions. (A) The basin is hydrologically closed and the lake is probably saline; extensive salt flats surround the lake and are flooded only following rare rainstorms. (B) A deep rift lake. In both cases the asymmetry of the basin has a strong influence on sediment distribution. This is particularly apparent in (B), where the deepest water is close to the border fault and the axial drainage system also tends to be located here owing to maximum subsidence in this part of the basin. Adapted with permission from Leeder MR and Gawthorpe RL (1987) Sedimentary models for extensional tilt block/half garben basins. In: Coward MP, Dewey JF and Hancock PL (eds.) *Continental Extensional Tectonics*, pp. 139 152. London, Geological Society Special Publication No. 28.

African rift. The distribution of different sediment types closely reflects the asymmetry and varied bathymetry of the basin (Figure 12), while structurally determined sublacustrine topography exerts a major influence on deep-water sedimentation. Fault scarps form steep slopes, which tend to be unstable, generating debris and turbidite flows and leading to widespread sediment redeposition (Figures 7 and 12). Furthermore, studies of Lake Baikal and the East African rift lakes clearly demonstrate that many of the principal sublacustrine canyons along which sediment is channelled from shallow water to deep water are fault controlled. In addition to these structural effects, sedimentation in Lake Baikal has been strongly influenced by variations in the types and amounts of sediment delivered to the basin resulting from changes between glacial and non-glacial conditions, while the East African lakes have been subject to major climate-driven changes in sediment supply and lake level (on the scale of hundreds of metres). The impact of climate change and the active tectonism have resulted in complex depositional histories in all these basins.

Reefs ('Build-Ups')

B W Sellwood, University of Reading, Reading, UK

Introduction

Reefs are biologically generated accumulations of carbonate (*see* **Sedimentary Rocks:** Limestones) that grow upwards from the adjacent seafloor and are entities of their own making. They are generally considered to be robust structures (i.e., rigid or wave-resistant), although biogenic mud mounds are treated as reefs by many authors. There have been periods in the geological past when the main contributors to biogenic mounds appear to have been organisms lacking a rigid frame, and their constructions have had lime mud (matrix-rich) compositions. Thus a wide spectrum of structures have been loosely classified as reefs. It has therefore generally been considered useful to draw a distinction between reefs with a rigid calcareous frame and those without (i.e., mud mounds). As communities growing on the accumulated debris of their own forebears, reefs are essentially unbedded constructions. The debris derived from the reef-dwellers fills the interstices between *in situ* constructors and also forms aprons of bedded resedimented material on the flanks of the edifice, and in adjacent hollows. Such aprons provide critical evidence that biogenic activity produced an elevated mound in the first place, and may indicate that upward growth of the mound had taken place into shallow waters, where strong currents and waves were active.

Growing reefs are often strongly zoned ecologically and usually have a core, the main carbonate factory within the system, showing a distinct vertical succession from initial colonization through to culmination. The vertical zonation can frequently be related to upward growth in response to the filling of accommodation space (i.e., formed in response to 'transgression' with the bulk of the reef pile accumulating during a 'highstand'). Reef successions are often stacked one on top of the other, separated by lowstand emersion surfaces (often 'karstic' in character).

Modern Reefs

Modern reefs (Figure 1), dominated by scleractinian corals (*see* **Fossil Invertebrates:** Corals and Other Cnidaria), reflect a balance between growth and destruction. Coral growth produces a rigid framework ('framestone'(Figure 2)), sheeted encrustations generate 'bindstone'(Figures 3 and 4), whereas meadows of upstanding but flimsy (generally noncoral) organisms may passively trap fines to form mud mounds ('bafflestone' after lithification (Figure 5)). Attached

organisms and those living in any cavities and crevices contribute to the overall community, and some will have fossilization potential, whereas many will not. Destructive processes may be both physical (waves and currents) and biological (raspers, borers, and grazers). *In situ* collapse (following bioinfestation) and downslope relocation, as gravel-grade rubble, produces 'rudstones'(Figures 6, 7 and 8), whereas mud slides and debris flows, with blocks entrained or embedded within slurries of carbonate fines, produce 'floatstones' (Figure 9). Sand-grade material generated by grazers may itself be rendered still finer by biological degradation.

Corals generally remain in place after death. Cores through coral heads reveal regular annual growth layers, which provide a precise year-by-year record ('sclerochronology') of climate-related, anthropogenic, volcanogenic, and other events that leave a geochemical signature within the coral frame. Bioinfestation by macro- and microborers degrades skeletal structures, leading to the obliteration of original, and often characteristic, textures in grains and generates micritized 'peloids'. These processes also contribute to reef sediment, particularly the fines, as

Figure 6 Rudstone of coral debris. Quaternary, Barbados. Scale at centre 10 cm.

Figure 8 Rudstone of stromatoporoids, Devonian, Belgium.

do faecal and pseudofaecal material generated by the reef dwellers. However, many reef-dwelling organisms are microcarnivores and suspension-feeders highly sensitive to the amount of turbidity in the water, so reefs grow best on windward platform margins where wave surge cleanses the reef of the inhibiting fines. In such sites daily and seasonal temperature fluctuations are small, as are salinity fluctuations, the reef community generally thriving best in well-oxygenated waters within tight limits of normal marine salinities (~35‰ (range 27–40‰)), warm temperatures (18–36°C), and low nutrient content (phosphates, etc.). Investigations, using dynamite, have shown that the robustness of many reefs results from early marine cementation of the reef structure. Wave pumping forces vast quantities of seawater saturated with calcium carbonate through the interstices of the reef, and 'isopachous cements' of 'Mg-calcite' (and 'aragonite', which is often 'botryoidal' in form) grow actively and rapidly.

Figure 9 Floatstone. A reef derived boulder set in deep water mudstones and packstones, Permian Capitan Reef Complex, McKittrick Canyon, New Mexico, USA.

Reefs formed immediately adjacent to shorelines (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves) are termed 'fringing reefs'. Offshore reefs form a barrier, behind which is a 'lagoon'. Barrier reefs, generally circular in plan and with a central lagoon, are termed 'atolls', which, in the open waters of the Pacific and Indian Oceans, were initiated around volcanic islands and continued to grow upwards following the submergence of the original edifice. This mechanism was originally suggested by Darwin (1842) and was confirmed by the Funafuti boring, funded by the Royal Society of London. Lagoons behind barrier reefs may have patch reefs, which can form miniatolls, such as those behind the Great Barrier Reef off eastern Australia. Patch reefs (e.g., Figure 1) rise from depths of a few metres, and between them are usually extensive spreads of muddy lime sand anchored by sea grasses (e.g., *Thalassia*).

Platform margin reefs drop off, often precipitously, into deep water where the 'fore reef' comprises a zone predominantly receiving reef-derived debris, carbonate sand, and tumbled blocks (talus). The 'reef front' rises from this deep water. One hundred metres, in the clearest waters, is about the maximum depth in which coral colonization occurs but depths are usually less than this. The plate-like growth forms of the pioneers 'stabilizing' reef foundations in these gloomy waters are an adaptation for capturing the maximum amount of light. Coral polyps live symbiotically with zooxanthellae algae within their tissues, so enough light for their photosynthetic activities is an essential component in reef colonization and growth. Into shallower depths platy forms give way to 'colonization' by branching forms as architectures favouring food collecting take over in habitats where light is no longer a limiting factor. Massive, and finally encrusting, forms 'diversify' and proliferate in wave-activated depths approaching the reef crest. The reef crest is the highest energy zone impacted by breaking waves. Encrusting forms often 'dominate' there, but if wave energy is of moderate intensity they may be accompanied by forms with abbreviated branches and robust hemispherical shapes. The 'reef flat', often exposed at low tide and as such inhospitable to corals, is crossed by channels through which the surf surges. These are usually floored by sand that is carried lagoonwards. James (1983) suggests that reefs of many ages show a similar succession in growth forms (stabilization, colonization, diversification, domination) even though the organisms generating the reefs are often from phyla different from those constructing modern reefs. In contrast to the seaward zone the 'back reef' is a tranquil place, receiving much of the mud-grade carbonate generated by the reef. Abundant sand- and mud-producing organisms live there, particularly calcareous green algae (e.g., codiacians such as *Halimeda*). Stubby and dendroid growth forms dominate this habitat with species adapted to rapid upward growth in muddy environments.

Reefs through Time

This topic has been extensively reviewed. Prior to the advent of grazing metazoans in the Early Cambrian stromatolites were the prime reef builders. Stromatolitic reefs in Western Australia, formed between 3.0 and 3.5 Ga, and through the Archaean and Proterozoic large and increasingly complex structures and ecosystems, were formed by *Cyanobacteria* and other microorganisms ('microbes' such as noncalcified and calcified *Cyanobacteria*, Eubacteria, fungi, and other protozoans). These same communities are considered by many to be responsible, through their photosynthesizing activities, for changing the character of the atmosphere from its initial reducing (CO_2-rich state) to one with free oxygen (around 2.32 Ga).

The first metazoan reef mounds a few metres across were constructed in the Early Cambrian by 'Archaeocyathans' (sponge-like organisms) encrusted by calcitized algae and surrounded by carbonate sands rich in pelmatozoan debris. They have an apparently wide palaeolatitudinal spread (60° S to 30° N) and are particularly well described from Newfoundland, Labrador, and the Siberian Platform. Archaeocyathans became extinct at the end of the Early Cambrian and reef structures disappeared until the mid-Ordovician. At that time colonial corals and sponge-like 'stromatoporoids' made their first appearance and dominated palaeotropical reef associations, accompanied by an increasingly diverse array of sponges (*see* **Fossil Invertebrates:** Porifera), bryozoans, and calcareous algae, until the Late Devonian. Brachiopods (*see* **Fossil Invertebrates:** Brachiopods) and pelmatozoans contributed in a major way to these build-ups. Diversification continued through the Silurian and Devonian, a time of exceptionally high global sea-levels, which generated vast tropical epicontinental seaways within which grew abundant reefs dominated by sponges (stromatoporoids) and corals; reefs extended from 40° to 60° poleward of the equator. By Late Devonian times (**Figures 7** and **8**) reef systems probably rivalled modern reefs in terms of both their scale and complexity (some belts exceeding 2000 km in length). Many of the organisms contributing to these structures produced calcitic rather than aragonitic skeletons, and internal cavities within the reef systems were elongate lensoids with smooth flattish floors and complex, often crenulate ceilings. Termed 'stromatactis', and filled with radiaxial calcite spar, these cavities have long been a topic of controversy, as to whether they represent a long extinct organism group, dilation cracks caused by down-slope movement of partially cemented sediment, methane seepage, or strange burrow structures. That they were open cavities within the mounds, and preserved by early cementation processes, is confirmed by their internal sediment fillings and the lining cement phases.

A major extinction (*see* **Palaeozoic:** Devonian) event took place within the Late Devonian, considered by many to rival that at the End Permian in terms of its severity (*see* **Palaeozoic:** End Permian Extinctions). This caused the end of the coral-stromatoporoid reef systems, with mud mound systems apparently lacking rigid frame builders and dominated

by sponge-algal-microbial-foraminiferal communities continuing. The Early Carboniferous was a time of mud-mound communities (e.g., Waulsortian bank facies), the absence of major reef systems at this time being attributed to an overall decrease in global temperatures. The pattern of a relative absence of large frame builders continued through the Late Carboniferous and Early Permian when mound communities were dominated by calcareous algae, sponges, and bryozoans. During the Permian tropical and subtropical carbonate systems became dominated by aragonite, rather than calcite, a situation mineralogically similar to the Cenozoic and Recent.

Many mid- and Late Permian reefs, like the classic Capitan complex on the margins of the Delaware basin (Figures 9 and 10), most probably accumulated as a series of marginal mud mounds anchored by very early marine cements. Sponges, phylloid algae, and microbial precipitates compose the major components and debate has continued over many years about the architecture, palaeobathymetry over the reef, and other aspects of palaeoecology and geometry. It is clear that the evolution of the system was influenced significantly by sea-level changes, and considerable palaeobathymetry between reef and basin can be demonstrated by the presence of rudstones and floatstones that can be traced up to the reef from the basin floor. Another set of famous, but still controversial reefs are those of the Late Permian Zechstein basin of northern Europe. Communities within these reefs are highly zoned, containing bryozoans and stromatolites, with reef base, reef core, reef flat, reef crest, and patch reef communities all being recognized, the latter growing upon a distally steepened ramp. During the Late Permian reefs with corals (rugose corals that may have lived symbiotically with zooxanthellae and tabulates) are confined to the Australasian rim of the Pacific and the Middle East. Other biota within these reefs were calcareous algae, bryozoans, foraminiferans, and brachiopods. With the exception of coral communities in East Timor and the Salt Range of Pakistan, most of these build-ups occur within the palaeotropics.

There was a sudden and complete disappearance of high diversity reef biota at the end of the Permian (*see* **Palaeozoic:** End Permian Extinctions), and a global hiatus of about 10 Ma occurs before the renewal of reef development in the early Triassic. Triassic reefs were generated by a range of organisms including microbes; scleractinian corals (direct ancestors of modern corals); sponges; calcareous algae (dasyclads); bivalves; and serpulids. Microbial reefs dominate the earlier Triassic, sponge reefs the mid-Triassic, and coral reefs the Late Triassic. Throughout the Triassic great changes occur in the latitudinal distribution of reefs, expanding from an equatorial and tropical distribution in the mid-Triassic to a maximum of around 35° N and S in the Late Triassic. A mass extinction event at around the Triassic/Jurassic boundary caused a near extinction of reef biota and earliest Jurassic (Hettangian) reefs are extremely rare. Reef complexes, regarded now as classic locations, grew in the Tethys. Those in the Dolomites of northern Italy (Figure 11) were strongly controlled by sea-level changes, volcanic eruptions, and palaeobathymetry, and exhibit a wide range of facies and at a seismostratigraphic scale. Allochthonous (reef-derived) material is abundant; back-reef lagoonal and intertidal facies are also well developed. Some reefs have atoll-like geometries. The principle constructors in some earlier cases were encrusting and binding organisms, often termed 'problematica', of

Figure 10 Permian Capitan Reef Complex, McKittrick Canyon, New Mexico. Reef facies (massive face at upper left); fore reef talus (comprising lower ground and area to the right).

Figure 11 Triassic reef associated facies, talus, and bedded back reef lagoonal sediments. Dolomites of northern Italy.

which one such is 'Tubiphytes'. Later reefs were made by calcareous sponges, corals, red algae, and problematic calcareous binders. Flügel emphasizes that although Late Triassic reefs exhibit some 'modern' traits as would be found in recent coral thickets, there are some important differences too. Modern corals are primarily constructors, whereas Triassic ones seem to have been bafflers and binders. There would have been fewer nooks and crannies in Triassic reefs, and there appears to have been significantly less by way of bioerosion, predation, and grazing. Finally, significant numbers of Triassic corals were adapted to colonizing unstable sandy and muddy substrates, whereas modern species require a firm seafloor.

Following their initial setback resulting from the end-Triassic mass extinction reefs, often with corals as a significant component, reappeared in the Early Jurassic, firstly in Morocco (Figure 12). As sea-level rose eustatically through the period, to reach a peak in the Oxfordian, so reef fortunes rose too. With the break-up of Pangaea and the formation of new seaways, reefs proliferated. Coral reefs are confined between about 30° N and S during the Early Jurassic, expanding to 35° N in the mid-Jurassic and to 45° N in the Late Jurassic. Resedimented coral boulders occur within Kimmeridgian deep-water debris flows on the margins of the North Sea in northern Scotland. Jurassic reefs were constructed by a range of organisms (sponges, microbes, bivalves (e.g., oysters and ancestors to the Cretaceous rudistids)), as well as corals.

The Cretaceous (Figures 13 and 14) saw the rise of rudists, heterodont bivalves that became very important reef builders that underwent a great proliferation after the Early Aptian (caprinids and caprotinids), particularly through the Tethyan region. They range overall from end-Jurassic to end-Cretaceous, once again tracking the general trend in eustatic change

from Early Cretaceous lowstand to Late Cretaceous highstand and subsequent fall. Another group of rudists, the radiolitids, appear in the Aptian and underwent a major proliferation through the Late Cretaceous, despite a setback at the Cenomanian–Turonian boundary. From the Cenomanian there is a great expansion in the geographical range occupied by rudistids with a new group, the hippuritids, markedly pipe-like forms, contributing in a major way to build-ups. In the Early Cretaceous the rudistids are associated with corals, but there is an increasing tendency for ecosystems to become rudist-specific, to the extent that biological mechanisms have often been invoked to explain the dominance of single species within communities. Rudist reef complexes are associated with high-energy shelf grainstones and platform margin talus, and around the margins of the Gulf of Mexico and in the Middle East (Arabian/Persian Gulf) areas these build-ups, and their associated facies, are associated with prolific hydrocarbon production. Rudist reefs were confined to between about 30° N and S during the Late Cretaceous, whereas reefs with corals extended further polewards (by about 10° further of latitude). However, reef communities suffered badly at the Cretaceous–Tertiary boundary and, although mud-mound and bryozoan build-ups occur in the Danian (e.g., in Denmark) and through the Eocene, reef systems did not fully recover until the Oligocene when they took on a nearly modern character.

In the Tertiary reef systems reached their maximum northern extent during the Miocene (Burdigalian (**Figure 15**) to Messinian (**Figures 16, 17 and 18**)) when extensive reefs grew in the Mediterranean area. Tortonian reefs have a diverse coral biota, but species were progressively lost into the Messinian in this area where monospecific associations (dominated by the tolerant genus *Porites*) prevailed shortly

before the onset of the 'salinity crisis'. Debate still continues as to whether lowering temperatures or rising salinity caused these restrictions, but following the resumption of normal marine sedimentation in the Pliocene coral reefs were never again developed at these latitudes. Today, Bermuda and the Gulf of Suez represent the most northerly outposts of shallow, warm-water reefs in the northern hemisphere, and in the latter reefs grow on the maritime fringes of alluvial fans, a situation which also occurred along this rift during the mid-Miocene.

In deep cold waters lacking a high turbidity, and with slow sedimentation rates, coral reefs do grow today, but these are made by the ahermatypic (non-zooxanthellate) coral *Lophelia*. These form major edifices along the Atlantic margins, but their growth rates are slow and they are extremely susceptible to disturbances from fishing and other offshore activities, which is why they are protected by nature conservancy measures.

Shoreline and Shoreface Deposits

J Howell, University of Bergen, Bergen, Norway

Introduction

A shoreline is the interface between a standing body of water, typically the sea, and a landmass. Over geological time, shorelines are highly transient features and the depositional and erosional systems associated with them are extremely dynamic. The shoreface *sensu stricto* is defined as the zone that lies between the low tidemark and the fair weather wave base (the maximum depth at which everyday wave movements affect the seabed). The shoreface is part of a linked depositional system that includes all of the coastal region affected by wave action, from the top of the beach, seaward, to the mean storm wave base (the maximum typical depth at which the storm waves move sediment on the seafloor) (*see* **Sedimentary Environments:** Storms and Storm Deposits).

At the shoreline, wave processes are the most significant agents of erosion, sediment transport, and deposition, although fluvial, tidal, and biogenic processes are also important and may be locally dominant. Sediments deposited in the system may be siliciclastic, carbonate, or a mixture of the two, and grain sizes can range from those of clay particles to boulders. The position of the shoreline is highly sensitive to changes in sea-level and sediment supply, and understanding shoreline systems is central to sequence stratigraphy and basin analysis. Shoreface deposits form important hydrocarbon reservoirs and aquifers in many parts of the world, and some contain placer mineral and gem deposits. Modern systems are environmentally sensitive areas and many of the world's coastlines are heavily populated and susceptible to sea-level change. The study of shoreline processes and deposits includes aspects of geology, geomorphology, biology, and oceanography.

Both physical and biogenic processes (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves) occur at shoreline systems. All clastic, coastal depositional systems can be classified within a triangular diagram that summarizes the relative importance of fluvial, tidal, and wave processes (Figure 1A). Away from fluvial input points, the key controlling factor is the tidal range. In areas with a moderate to low tidal range, narrow beaches dominated by wave action occur. Conversely, in areas with a high tidal range, broad low-lying, muddy tidal flats are created (Figure 1B). The wave-dominated, beach-related systems that make up the majority of the world's coastlines are the focus here (but *see* **Sedimentary Processes:** Fluvial Geomorphology).

Wave Processes

Surface water waves are formed by the movement of the wind across a standing body of water. Wind shear effectively drags the upper layers of the water and horizontally compresses them, producing waves. The key features of a wave are its length and height (Figure 2). Within the water body, the vertical motion at the water surface sets up circular orbital motion that is translated downward. This downward translation of energy typical moves the water in a series of orbital motions to a depth that is approximately half of the wave length. This depth is termed the 'wave base' (Figure 2), and waves that occur in water that is deeper than the wave base will not move sediment on the seafloor. Because the depth to the wave base is controlled by the size of a wave, it varies both between basins and over time within an individual basin. In large, open bodies of water with a large fetch (such as the major oceans), the wave base may be in excess of 100 m, whereas in enclosed seas and lakes, it may be less than 10 m. Wave size and the depth to the wave base also vary within an individual setting on a daily and seasonal basis, depending on changes in the weather. During storms, short-term, larger waves result in a deep wave base, whereas during fair weather periods, the wave base is much shallower. It is common to consider marine depositional systems in terms of two hypothetical surfaces,

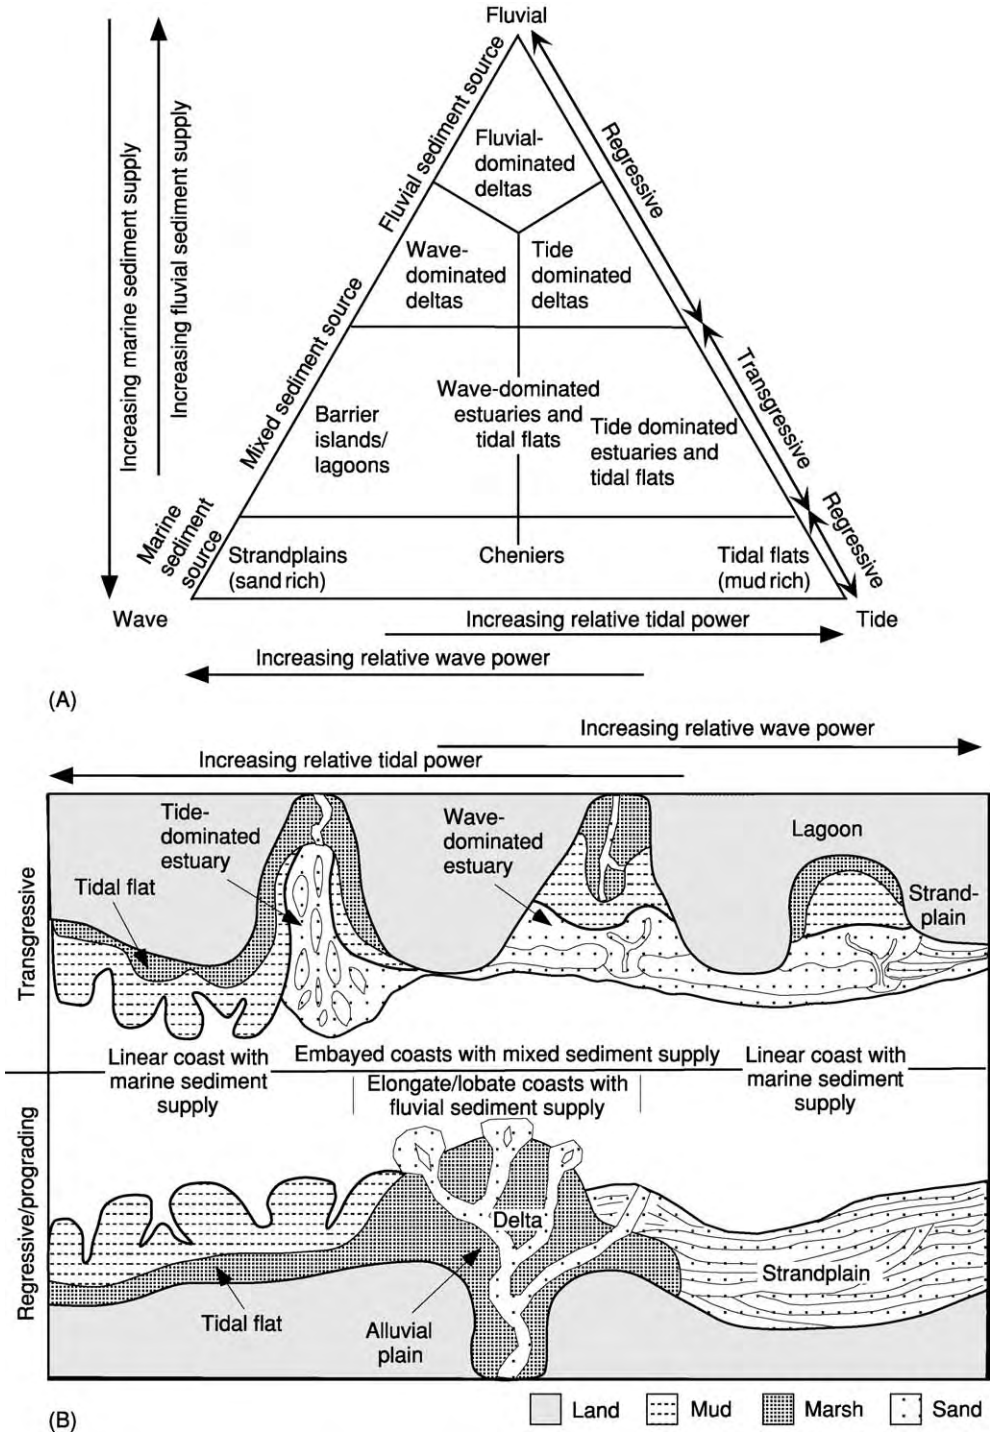

Figure 1 Classification of clastic shallow marine systems. (A) The relative importance of fluvial, tidal, and wave processes. (B) Transgressive and progradational coastal systems with varying degrees of fluvial, tidal, and wave influence. Reproduced with permission from Dalrymple RW, Zaitlin BA, and Boyd R (1992). Estuarine facies models: conceptual basis and stratigraphic implications. *Journal of Sedimentary Petrology* 62: 1130 1146.

the mean storm wave base (SWB) and the mean fair weather wave base (FWWB). The mean SWB is the depth at which typical storms affect the seabed for short periods of time (in the order of hours to days); the FWWB reflects the typical wave climate that is present within the basin between storm events.

Waves that are formed in the open ocean are pushed towards the land. As waves approach the coastline,

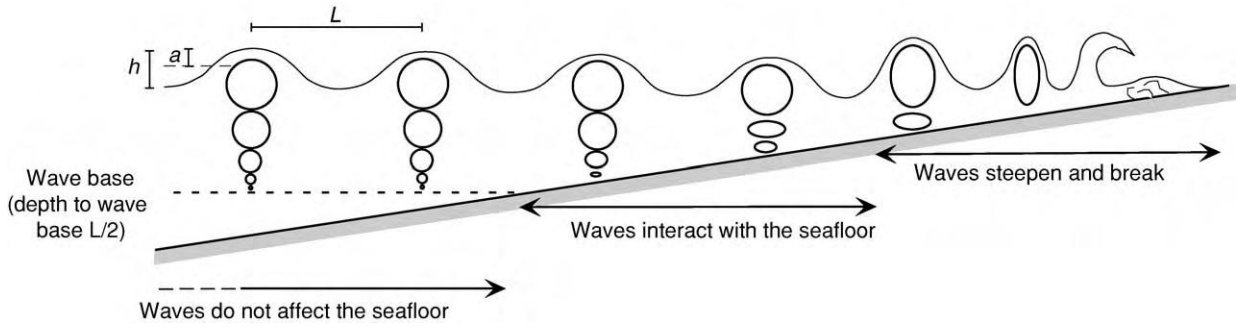

Figure 2 Key features related to water waves approaching a smooth dipping coast; *L* is the wave length, *h* is the wave height, and *a* is the wave amplitude.

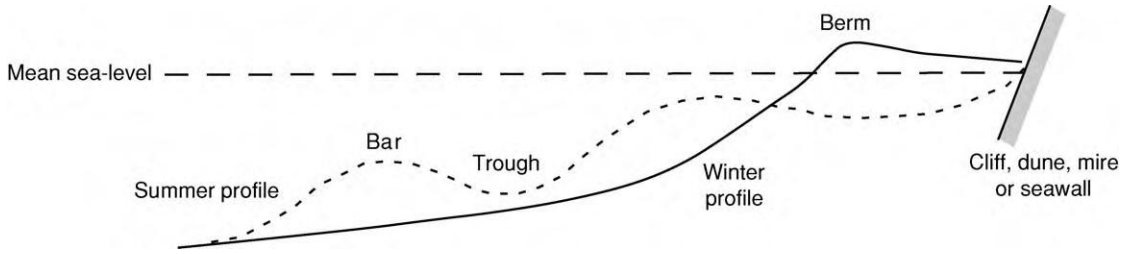

Figure 3 Typical summer and winter beach profiles. During the summer months, fair weather waves move sediment onshore and build up a berm. Winter storms erode the beach and deposit the sediment in the shoreface and offshore transition zone.

the water depth becomes less than the wave base and the waves interact with the seafloor. Waves hitting the coast may be classified as reflective, dissipative, or intermediate forms. Reflective waves strike very steep coastlines (with features such as cliffs or a seawall) and the majority of the energy is reflected directly back into the water body. Purely dissipative waves gradually lose their energy through frictional interaction with a very gently dipping seafloor and do not break at all. A majority of the waves that affect active shorelines are intermediate between these two forms. In intermediate cases, interaction with the seafloor slows the waves and pushes them up; the waves steepen until they eventually collapse or break. If the shoreline is steep, the waves will break as plunging forms, whereas if it inclines more gently, the waves will tend to surge in a landward direction. Steeper shorefaces with plunging waves tend to be simple systems in which the waves break directly on the beach. Most shorefaces dip gently and have a complex topography, including numerous bar forms over which the waves may break before reaching the shoreline, to reform and then break again. These systems include complex sets of plunging and surging waves.

During fair weather periods, waves tend to move sediment in an onshore direction because water loss due to percolation into permeable beach sediments reduces the efficiency of the backflow. Large storms tend to erode the beach and to deposit sediment offshore, or in the case of barrier systems, in the lagoon behind the beach. During the summer months, when few storms occur, there is a net onshore migration of sediment; during the winter storm period, the beach is frequently eroded and does not have time to be repaired. Consequently, typical summer and winter profiles for beaches may be defined (Figure 3). The preserved rock record is a complex mixture of the depositional products of the repeated seasonal changes.

If waves approach the shoreline perpendicularly, there is no net movement of sediment along the coast. However, in many cases, waves from the open ocean approach the shoreline obliquely. This results in an oblique onshore movement of sediment with the incoming wave. The returning swash tends to be more perpendicular to the shore, which in turn leads to migration of sediment parallel to the shore; this is termed 'longshore sediment transport', or longshore drift (Figure 4). Transport of sediment by longshore drift is a key factor in moving volumes of sediment and in controlling the morphology of wave-dominated shoreline systems.

The sedimentary structures produced by waves show an increase in bedform asymmetry towards the shoreline, passing from oscillatory, symmetrical wave ripples near the wave base into combined-flow wave ripples as the water becomes shallower (Figure 5). In the shallowest part of the system, shear between the water mass and the seabed can

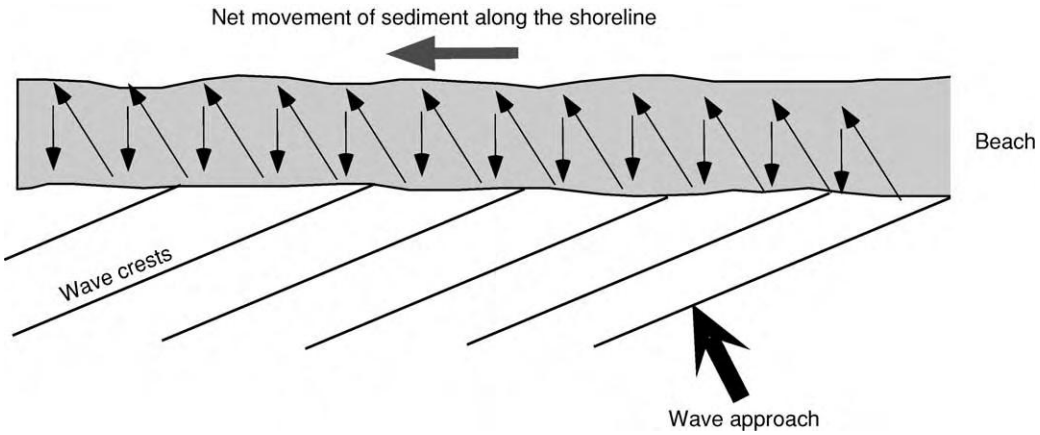

Figure 4 Longshore sediment transport (longshore drift). Waves approach the shoreline at an oblique angle. Sediment is moved up and across the beach by the incoming wave; the returning flow is weaker and tends to be straight back (i.e., shore normal). The net result is that sediment is moved along the coastline.

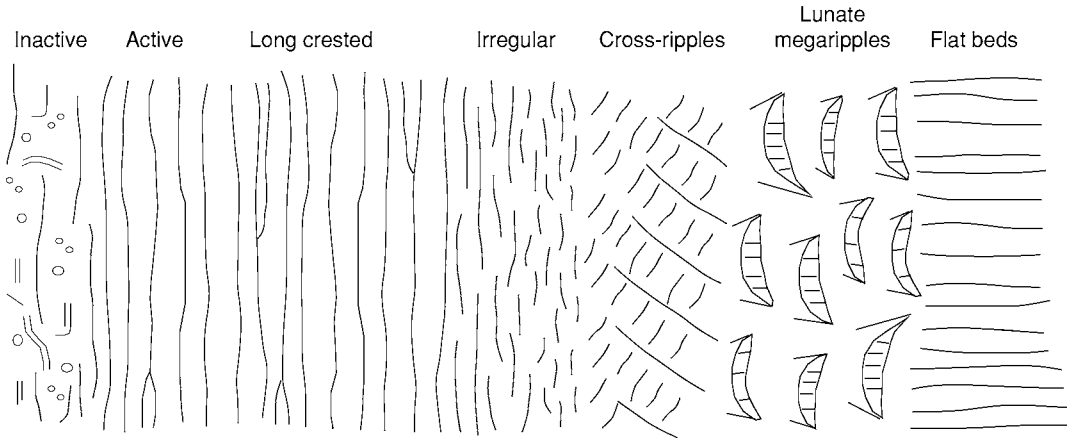

Figure 5 Plan view of the shoreface showing the distribution of bedforms resulting from the onshore approach of shoaling waves. Reproduced with permission from Clifton NE, Hunter RE, and Phillips RL (1971) Depositional structures and processes in the non barred high energy nearshore. *Journal of Sedimentary Petrology* 41: 651 670.

produce a variety of current-generated structures, including ripples, plane beds, and dunes, producing trough and tabular cross-bedding. Breaking waves generally produce upper-phase plane beds, although the returning swash current may also generate current ripples. In the deeper part of the system, combined flow associated with very large storm-related waves produces compound, three-dimensional low-angle bedforms called hummocks, which in turn produce hummocky cross-stratification (*see* **Sedimentary Environments:** Storms and Storm Deposits).

Classification and Geomorphology of Shoreline Systems

Geomorphologically, coastal systems can be characterized by the medium- to long-term movement of the shoreline (Figure 1B). In transgressive systems, the shoreline moves towards the hinterland and land is lost to the sea, whereas in regressive systems, the shoreline moves basinward and new land is created on the coastal plain. These movements are controlled by changes in sea-level and by the amount of sediment that is supplied to the system. Sea-level change may occur due to global changes in sea-level (eustasy) or may be driven by local uplift or subsidence within the basin. Commonly, a combination of the two forces is in play; this is termed 'relative sea-level change'. If relative sea-level is falling, the shoreline will move basinward (termed a 'forced' regression). Sea-level rise does not always lead to transgression, because the movement of the shoreline also depends on whether enough sediment is supplied to the system to fill the new space that is created. If more sediment is supplied than space is created, then the shoreline will prograde (i.e., will be regressive). If, however, the

rate of space creation is greater than the rate of sediment supply, then the shoreline will move landward (i.e., will be transgressive).

Transgressive shorelines may be further subdivided into low- and high-relief forms. Low-relief transgressive shorelines generally occur when relative sea-level rise floods a former delta or coastal plain. In such cases, systems may contribute to the geological rock record and their deposits will either be barrier islands in systems with a moderate to low tidal range, or tidal flats in systems with a higher tidal range. High-relief transgressive shorelines occur where the sea-level rise is flooding bedrock. In such cases, the systems are erosional. High-relief transgressive shorelines do not contribute to the geological rock record, although they are an important part of modern systems (see later).

Progradational Wave-Dominated Shoreline Systems

Progradational shoreline systems, which contribute significantly to the geological rock record, are classified by the dominant depositional mechanism: wave, fluvial (*see* **Sedimentary Processes:** Fluvial Geomorphology), or tidal. Progradational wave-dominated systems include shorefaces and wave-dominated deltas. In a shoreface, the sediment is introduced by longshore drift; in a wave-dominated delta, the sediment is originally introduce by a fluvial system and is then reworked by wave processes. In reality, especially in the rock record, it can be very difficult to distinguish the two, and because the depositional processes are the same, it is useful to consider them as largely synonymous. In both cases, the system includes a beach that lies between the low tidemark and the next significant feature in a landward direction, which may be dunes, a coastal forest, a mire, a cliff, or in many modern systems a seawall. Between the low tidemark and the FWWB is the shoreface, which includes the sediment that is being reworked by fair weather wave action. Seaward of the FWWB is the offshore transition zone where, for the majority of time, deposition consists of very fine-grained suspended sediment, with brief influxes of storm-derived coarser deposits. Seaward of the SWB is the offshore shelf where waves no longer play a role in the introduction or deposition of sediment (**Figure 6**).

Within a wave-dominated system, sediment is introduced by longshore drift, either from the reworking of a fluvial system (wave-dominated delta) or from wave erosion of the bedrock or older shoreline deposits. In plan view, a variety of features may exist within the depositional system. Offshore, seaward of the point at which the storm wave base interacts with the seafloor, deposition is restricted to mud deposited from suspension or to coarser sediments introduced by sediment gravity flows. In the zone between the SWB and FWWB, storms deposit hummocky cross-stratified

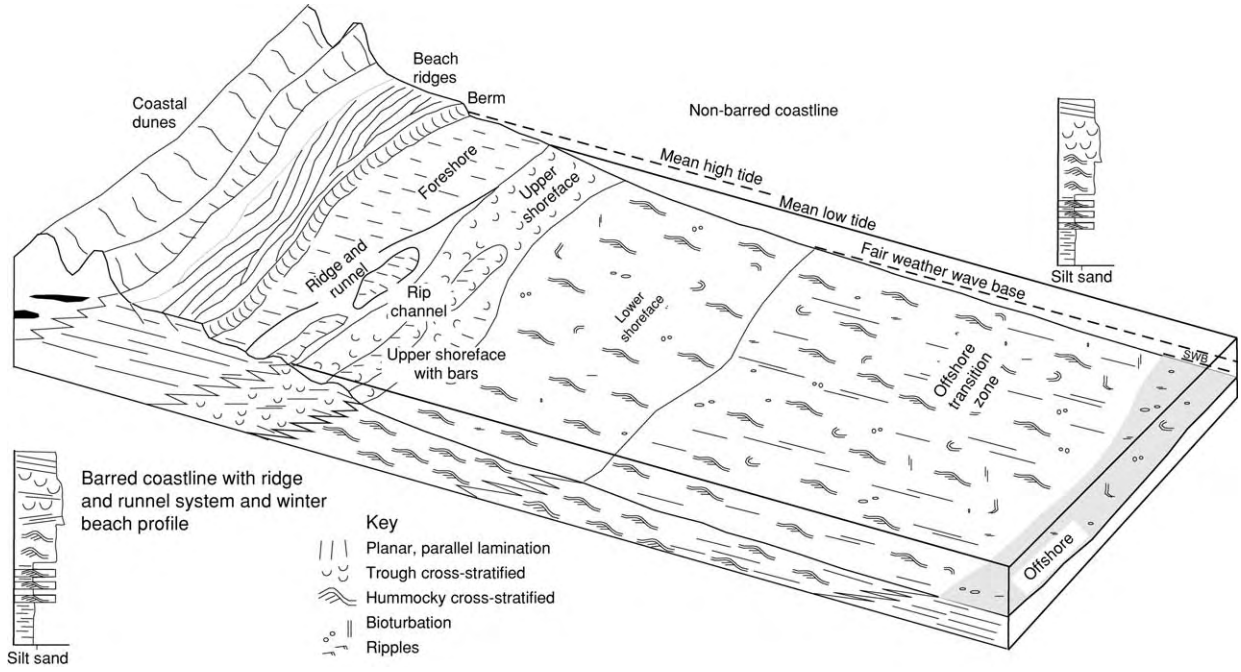

Figure 6 Facies model for a progradational wave dominated shoreline system. View shows both barred and non barred coastlines. Sediment is introduced by longshore drift. No scale is implied because the depths to the fair weather wave base and the storm wave base (SWB) are controlled by the size of the basin and the local climate.

(HCS) sheets of sandstone, typically less than 0.5 m thick; thin layers of coarser material (up to granule grade) may also be deposited if such material is available on the beach. These sheets have erosive bases whereas the top surfaces commonly exhibit wave ripples formed during the waning part of the storm. Bioturbation of the storm bed by opportunistic organisms is common. Between storm events, mud is deposited from suspension.

The shoreface is the interval that lies landward of the point at which the fair weather wave base interacts with the seafloor. Within the lower part of the shoreface, sediment is deposited as sheets of HCS sand during storms, and fair weather wave action prevents the deposition of mud between the storm events, resulting in a sand-rich depositional system. The point at which the fair weather waves actively move sediment in a landward direction marks the base of the upper shoreface. The upper shoreface may be a simple seaward-dipping surface or it may contain one or even several large bar forms. Simple, 'non-barred' shorelines are generally steeply dipping and coarse grained. They are covered with small dune forms that migrate in a landward and longshore direction; plunging waves generally produce seaward-dipping planar laminations on a relatively simple beach (**Figure 7**). Non-barred shorelines prograde through the steady addition of sediment to the beach and shoreface. Modern examples include the Pacific coast of North America. The Book Cliffs of Utah display superb Cretaceous examples of non-barred shoreline deposits (**Figure 7D, E, H,** and **J**).

Barred shorelines are more common than non-barred systems and contain large (up to 50 m wide and hundreds of metres long) shore-parallel barforms separated by narrow rip-channels that run perpendicular to the shoreline. Water and sediment are carried in an onshore direction by incoming waves that break over the bars and in an offshore direction by currents running through the rip-channels. The combination of these processes generates circulatory cells (termed 'longshore cells') within the shoreface. Barred shorelines are extremely dynamic and change markedly on a seasonal basis. Bars are generally built during the winter months as storms move sediment offshore from the beach. Bars can be symmetrical or asymmetrical and contain a series of seaward-dipping planer-beds deposited by storms on the seaward side and trough cross-bedding and landward-dipping planar-beds deposited by fair weather wave reworking. Rip-channels are either erosional or contain seaward-directed trough cross-bedding. During the summer months, the bars migrate landward and may emerge above the low tidemark, where they become part of the beach.

Within barred shorelines, the beach is more complex, compared to the simple seaward-dipping planar surface that exists in non-barred systems. Beaches within barred coastlines comprise a series of subzones, not all of which are always present. The lower intertidal portion includes a series of low, shore-parallel barforms, or 'ridges', separated from one another by hollows, or 'runnels' (**Figure 6**). Sedimentary features within this ridge and runnel system include low-angle dipping planar laminations on the ridges and shore-parallel current ripples formed by the draining of the runnels as the tide recedes. These ridge and runnel systems generally develop during the winter months when storms occur most frequently, but may also be related to the emergence of landward-migrating bars during the summer period.

The main part of the intertidal zone is termed the 'foreshore' and comprises a series of seaward-dipping planar surfaces formed by the breaking waves. The mean grain size of the sediment will strongly control the dip of the foreshore. If the grain size is coarse, the water brought onshore by the breaking waves will rapidly percolate into the sediment, reducing the backwash and producing a steep beach. Conversely, if the sediment is fine and less permeable, the beach will be gently dipping. The top of the foreshore is marked by a ridge called a 'berm'. The berm builds during the summer months as the fair weather waves push sediment onto the beach. In the absence of large storms, beaches may develop a series of parallel berms.

Beyond the berm lies the backshore. This is the area above the mean high tidemark, where sediment is introduced only during extremely high tides or by storms. If a lot of coarse (cobble to pebble grade) material is available, a storm ridge may be formed. This is typically composed of well-rounded, well-sorted, discoid clasts with a seaward imbrication that are thrown up during storms and are coarse enough to resist fair weather reworking. In the absence of a storm ridge, the backshore may comprise partially vegetated sand flats in which aeolian processes rework the sediment that is infrequently washed in.

Vertical Succession through a Wave-Dominated Shoreface Succession

The vertical succession deposited during the progradation of a wave-dominated shoreline succession reflects the lateral facies relationships as described. The onshore coarsening of grain size and increasing bedform asymmetry are recorded vertically in the rock record (**Figure 6**). A typical vertical succession from base to top will exhibit mudstones and siltstones deposited in the offshore setting at the base. Moving upward, the appearance of the first significant

Note the landslip deposits in the midground and the steep, retreating cliffs of chalk in the background. The foreshore is covered in a thin veneer of sand reworked from the cliffs.

hummocky cross-stratified storm beds represents the SWB and marks the base of the offshore transition zone (OTZ), which is characterized by interbedded sandstones with HCS and bioturbated mudstones. There is an upward increase in the thickness and the proportion of sandstone beds within the OTZ to the point at which they become amalgamated and no significant mudstones interbeds are observed. This point in the succession represents the position of the FWWB. The overlying amalgamated storm deposits are deposits of the lower shoreface. The lower shoreface also locally includes intervals that are heavily bioturbated, and top-truncated hummocks sometimes termed 'swaley cross-stratification' (SCS).

As previously noted, the upper part of the shoreface in a non-barred coastline will comprise simple landward and longshore migrating dunes that produce trough cross-bedding; this cross-bedding passes up into the seaward-inclined planar cross-bedding that represents the foreshore. In a barred coastline system, the vertical succession will be more complex, with a series of landward- and seaward-dipping planar stratified beds, interbedded with trough and ripple cross-stratified units and frequent erosion surfaces. In such cases, it may be difficult to distinguish the upper shoreface from the beach, except by the vertical transition to the overlying backshore deposits.

Muddy Coastlines and Cheniers

The majority of depositional wave-dominated shorelines are sand rich because waves will rework mud-grade material, moving it offshore in suspension. However, if mud is the only material present and is available in large enough quantities, muddy wave-dominated coasts can occur. Such systems build very large, low-angle dipping muddy barforms that are held together by the cohesiveness of the sediment. The very low angle dissipates all wave action and prevents wave erosion. Periodic influxes of sand and/or concentrations of shell debris can produce seaward-dipping beds associated with prominent ridges on the beach. These are termed 'cheniers'. Such systems are seen on the Surinam coast of South America and in areas adjacent to the Mississippi delta.

Low-Relief Transgressive Coastlines

Low-relief transgressive shorelines occur when the rate of sediment supply is less than the rate of relative sea-level rise and the coastal zone is a low-lying feature, typically a former depositional surface such as an abandoned delta top or coastal plain. In systems with a moderate to low tidal range, the shoreline will generally develop barrier islands. Barrier islands are linear, shore-parallel strips of land that separate the open ocean from a sheltered lagoon or intertidal flat area; the intertidal area may be connected to the marine realm through tidal inlets. There are extensively developed barrier islands on the Texas gulf coast (Figure 8). Many of the processes that are active on the seaward side of the barrier are identical to those described for the shoreface and beach systems in the previous section. The key difference is that

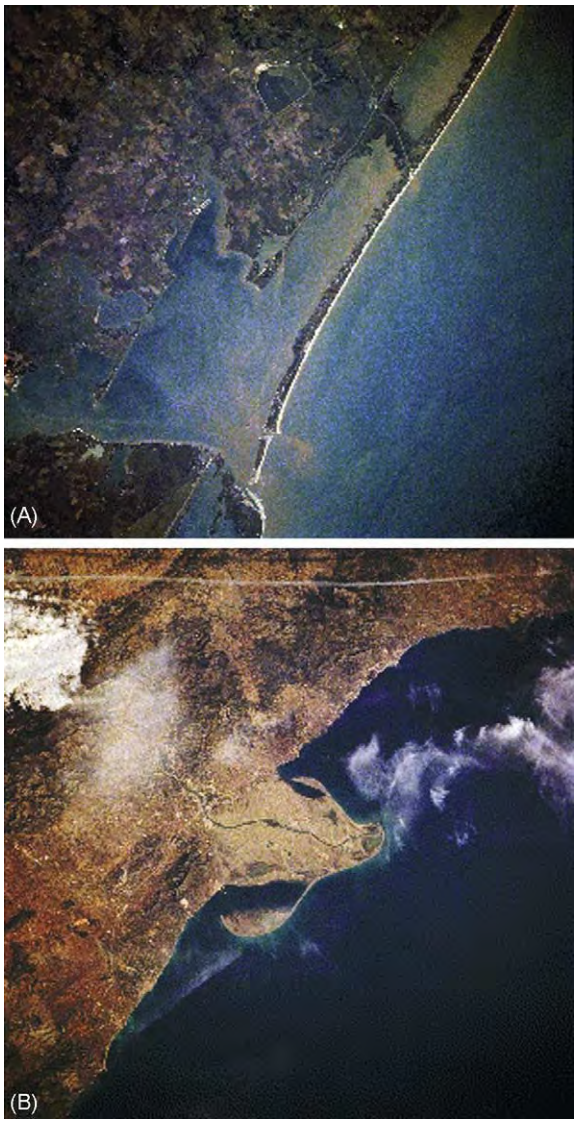

Figure 8 Space shuttle photographs of transgressive wave dominated shorelines. (A) Matagorda Bay, Texas, USA. A narrow barrier island system shelters the lagoon from the open ocean. The irregular left hand side of the barrier island is due to washover fans. Note the small tidal inlets towards the base of the photo. (B) Ebro Delta, Spain. Thirty five dams along the river have signifi cantly reduced the sediment supply to the delta, which has subse quently been transgressed due to relative sea level rise caused by compactional driven subsidence. Note the development of spits and barriers on the wings of the delta. Both images courtesy of Earth Sciences and Image Analysis Laboratory, National Aeronautics and Space Administration Johnson Space Centre.

during large storms, some of the sediment is washed into the lagoons and is deposited as sheets of planar bedded and rippled deposits; these are termed 'washover fans' (Figure 9). Because sediment is removed from the seaward side of the barrier and is deposited on the landward side, the shoreline moves landward. This process, termed barrier 'rollover', can be relatively rapid. Parts of the modern-day Galveston Island in Texas have migrated 80 m in the past 100 years. Generally, the migrating barrier system leaves very little sediment behind and the geological record of the transgression is an erosive surface, often associated with a lag of pebble or shell debris, concentrating the coarsest material from the underlying unit. The barrier island will be preserved at the point at which it stops migrating landward and the system starts to prograde. If the sea-level rise is very rapid, the entire barrier complex may be preserved by drowning.

Barrier island systems that occur in mesotidal settings are cut by tidal inlets through which tidal flows connect the lagoon with the open marine realm. In such cases, the barrier is also locally reworked by tidal currents passing through inlets. Deposition associated with the tidal inlet will include small subaqueous deltas on the landward and seaward sides, termed 'flood' and 'ebb' tidal deltas, respectively. These deltas are composed of rippled and planar cross-stratified sandstones that interfinger with the shoreface deposits on the seaward side and with the lagoonal muds and washover deposits on the landward side. Deposition of trough and tabular cross-bedding, often showing tidal draping, may also occur within the inlet channel. This will frequently be reworked but can be preserved if the position of the inlet migrates laterally.

Although numerous authors have discussed progradational barrier systems, especially in modern settings, geologically such features are very short lived; they represent the transition from transgressive barrier systems to land-attached shorelines because, if the barrier progrades, the lagoon will rapidly (over geological time) be infilled. Progradational systems with a strong component of longshore sediment transport can also develop beach-attached spits and even barrier systems that also shelter a lagoon on their landward side; however, these lagoons may be quickly filled by sediment that is introduced from the landward side by runoff and is washed over by storms from the seaward side.

High-Relief Transgressive Coastlines

High-relief coastlines may occur when the system is in net erosion and the wave action produces a cliff. The dominant processes are wave action and mass wasting. Fluvial and tidal processes are negligible. Wave action undercuts the cliff, which eventually collapses onto the foreshore; the cliff sediment is then reworked by wave processes and is transported either offshore or along the coastline by longshore drift. In its simplest form, a rocky coastline typically comprises a cliff and a wave-cut platform (Figure 10). The nature of the bedrock geology, rates of relative sea-level fall, and the wave climate will characterize any particular example. Variations in the bedrock geology due to lithological variations and structural geology (presence of faults and fractures) will result in differential erosion, leading to a variety of landforms, including stumps, stacks, arches, and caves

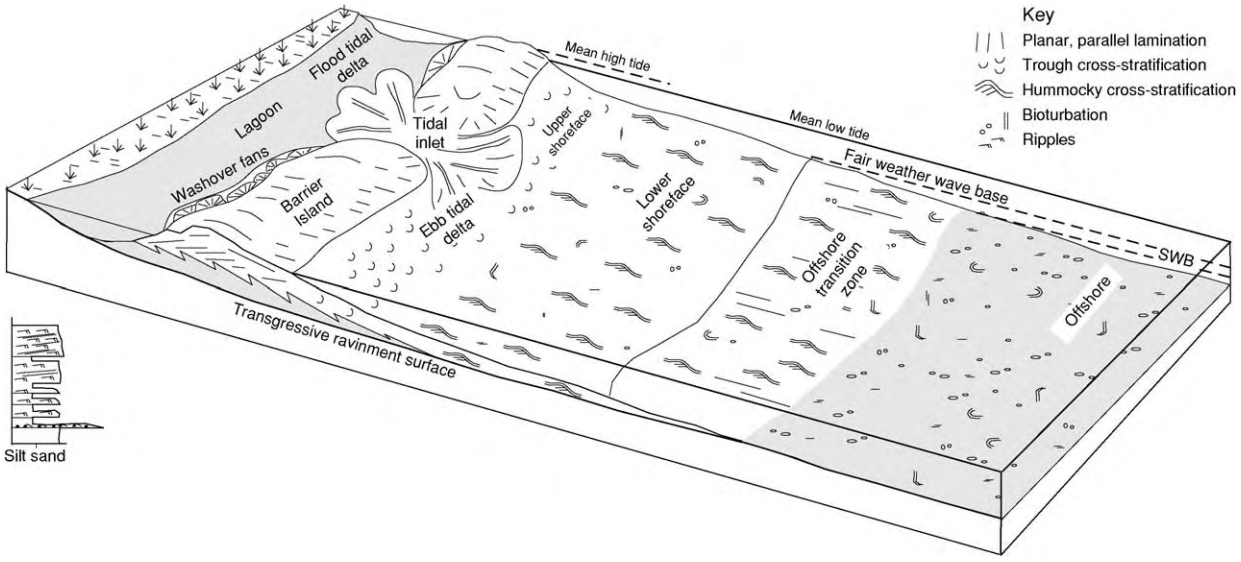

Figure 9 Facies model for a transgressive wave dominated shoreline system. The barrier island migrates landward through erosion on the seaward side and by deposition in washover fans and flood tidal deltas. SWB, Storm wave base.

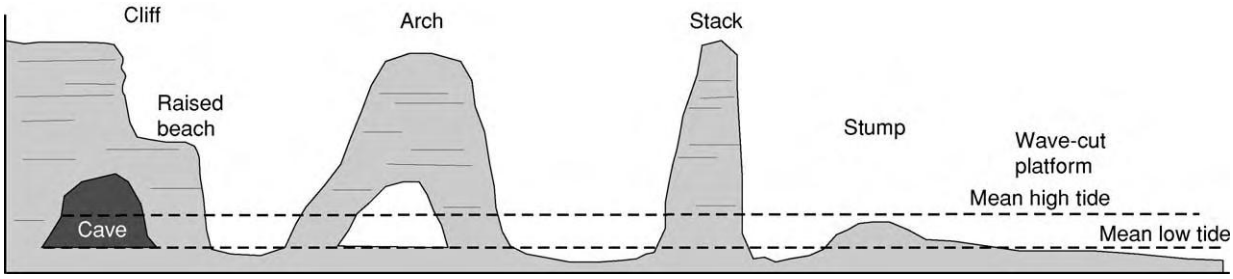

Figure 10 Geographical features of a high relief erosional coastline.

(Figure 10). Changes in relative sea-level may lead to the formation of wave-cut terraces or marked wave-cut notches.

The geomorphological character of a cliff is a product of the bedrock geology and the climate. Hard, resistant bedrock will result in high, steep cliffs that retreat slowly and show pronounced wave-cut notches at the base; softer deposits will result in lower, less steep, rapidly retreating clifflines. The process of cliff retreat is enhanced in a wetter climate and is retarded in more arid regions. The wave-cut platform is a horizontal to low-angle seaward-dipping surface that occurs between mean high watermark and wave base. The wave-cut platform may be covered in a thin veneer of reworked sediment or may be bare. Where present, sediment may range in grain size from sand particles to boulders. Clasts are generally well rounded due to frequent reworking by waves. Wave movement of the retreating cliffline-derived sediment is a key process in the scouring of the platform.

As erosional features, rocky coastlines have little preservation potential in the geological rock record, although they may account for significant amounts of geological time. Preservation will be limited to an erosional surface that records the final position of the shoreline prior to a change in conditions that led to the onset of deposition. Immediately above this surface a thin veneer of sediment may be preserved.

Storms and Storm Deposits

P Myrow, Colorado College, Colorado Springs, CO, USA

Introduction

Numerous studies of modern shelves indicate that storms have wide-ranging effects in a spectrum of environments from outer shelves to coastal plains. Early oceanographic studies led to interest in finding analogues in the rock record. Resulting facies models for storm-influenced depositional systems were not published until the late 1970s and early 1980s, later than for many other depositional systems (e.g. fluvial, tidal-influenced shoreline, submarine fan). There are a number of reasons for this. First, the oceanographical study of modern storms is extremely difficult. Direct observations are challenging and dangerous. Quantitative analysis also required the development of current meters and other devices that could survive the effects of strong storm-generated currents and waves. Second, storms are extremely complex systems that include strong currents and waves, both of which vary both temporally and spatially during an individual storm. Third, although tempestites, individual storm-generated sandstone beds, were attributed to deposition from storm-generated currents fairly regularly by the mid-1970s, features considered to be diagnostic of deposition by storm processes, such as hummocky cross-stratification (HCS), were not identified early in the study of sedimentary structures. Many case studies of ancient storm-influenced deposits and modern settings indicate that storms have wide-ranging effects in a spectrum of environments from outer shelves to coastal plains. The most common storm deposits in the rock record are interbedded sandstone and bioturbated shale (Figure 1). The sandstone beds were deposited as a result of powerful near-bottom water motions produced by waves and currents, and these are the main focus of the following discussion. Additional storm-generated features include gutter casts, pot casts, gravel and conglomerate accumulations, and reworked or transported shell beds.

Figure 1 The deposits of storm influenced shelves consist of tempestites or storm generated sandstone beds and shale beds deposited between storm events. Note how the sandstone beds tend to pinch and swell in thickness, a common feature of tem pestites. These strata, exposed in the central Transantarctic mountains, were deposited along the East Antarctic continental margin during the Cambrian. Hammer for scale.

Early Facies Models

Early studies established the basic idea that storms result in the transport of sediment from generally well-sorted shoreline sources onto shelves, as deduced from lithofacies patterns of decreasing bed thickness and evidence for less powerful currents from onshore to offshore. Despite more than 30 years of work on storm-influenced shorelines and ancient deposits, there remains considerable debate concerning the processes by which sediment is transported seawards during storms. Early discussions of storm processes produced two radically different perspectives from oceanographers and from geologists who worked on ancient deposits. Stratigraphical and sedimentological data indicated a potential role of density-induced forces, in part because many tempestites closely resemble turbidites. The first facies model of storm-influenced shelves invoked the mobilization of sand at the shoreline, the creation of dense dispersions, and subsequent gravity-driven offshore transport. Data from many ancient deposits indicate transport nearly perpendicular to the shore for long distances. In this view, storm-deposited sandstone beds are indicative of nonuniformitarian processes, and the very rare storm events responsible for these beds (with recurrence intervals of tens of thousands of years) are presumably significantly different (quantitatively if not qualitatively) from those studied by oceanographers.

Oceanographic Studies

Although the results of major storms on modern shorelines were first described in the late 1960s, the dynamics of modern storm-generated flows were not outlined until the 1980s by oceanographers who described the effects of storms on shelf and nearshore circulation. Winds generated by storms move surface water, which is in turn deflected by Coriolis

acceleration. This deflection affects much of the water column and results in net transport at 90° to the wind direction (to the right in the northern hemisphere). One common consequence of such transport is that under certain wind conditions surface waters may move towards, and bank up against, the shoreline. The resulting sloping sea surface causes an onshore–offshore pressure gradient, which tends to drive flow offshore along the sea bottom. Coriolis force affects water particles moving in this flow at right angles to the flow direction, and an equilibrium is eventually established between the offshore-directed pressure gradient and the Coriolis force, such that the majority of storm-generated flows are alongshore. The surface flows are more landward oriented, and the bottom flows, which are affected by bottom friction, tend to be oriented at a slightly higher angle offshore.

The conflict between the oceanographical observations of shore-parallel geostrophic storm flows and the geological data that indicates both cross-shelf transport and the deposition of turbidite-like beds has never been fully resolved. Theoretical work and numerical simulations of combined-flow boundary layers (Figure 2) are important in addressing this problem and have been used by some workers to suggest that offshore transport of sand could take place during storms under combined flow. Since geostrophic currents are oriented slightly oblique to shore, the offshore component of the flow is added to the seawards strokes of storm waves and acts against the shorewards strokes, resulting in an asymmetry of shear stress. It was thus postulated that this asymmetry was responsible for the offshore sediment transport of sand and for the unimodal offshore-directed sole-mark orientations on the bases of tempestites. Studies in the ancient sedimentary record have affirmed the importance of geostrophic combined flows in some shoreface and nearshore storm deposits, but it remains unclear to what degree such flows are responsible for cross-shelf transport in modern systems or to what degree they were responsible for the deposition of ancient tempestites.

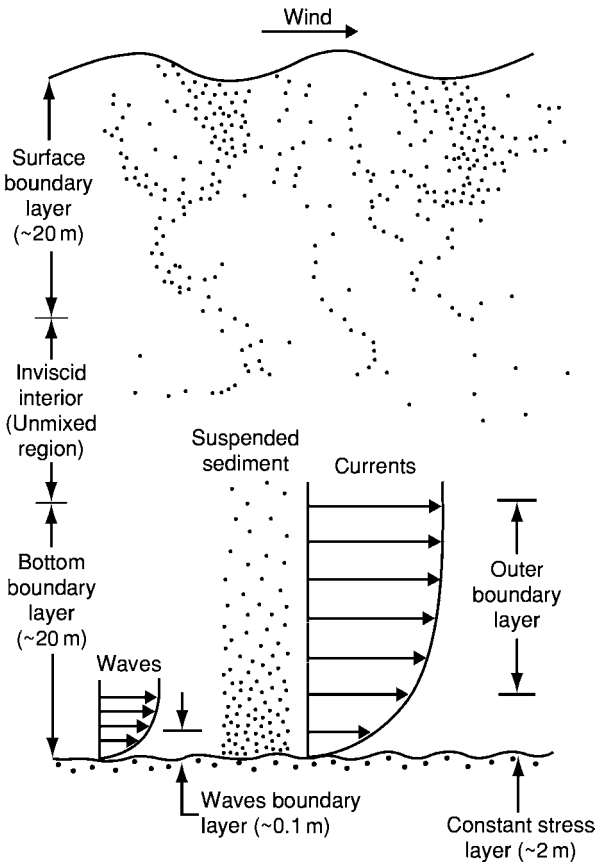

Figure 2 Subdivision of the water column into three layers during storms: a highly turbulent surface boundary layer, an inviscid interior or core flow layer, and a bottom boundary layer. The bottom boundary layer consists of a thin wave bound ary layer and a thicker outer boundary layer produced by cur rents. Modified from Trowbridge and Nowell (1994).

Interpreting Ancient Tempestites

The large number of case studies of tempestites has led in recent years to a greater appreciation of the potential variety of storm processes. A wide range of storm deposits result from spatial and temporal variability in the degree to which three fundamental processes operate: geostrophic currents, storm-generated waves, and excess-weight forces (Figure 3). For instance, some studies have shown that geostrophic flows are in fact agents of transport and deposition in tempestites, as determined in part by shore-parallel palaeocurrents. Such flows cannot explain successions with offshore-directed palaeocurrents or sole markings, such as 'classic' flute marks, that are inconsistent with formation in the presence of waves. In fact, the wide range of sole-mark geometries alone supports genesis from various types of flows. Bidirectional and multidirectional orientations of prod marks and groove marks indicate strong wave activity. Flutes, unimodal prods, and well-oriented grooves probably reflect erosion by powerful unidirectional flow. Finally, a range of sole marks including curvilinear and quasi-sinusoidal forms record erosion by a variety of combined flows.

The internal structures of tempestites are equally diverse and relate to the temporal and spatial histories of the three basic components of storm-related flow described earlier. Most tempestites contain evidence of flow deceleration in the form of either normal grading or particular successions of stratification. They also contain stratification representative of a wide range of bedforms, from purely unidirectional

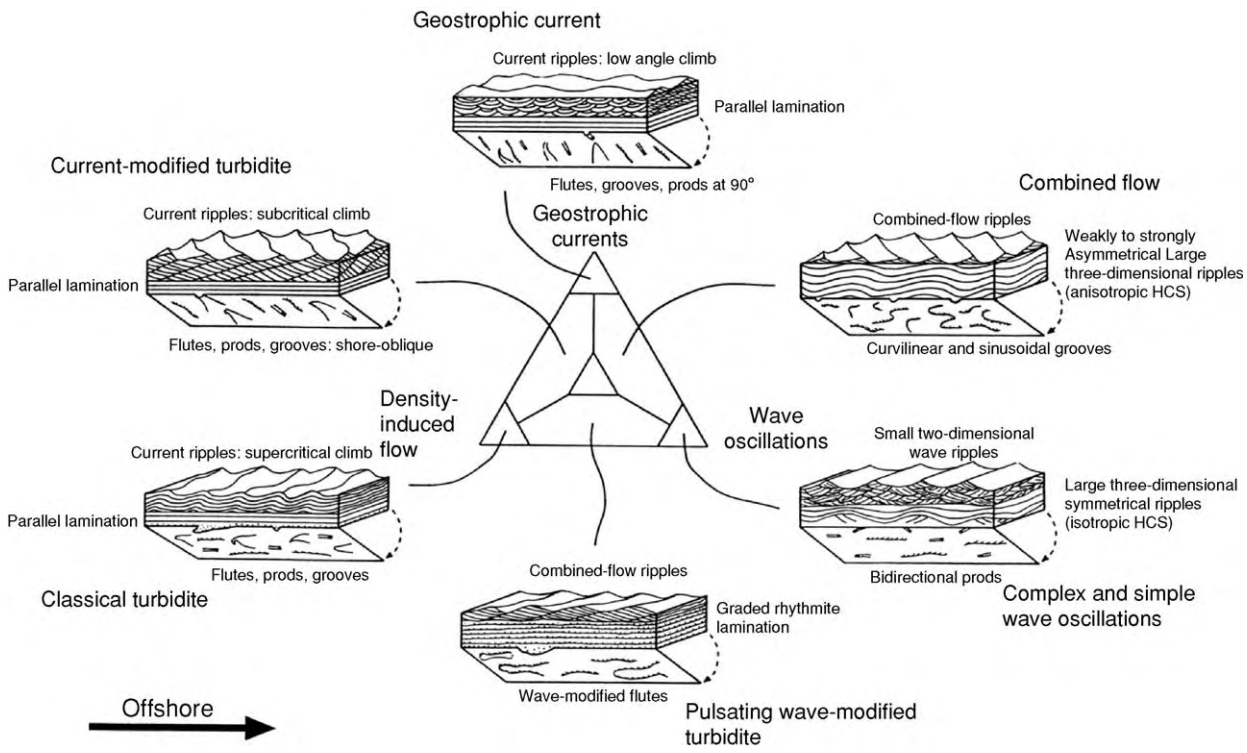

Figure 3 Heuristic model for the origin of stratification and sole markings for various possible combinations of storm processes. The diagram has three corners, representing density induced flow due to excess weight forces, geostrophic currents, and wave oscilla tions. The potential history of a storm event, in this three part system, is extremely variable. The deposits of flows near the corners are well understood, but the central triangle and intermediate fields are poorly understood since so little is known experimentally about these fields, except for some information on simple rectilinear combined flows. HCS, hummocky cross stratification. Reproduced from Myrow PM and Southard JB (1996) Tempestite deposition. *Journal of Sedimentary Research* 66: 875 887.

to purely oscillatory flow, including a spectrum of combined flows (Figure 4). The most diagnostic feature of storm deposition is HCS at various scales (Figures 5 and 6). The characteristics of HCS are well described and have been studied experimentally and with grain fabric analysis. There does not appear to be a size break in the bedforms that create HCS, namely three-dimensional, symmetrical to weakly asymmetrical, subaqueous dunes. Bedforms on modern shelves with HCS-like lamination have been attributed to combined flows, and experimental work has shown that hummocky bedforms are stable in complex oscillatory flows and wave-dominated combined flows (i.e. low velocities of current component).

Details of the geometry and internal structure of ancient tempestites indicate that beds range from those deposited in single events to those representing amalgamated accumulations produced by multiple events. The latter include thick beds that grade laterally into thinner beds separated by thin shale beds. These suggest that transport of sand onto shelves is in some cases incremental and involves a succession of storms. Some beds that appear to result from single events are potentially remobilized sand that simply records the last stage of transport and deposition.

Other tempestite beds show little or no evidence of amalgamation and are suggestive of powerful offshore-directed unidirectional flow during the erosional and initial depositional conditions of the storm. The nature of such flows is difficult to determine from the ancient. In many cases they may have been driven, at least in part, by excess-weight forces, caused by high near-bed suspended-sediment concentrations (SSCs). 'Sediment equilibrium' conditions exist when SSCs are caused by resuspension of sediment by storm-generated currents and waves. Very high SSCs (up to 4 g l ^{1}) and resulting powerful seaward-directed sediment-laden flows have been documented from shorefaces and inner-shelf settings. It is less clear to what distances such flows can carry sand offshore on the relatively low gradients common to modern continental shelves.

Excess-weight forces can also be generated extrinsically ('sediment disequilibrium' conditions), for example when rivers discharge sediment-laden floodwater into standing bodies of water and thus produce hyperpycnal (bottom-hugging) flows termed oceanic floods. Oceanic floods on the continental shelf of northern California adjacent to the Eel River have high SSCs (up to 2.5 g l ^{1}) of silt and

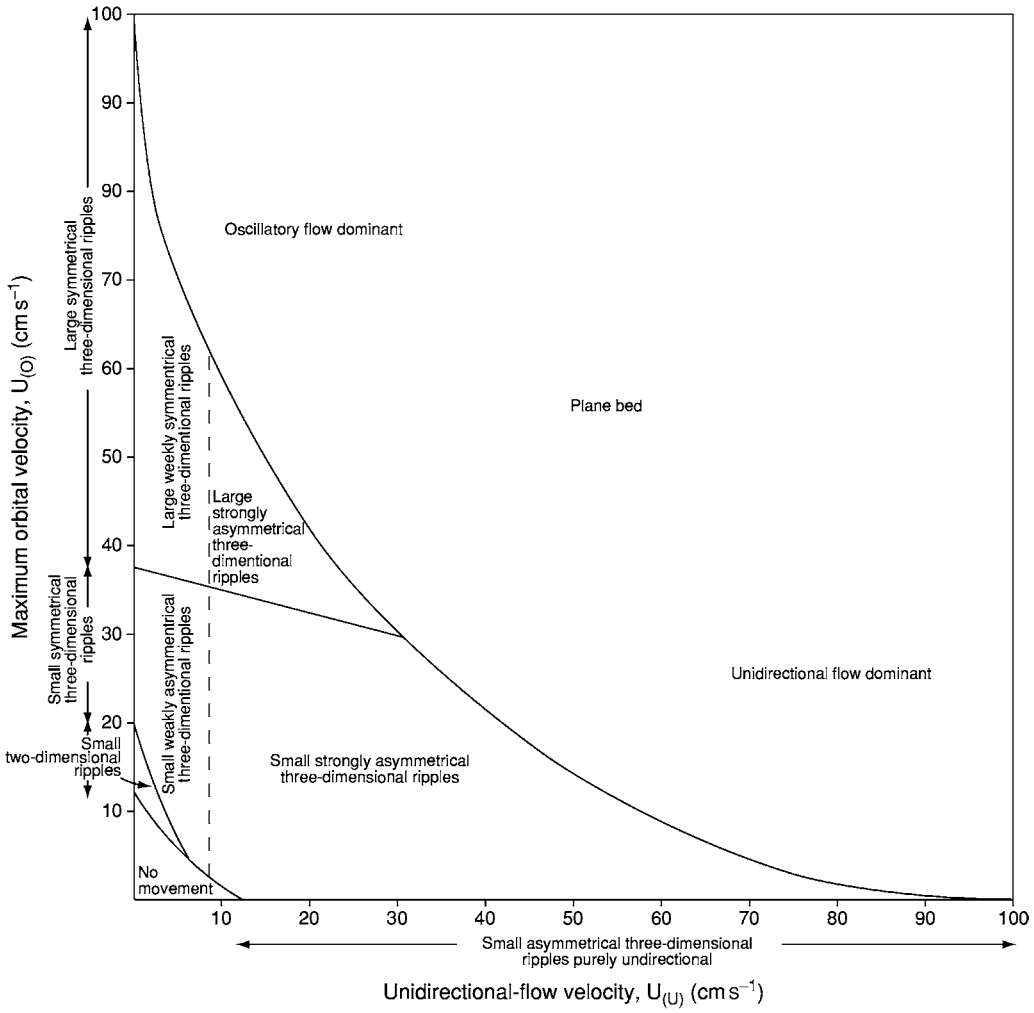

Figure 4 Bed configuration stability diagram for combined flows in fine sand. Based on published data and on data from Arnott RW and Southard JB (1990) Exploratory flow duct experiments on combined flow bed configurations, and some implications for interpret ing storm event stratification. *Journal of Sedimentary Petrology* 60: 211 219 and Southard *et al.* (1990). The left side of the diagram (up to U_U of 25 cm s^{-1}) is drawn from the data in Arnott and Southard (1990), and the right side is extrapolated.

clay even at mid-shelf depths (50–70 m). Such floods are potentially a geologically important process for cross-shelf sediment transport, although it is unknown whether they could transport very fine and fine sand, the grain sizes that dominate most ancient tempestites. Facies models for some ancient sandstone tempestites cite nearshore sediment bypass (Figure 7), which is consistent with powerful unidirectional flows in very proximal positions, possibly associated with hyperpycnal oceanic floods.

In both sediment equilibrium and sediment disequilibrium conditions sediment may be transported in combined flows produced by a combination of excess-weight forces and storm waves. Such wave-modified turbidity currents differ from classic turbidity currents in that storm waves enhance boundary-layer shear stress and eddy viscosity, which reduces deposition from suspension and thus enhances gravity-driven transport. As long as turbulent diffusion by waves does not destroy the density stratification, it provides the energy necessary to maintain gravity-driven flow on relatively low gradients. This process has been documented in the cross-shelf movement of modern fluid mud layers, but not for sand-sized sediment. Ancient examples of wave-modified turbidites have internal sedimentary structures, including combined-flow ripples, that reflect the influence of both waves and gravity-driven flow (Figure 8).

Whereas the preceding discussion has emphasized the range of possible processes responsible for tempestite deposition and thus has explained the wide variety of sole marks and internal sedimentary structures in the ancient, there are two important aspects of tempestites that remain controversial. First, beds in the ancient that are interbedded with shale and were therefore deposited below the fair-weather wave base

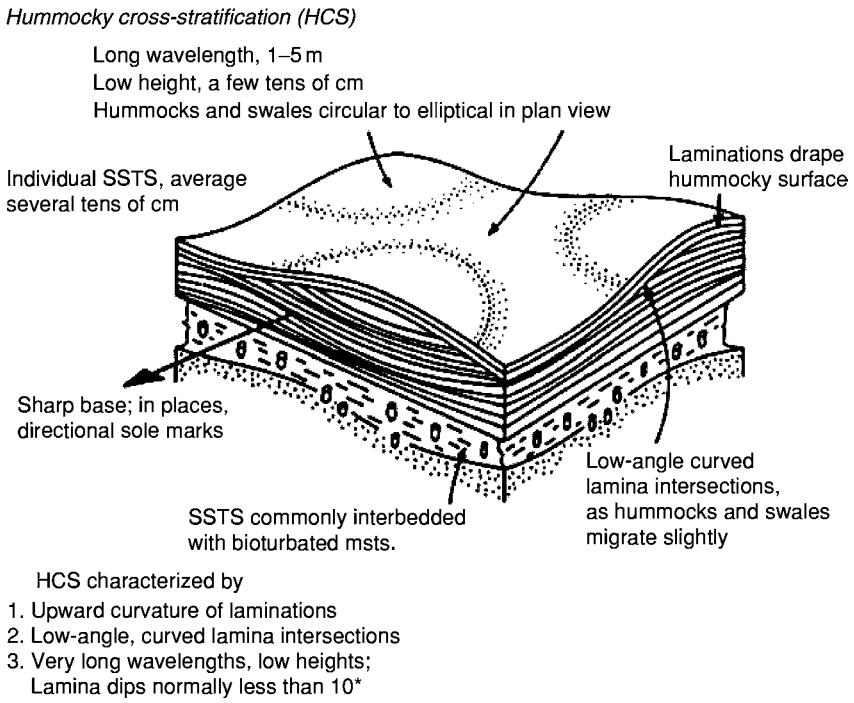

Figure 5 Block diagram illustrating the diagnostic features of hummocky cross stratification (HCS). Modified from Walker RG (1984) Shelf and shallow marine sands. In: Walker RG (ed.) *Facies Models*, 2nd edn., pp. 141 170. Reprint Series 1. Toronto: Geoscience Canada.

are considerably thicker than sand beds deposited on the shelf as a result of modern storms and appear to have a greater cross-shelf distribution than their modern counterparts. In unusual settings, such as the shallow (less than 20 m), flat, epicontinental shelf off the Yukon Delta in the Bering Sea, sand is carried offshore up to 100 km, although the beds range in (precompaction) thickness from 10–20 cm in the nearshore to less than 5 cm offshore. In this case, strong friction forces may have aided offshore transport, and thus such a setting may be a good analogue of epicontinental deposits, including those of the Cretaceous interior seaway of North America. In many modern settings sand beds of any appreciable thickness do not extend much below 5–10 m water depth. The thicknesses of modern storm beds fall in the small-to-average range for ancient tempestites, which commonly reach (compacted) thicknesses of many tens of centimetres and locally up to a metre or more. It is unclear to what degree thinner modern tempestites may simply reflect insufficient study of the modern, particularly since their record is commonly rapidly lost offshore owing to bioturbation. It

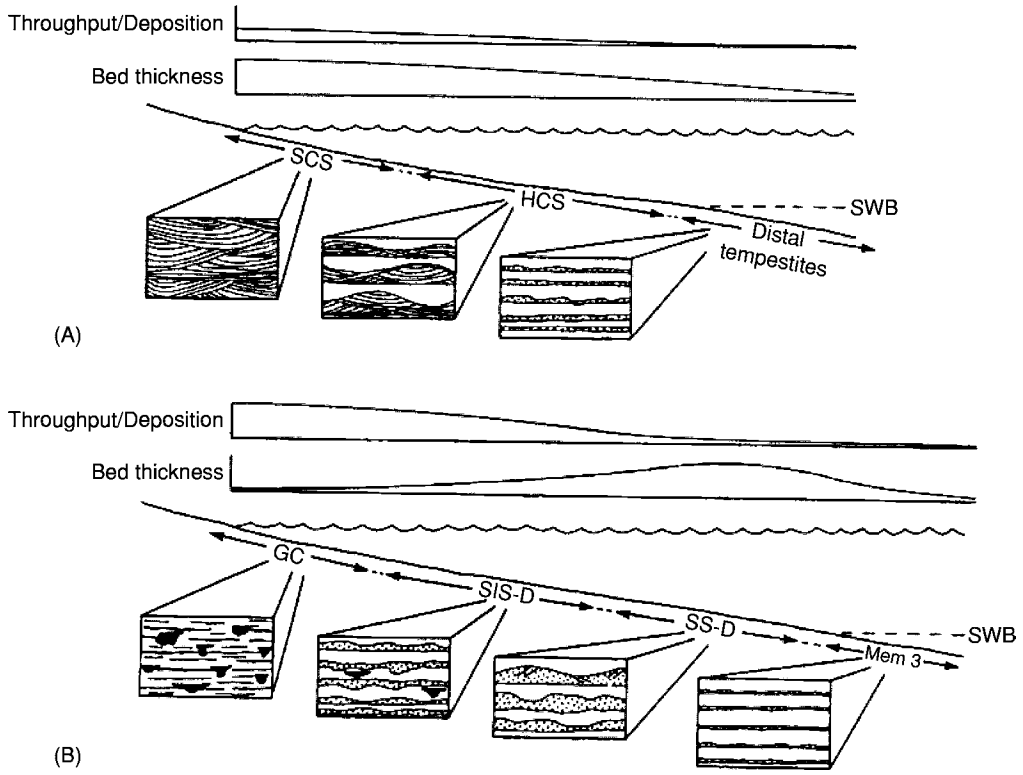

Figure 7 Comparison of (A) standard tempestite model and (B) bypass model (Myrow 1992). The spatial distribution of facies in each model is illustrated with onshore offshore profiles and associated qualitative changes in bed thickness. The degree of sediment bypass (throughput to deposition ratio) is plotted above each profile. (A) Proximality trends in the standard model include constantly decreasing bed thickness away from the shoreline with a shift from swaly cross stratified sandstone to hummocky cross stratified (HCS) sandstone to distal turbidite like beds. (B) The bypass model shows a bed thickness trend that first increases then decreases away from the shoreline. The proximal setting is one of bypass, with erosion being the dominant process during storms (many gutter casts). Passing seaward, gutter casts die out and bed thickness increases. HCS is formed in the thicker sandstone beds farther out on the shelf. Below the storm wave base (SWB) distal tempestites are turbidite like in character. The shelf gradient for the two models is shown to be the same simply for convenience.

is also difficult to establish accurate water depths of deposition from ancient shelf deposits, so the degree to which the ancient is nonuniformitarian in terms of bed thickness and cross-shelf transport is still unresolved. Finally, comparison of ancient shelf deposits with modern shelves is hampered by the fact that the latter may be strongly out of equilibrium owing to Holocene sea-level rise.

A second problem, seemingly forgotten in the literature, is that the time between the deposition of successive tempestite beds in many deposits is seemingly many orders of magnitude too large to explain simply as a series of storm events. Data tabulation suggests that preservation recurrence intervals (time between deposition of successive tempestite beds) in a small sample of ancient successions are of the order of 400–15 000 years. High-precision geochronological studies have never been done on tempestite successions, but they are necessary to establish a reasonably accurate picture of the recurrence interval of tempestite beds in the ancient. If one assumes that the recurrence intervals calculated for the ancient are reasonably accurate, then two possibilities arise for their explanation. The simple explanation would be that only extremely large and rare storm events are preserved in the rock record and that, given the recurrence intervals mentioned above, such events would potentially be qualitatively or quantitatively different from any documented in recent deposits. Such a stance might be difficult to justify on the basis of the physics of storms or on basic oceanographical principles, although changes in the Earth's climate, ocean circulation, and palaeogeography could certainly lead to nonuniformitarian atmospheric circulations including extremely large storms.

An alternative explanation is that the apparent recurrence intervals are artefacts of processes that bias the stratigraphical record. Given the range of recurrence intervals, there exists the possibility that relative sea-level changes may have played a role by shifting the source of sandy sediment seaward or landward. In other words, shoreline migration may

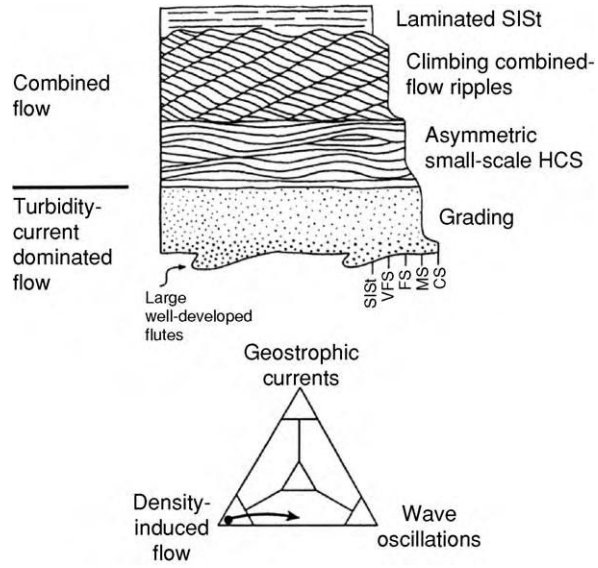

Figure 8 Generalized wave modified turbidite bed. Temporal history of generalized bed is shown in the triangular diagram of storm related effects (see also Myrow PM and Southard JB (1996) Tempestite deposition. *Journal of Sedimentary Research* 66: 875 887). HCS, hummocky cross stratification.

have enhanced apparent cross-shelf transport. Sedimentological data must therefore be combined with sequence-stratigraphical data to understand better the bed geometries and transport distances of ancient tempestites. The stratigraphical distribution of tempestites may also be understood within a sequence-stratigraphical framework, particularly as sea-level has a strong control on shelf profile. For instance, geostrophic flow may be more common during transgressive to early highstand conditions, when accommodation space is higher and there is greater potential for Coriolis deflection, whereas more offshore-directed flow may take place during late highstand conditions characterized by greater bottom friction. Tempestites are probably more abundant during late highstand to early lowstand systems tracts of third- or higher-order sequences, when sand is mobilized from the coast during relative sea-level fall.

Carbonate Systems

Although the previous discussion applies to both carbonate and siliciclastic systems, there are also depositional features that are specific to, or most common in, carbonate systems. The most abundant such features include flat-pebble conglomerate beds and shell-bed accumulations. Flat-pebble beds are an important component of carbonate deposits, particularly in Cambrian and Lower Ordovician strata, and are generally considered to be accumulations of intraclasts produced by the storm reworking of early-cemented carbonate in shoreline and shallow subtidal environments. Detailed sedimentological analyses indicate that some flat-pebble beds were deposited from storm-generated combined flows, although it is likely that there are many other processes that could produce such beds.

Shell-rich grainstone tempestites accumulate as a result of winnowing by storm waves, commonly in shoreline and nearshore settings, and they have characteristics that are different from those of tempestites produced in condensed sections within maximum flooding intervals. In shallow epicratonic seaways, winnowing and concentration of shell debris occurs during lowstand conditions, and further reworking and basinward transport occurs during early transgression. Pronounced trends in the thickness, number, and character of shell beds occurred over the Phanerozoic, and these relate to evolutionary trends and complex taphonomic variables.

SEDIMENTARY PROCESSES

Contents

Erosional Sedimentary Structures

J Collinson, John Collinson Consulting, Beech, UK

Introduction

The accumulation of sediments into the rock record is not a process of continuous deposition, but rather the net result of interaction between episodes of deposition, non-deposition, and erosion. The erosional episodes are commonly recorded by distinctive sedimentary structures whose recognition and interpretation enhance the overall understanding of the sedimentary record. This article deals with some of the processes involved in sediment erosion and also reviews the range of distinctive structures that are produced both on present-day sediment surfaces and in the rock record. It deals solely with features that are present where overall accumulation has occurred or could occur. It does not deal with erosional features that form in subaerial landscapes undergoing long-term erosion.

Erosive Processes

Critical Erosion Velocity

When water or air flows over a bed of loose particles, the boundary shear stress caused by the moving fluid tends to initiate particle movement. There is a critical boundary shear stress (sometimes expressed as a critical erosion velocity) above which particle movement occurs. For sediment of rather uniform grain size, the critical shear stress will increase as the grain size increases. However, for small grain sizes (silt and mud), the situation is less straightforward, as the combined effect of increased cohesive strength and lower surface roughness means that higher velocities are needed to initiate movement. This relationship is illustrated for water in the Hjulström–Sundborg diagram (Figure 1), which operates ideally for well-sorted sediments. A poorly sorted substrate may be winnowed as the critical shear stress of the finer particles is exceeded, leading to the development of an armoured lag on the surface that inhibits further erosion.

Sediment Cohesion

The cohesive strength of damp or wet, fine-grained sediment results from the increasing importance of intergranular electrochemical forces as the surface area to volume ratio of the grains increases and as clay minerals make up an increasing proportion of the sediment. The cohesive strength of fine-grained sediments increases with the time following deposition and is augmented by shallow burial. As well as influencing the critical shear stress of fine-grained sediment, the cohesive strength also complicates the way in which fine-grained sediments are eroded. The particle-by-particle erosion that characterizes non-cohesive sediment is replaced by the erosion of grain aggregates of cohesive sediment. These range from small rip-up clasts to larger blocks of eroded mud (Figure 2). A cohesive substrate is also able to retain detailed erosional relief and to stand at steep, even overhanging, angles. This is critical to the preservation of the many erosional structures discussed below.

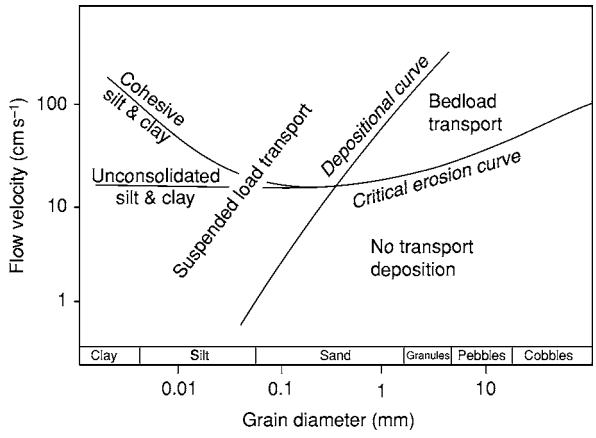

Figure 1 Plot of grain size against stream power showing the velocity at which sediment is set in motion or eroded. Note the different behaviour of fine grained sediment depending on whether it has had time to develop cohesive strength.

Role of Abrasion

The relationships between the critical boundary shear stress and particle size, as expressed in the Hjulström–Sundborg diagram, are complicated further by the fact that natural currents capable of erosion are likely to be carrying material in suspension. Sand and silt particles within this suspended load will enhance the erosive capability of the current by providing an abrasive supplement to the boundary shear stress.

Erosional Sole Marks

Erosional sole marks are relatively small-scale structures preserved as casts on the bases ('soles') of sandstone or, more rarely, limestone beds usually in interbedded sandstone/mudstone sequences. They vary in style and are valuable indicators of erosional and depositional processes. They also provide palaeocurrent information and act as 'way-up' indicators in deformed successions. Their common occurrence on the bases of sandstone beds in interbedded sequences suggests that the sands were deposited as episodic, high-energy events in settings in which quiet conditions normally prevailed, with background sedimentation being from suspension. The fact that erosional sole marks occur on the bases of the sandstones suggests that the high-energy events were erosional in their initial stages, prior to the onset of sand deposition. Such surges, which decelerated through time, typically occur as turbidity currents in deep water, as

Figure 2 Blocks of cohesive mud occurring as clasts in the base of a channel. Recent terrace deposits, Tana Valley, Norway.

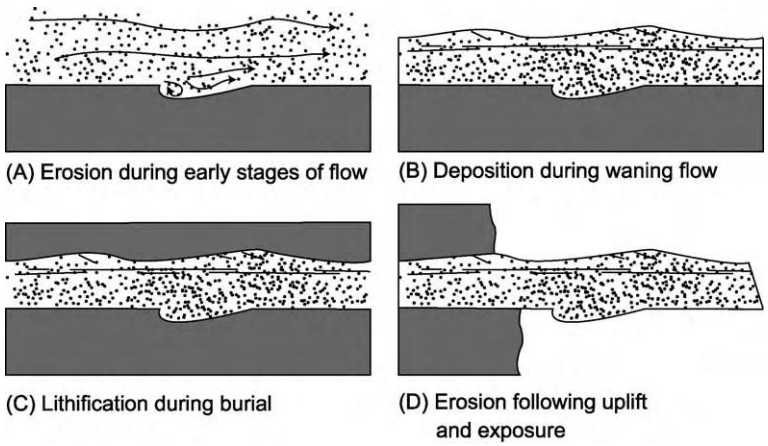

Figure 3 Schematic diagram to show the main stages in the development and preservation of erosional sole marks in an interbedded succession of cohesive sediment and coarser, high energy event beds.

storm surges in shelf settings, and as flood events in deltaic and alluvial settings.

The erosive initial stages of such flows are likely to be highly charged with suspended sediment, which may include coarse particles and, consequently, erosion may result from a combination of both fluid shear and grain abrasion. If the transported clasts are sand and silt, abrasion will augment and accelerate fluid scour. If, on the other hand, the clasts are quite large, their interaction with the bed may create distinctive structures that relate directly to that interaction. Such structures are 'tool marks'. Erosional forms created by both types of process occur initially as negative relief on the bed, and their preservation and later recognition depend on that surface being rapidly overlain by coarser sediment, giving a positive cast of the relief (Figure 3). The survival of the surface relief through the transition from erosion to deposition depends on the cohesive strength of the substrate, which typically preserves steep and detailed features.

Sole Marks due to Fluid Turbulence

These structures relate to the pattern of fluid turbulence close to the bed and are essentially smooth features related to fluid scour, probably augmented by abrasion. They may be classified into three main groups: obstacle scours, flute marks, and longitudinal furrows.

'Obstacle scours' occur around an object lodged on the bed. This is most often a pebble or a shell fragment and the scour is preserved as a horseshoe-shaped ridge that wraps around the upstream side of the obstacle (Figure 4). The ridge was a trough during erosion and its form results from the locally enhanced boundary shear stress as flow was forced to accelerate around the object. Spiral eddies which are shed off either side of the obstacle give the tails that gradually die out downstream.

Figure 4 Obstacle scour around a pebble on the base of a sandstone bed. The horseshoe shaped ridge is the cast of a scour trough eroded around the upstream side of the pebble as the flow accelerated past the obstacle. Eocene, Ainsa, Spanish Pyrenees.

'Flute marks' occur in isolation and in groups, sometimes in linear arrays parallel to flow. They are characterized by a rounded nose at the deepest part of the scour from which the structure flares away in a V-shaped form (Figure 5). The nose points upstream and the shape of the flute reflects the action of a local eddy at the bed, enhanced by the growing flute. Their shape in plan ranges from very sharp V-forms to features with a straighter transverse upstream edge. Flutes may have been initiated at some initial irregularity on the bed surface that caused flow separation and heightened bed shear stress. The irregularity responsible may sometimes be apparent, but in most cases is not. The separation eddy, in turn, led to local scour, enhancing the relief, so that, once initiated, a positive feedback loop was set up between the turbulence and the bed topography. The downstream flaring of the flute away from the nose reflects the mixing of the eddy back into the body of the flow. At the head

Figure 5 Flute casts on the base of a turbidite sandstone bed showing the noses pointing in the upstream direction. Eocene, San Sebastian, Spain.

of the flute, the axis of the separation eddy would have been transverse to flow and the axes would have rotated parallel to flow along the downstream flaring margins.

'Longitudinal furrows' occur on the bases of sandstone beds as patterns of broadly parallel ridges that have a rounded profile and are separated by narrower grooves. This reflects an erosional morphology of rounded parallel furrows separated by cuspate ridges. Along the furrows, it is quite common to find rounded noses that all point in the same direction, similar to small flutes. Indeed, there is a continuous series of erosional forms between clear flutes at one end and smooth parallel furrows at the other. The furrows are thought to result from the erosive effects of paired spiral eddies with their axes parallel to flow and with opposed senses of rotation. The furrows correspond to divergence zones where eddies direct flow down on to the bed, whilst the cuspate ridges lie beneath the convergence zones where flow components lift off from the bed.

'Gutter casts' are features that seem to occur preferentially in shallow marine settings where storm currents are typically the agent responsible. They differ from longitudinal furrows in being larger and separated from one another by areas of flat bedding surface rather than cuspate ridges (Figure 6). They are typically many centimetres wide and a few centimetres deep and they may be separated by flat sectors up to metres in width. Their fills sometimes carry a coarse lag in the base, often made up of fossil fragments. In plan view, they tend to be rather continuous, may be somewhat sinuous, and may split and rejoin, suggesting an anastomosing pattern. They probably result from rather sustained currents, possibly driven by wind or storm effects.

All the scours related to fluid scour have a strong orientation parallel to the current, which can be used to infer palaeoflow direction. With longitudinal scours without clear noses, it may be impossible to infer the sense of movement.

Figure 6 Lower bedding surface of a limestone bed from within a shallow marine interbedded limestone mudstone succession showing gutter casts. Ordovician, north west Greenland.

Tool Marks

These constitute a diverse suite of structures that are produced by the interaction of objects ('tools') carried by the flow with a soft cohesive substrate. The shape and scale of such structures vary with the nature of the tools and the way in which they impinge on the bed (Figure 7). Tools marks can generally be distinguished from structures produced by fluid scour by the fact that they tend to have sharp, often angular relief, reflecting the shape of the tool, compared with the much smoother shapes of fluid scour marks. The tools themselves are seldom seen associated with the tool marks that they created, and one can only imagine or infer what they may have been. They are most likely to have been pebbles, mud rip-up clasts, fossils, or wood fragments. In some cases, delicate relief on the marks can be related to features of the tool, such as ribbing on a shell.

Tools may interact with the bed in a variety of ways, and a loose terminology is applied to the results. Where tools remain in contact with the bed for some distance, they gouge 'grooves', usually with sharp margins and sometimes changing in form as the tool rotates slowly. Where the tools are in intermittent contact with the bed, a string of similar impact marks

Figure 7 A variety of tool marks on the base of a thin turbidite sandstone bed showing prod marks and bounce marks. The series of distinctive bounce marks towards the top of the slab is thought to have been made by a fish vertebra, unlike most tool marks where the nature of the tool is unknown. Oligocene, Polish Carpathians.

Figure 8 Chevron cast on the base of a turbidite sandstone. Ordovician, Kirkudbrightshire, Scotland.

with more or less regular spacing may form 'bounce marks'. These may be symmetrical or may have an asymmetry reflecting the differing angles of impact and rebound. Where tools make isolated impact with the bed, single impressions occur. These 'prod marks' commonly have a clear asymmetry, gently inclined on the upstream side, recording the low-angle approach trajectory, and steeper on the downstream end where the tool was lifted back into the flow.

Less common are 'chevron marks' where the tool appears to have been dragged across a rather viscous muddy substrate so that the sediment has been rucked into a series of chevron-like folds that face in a downstream direction (Figure 8).

Most tool marks are good palaeocurrent indicators and, in most cases, both direction and sense of movement can be deduced. Highly elongate forms, such as grooves and bounce mark sequences, give the best directional measure, whilst the asymmetry of prod marks provides the most reliable indication of sense of movement. It is often the case that a variety of forms occur together on the same surface and it is not uncommon for a range of directions to be present, suggesting that the current responsible changed direction whilst in the erosive mode.

Erosional Surface Forms

On present-day subaerial sediment surfaces, e.g., tidal flats, beaches, river beds, and desert flats, it is possible to find structures that record erosion by recent currents, both water and wind. Examples of these features also occur in the rock record, but they are less common than erosional sole marks because many are developed in sand, which is likely to be reworked by subsequent currents. Erosional forms are also detected and mapped on the seafloor by remote sensing techniques on both sandy and muddy substrates. Ancient small examples are seen in the rock record at outcrop, but some larger examples probably go undetected.

'Obstacle scours' occur around pebbles and shells on sandy river beds and on beaches. They are curved troughs that wrap around the upstream side of the obstacle and flare away downstream. They relate to the local acceleration of the current around the obstacle and the generation of a local eddy system. On stream beds, the sand may be rippled and the obstacle scour may, in effect, be a distortion of the ripple pattern. On beaches, the current responsible is the backwash of the waves and often they occur on an otherwise flat sediment surface.

'Wind ridges' occur where strong winds blow across damp sand as on a beach. As the sand dries out differentially, dry sand is set in motion by the wind, whilst damper patches retain some coherence and resist erosion. These will typically become streamlined as erosion goes on around them, producing ridges with blunt noses at their upwind ends and tails that flare away downwind. Rare examples are known in some ancient lake deposits where the surface was inundated and draped with finer sediment.

'Seafloor flutes and lineations' have been detected by remote sensing techniques, particularly side-scan sonar. They occur on both sandy and muddy seafloors and can result from both tidal currents and deep-sea turbidity currents. Lineations eroded in muddy seafloors may be many hundreds of metres in length and form spaced arrays. Large-scale flutes, which are

known from the surfaces of some submarine fans, are tens to hundreds of metres in length and seem particularly to be features of areas where large flows have spilled over from fan channels.

The recognition of ancient examples of such features requires exceptional exposure. The largest forms would commonly be categorized as channels. With extensive bedding surface exposure, large, flute-like forms (megaflutes) occur on the upper surfaces of sand units in turbidite sequences and are typically overlain by mud drapes and fills. It may well be the case that, where erosion was followed by the deposition of sand, the features usually go undetected.

Channel Forms

Channels occur in a wide range of settings as an integral part of the depositional process. In some cases, channels and their fills constitute only a small part of the succession; in other settings, the successions may be dominated by channel fills. Given good outcrop, the recognition of channels is often very straightforward, as an erosional surface, with significant relief, separating two discrete bodies of sediment, the overlying unit commonly being coarser grained than that below (Figure 9). The shapes of channel erosion surfaces are quite varied, ranging from strongly curved, concave-upwards forms to horizontal surfaces. The observed shape records the interaction of the active channel and its behaviour during its active life. Channels that maintain a stable position generate a cross-section that is very close to that of the active channel and the resultant sediment body is lenticular. Actively migrating channels generate an erosion surface with an extensive flat sector and steeper margins, so that the channel sediment body has a tabular shape. Channel stability reflects the energy of the flow within the channel and the stability of the material in the channel banks. With cohesive bank material, channels are less likely to migrate. For non-cohesive bank material, the greater tendency for migration means that channel margins are less likely to be seen in the rock record, and erosion surfaces have to be inferred from the concentration of larger clasts, both exotic and intraformational, in a lag conglomerate directly above the erosion surface. Where channel margins are cut into dominantly cohesive sediment, but with some interbedding of lithologies, it is quite common for the interbedding to be reflected in the morphology of the erosion surface. Stepped profiles and even overhangs may occur. These smaller features are often valuable for the measurement of channel trend directions, particularly where accompanied by sole marks, such as flutes.

Figure 9 Part of a channel margin within a turbidite succession. The stepped nature of the junction in part reflects the lithological differences in the underlying thin bedded succession. The thick beds of sand that make up the channel fill reflect the stronger currents that flowed through it. Namurian, North Derbyshire, England.

Other Erosion Surfaces

Many bedding surfaces have an element of erosion in their genesis, but hardly qualify as 'sedimentary structures' and will not be dealt with in detail. Marine transgressions may often be erosive in nature, and the landward advance of a shoreface may produce a horizontal and relatively flat surface (ravinement surface) recognized by a sharp upwards change from more nearshore to more offshore facies, possibly associated with a lag conglomerate. In aeolian settings, major bounding surfaces (supersurfaces) may be associated with erosion down to the water table and are recognized in some cases only on the basis of their wide extent.

Channel-like features may result from processes other than fluid scour, especially in finer grained sediments and particularly those deposited on subaqueous slopes. Instability, often due to rapid deposition, may give rise to failure and the initiation of slumps and slides. The surfaces over which such movements take place may have concave-upwards forms, especially in the up-slope slump scar area, and these can superficially resemble channels. Generally, the context and the associated sediments allow the differences to be recognized.

Other erosional forms result from the dissolution of lithified sediments, typically limestones, so that irregular palaeokarstic surfaces may be incorporated into the rock record.

Depositional Sedimentary Structures

J Collinson, John Collinson Consulting, Beech, UK

Introduction

Depositional sedimentary structures reflect closely the processes by which sediment was transported immediately prior to deposition, and therefore provide an important starting point for environmental interpretation through facies analysis (*see* **Sedimentary Environments:** Depositional Systems and Facies). Their interpretation requires an appreciation of the hydrodynamics or aerodynamics of fluid–sediment interactions.

Sediment Transport and Deposition

Excluding highly concentrated sediment–water mixtures, sediment is transported by fluid in two distinct ways. Finer grained material, commonly clay and silt, but sometimes including sand and coarser material, is carried along with the fluid in 'suspension', when particles are supported by the upwards component of turbulence. Coarser grained material tends to move in intermittent contact with the bed, once its critical boundary shear stress has been exceeded. This movement, referred to generally as 'bedload transport', takes place through rolling or, more commonly, bouncing of grains on the bed, a process called 'saltation'. At its most vigorous, saltation grades into suspension. Sand particles in saltation, on colliding with a bed of similar sand, set other grains in motion as their kinetic energy is dissipated, a process especially important in wind-blown transport.

Bedload Transport

Bedload transport in water results from unidirectional currents, wave action, and combinations of the two. Clearly, for waves to affect sediment movement, the bed has to be above wave base (i.e., within the depth range of the waves), and it is important in many settings to recognize the distinction between fair weather and storm wave base.

Suspension

Sediment is carried in suspension provided that the intensity of turbulence within the fluid remains high. A current that is underloaded with suspended sediment can take more material into suspension up to a certain critical capacity. Sediment is deposited when the level of turbulence can no longer support all the suspended grains. This usually occurs when the current decelerates, often as a result of flow expansion at a channel mouth, but also through the waning of a high-energy event, such as a storm or flood. Coarser particles, with higher settling velocities, fall from suspension first. Sedimentation is commonly accelerated in river mouth and estuarine settings where a freshwater suspension meets saline water and particles coagulate into larger flocs. Deposition from suspension occurs in many settings and produces a variety of types of bedding and lamination. 'Bedding' is used for units of centimetres or larger thickness, whilst 'lamination' is used for features at the scale of millimetres.

At coastal delta fronts, a floating plume of turbid freshwater floats over denser seawater and may extend many kilometres offshore before it disperses. In freshwater lakes, the reverse situation may apply, with denser turbid water hugging the lake floor as a density underflow. Such relatively sustained underflows contrast with more episodic underflow surges, which are features of deep marine settings. These turbidity currents carry a wide variety of grain sizes in suspension and the interaction of density contrast, down-slope movement, resultant turbulence, and

consequent sediment load leads to a phenomenon referred to as 'autosuspension'. Changes to the balance amongst the variables, mainly through changes in bottom gradient, lead to accelerations or decelerations and to phases of erosion and deposition, respectively.

Lamination in Fine-Grained Sediments

In settings in which low energy prevails, only the finest sediment, carried in suspension, settles as mud. If the bottom waters are well oxygenated, sediment will usually be disturbed by burrowing organisms and the depositional lamination destroyed. If the bottom waters are anaerobic, a fine depositional lamination may be preserved. In all cases, burial compaction flattens the original fabric and creates a foliation or lamination of later origin. Only where early cementation occurs, usually as concretions, is depositional and early postdepositional fabric and lamination preserved.

In areas of higher sediment supply, such as a coastal river mouth, lamination and bedding in sediments deposited from suspension often result from changes in river discharge. In marine settings, deposition from a floating turbid plume can give gradational thin bedding or lamination due to gradual changes in discharge or in the position of the plume. In lakes, where underflows are more common, bedding and lamination may be more sharply defined, particularly in proglacial settings where seasonal discharge variations are shown by varves (rhythmites; *see* **Sedimentary Environments:** Lake Processes and Deposits).

In certain tidal settings, particularly estuaries, where fine-grained suspended sediment occurs due to both river supply and erosion by waves and tidal currents, the deposition of mud is particularly associated with slack water periods between tidal flows. These occur four times a day in subtidal settings and twice a day in intertidal areas. High concentrations of suspended mud and the effects of flocculation cause the deposition of discrete 'mud drapes' within the space of a few hours. When associated with sand deposition, reflecting higher energy tidal flows, these help to create 'heterolithic facies', which are discussed below.

Aqueous Sandy Bedforms and their Internal Structures

Once sand or coarse silt begins to move under a unidirectional water current, the sediment surface takes on a succession of dynamic morphologies in response to changing current strength. These morphologies are termed 'bedforms', and their hydrodynamic significance and relationships to internal lamination in sands and sandstones are key elements in interpreting processes and environments of deposition.

Current Ripples and Ripple Lamination

When sand starts to move, the surface becomes covered by 'current ripples', small-scale, repetitive, asymmetrical bedforms, a few centimetres high and a few tens of centimetres in wavelength (Figure 1). Their dimensions scale with grain size rather than with the properties of the flow. Their asymmetrical profile parallel to flow has a steep 'lee side' facing downstream and a gently inclined 'stoss side' facing upstream. Soon after formation, current ripples have rather straight crest lines, orientated transverse to flow, but this pattern soon breaks down into more complex three-dimensional 'linguoid' geometries, whereby the ripples have strongly curved crest lines, usually convex downstream and with scour pits in front of gaps between adjacent ripples. These shapes are intimately related to the patterns of fluid turbulence over the ripples, with flow separation at the crests and downward-directed eddies converging to create lee-side scour pits. As an array of ripples moves downstream, sand is swept from the scour pits over downstream stoss sides and deposited on lee sides. Ripples and dunes (dealt with below) are together referred to as the 'lower flow regime' of bedload transport (Figure 2).

The deposition of sand on the lee sides of ripples leads to inclined lamination that records successive positions of the lee side. This cross-lamination is commonly defined by micas and other platy grains. It is preserved only when ripple migration takes place during vertical aggradation of the bed (Figure 3).

Figure 1 Small scale asymmetrical current ripples formed by a unidirectional flow from left to right. Gently inclined stoss sides are inclined upstream and steeper lee sides face downstream. Note the variability in the curvature of the crest lines. Tana River, Norway.

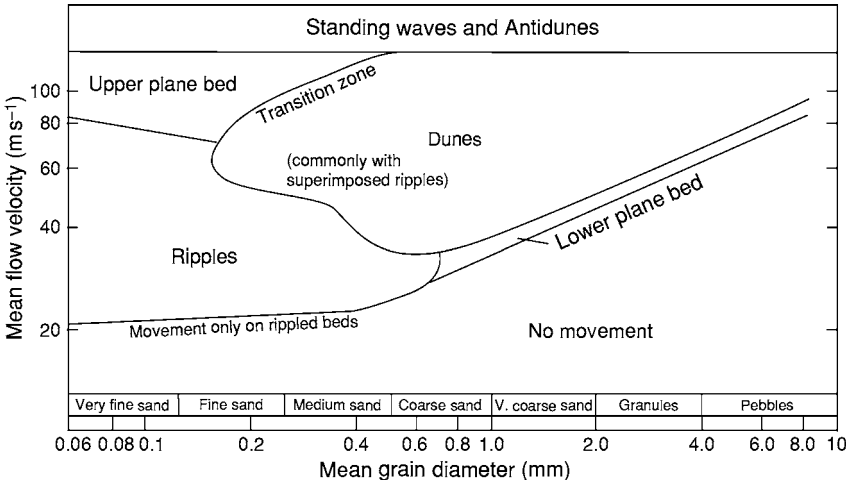

Figure 2 A plot of stream power vs. grain size showing the fields of occurrence of the main classes of bedform produced by unidirectional water flows.

Figure 3 Climbing ripple cross lamination in fine sand. The trajectories of the ripple crests reflect the balance between the rate of bed accretion and rate of ripple migration. Where the angle of climb exceeds that of the ripple stoss sides, stoss side lamination is preserved. Holocene terrace deposits, Tana Valley, Norway.

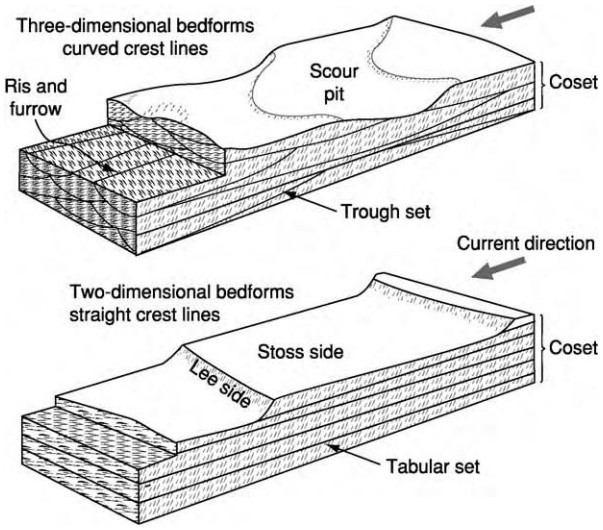

Figure 4 Block diagram to show the main types of three dimensional geometries of cross bedding and cross lamination and the terminologies used.

Where migration occurs without aggradation, lee-side scour removes the cross-laminated sand deposited by the preceding ripple. When aggradation occurs, the trajectory of the scour zone climbs downstream, allowing the partial preservation of cross-laminated sand. The angle of climb determines the extent of preservation, but, in many cases, the angle is not apparent because of the random component of erosion created by migrating scour pits. Where climb angles are high, due to high aggradation rates, the inclination of erosion surfaces between cross-laminated sets may be apparent, and the style is referred to as 'ripple drift' or 'climbing ripple lamination' (Figure 3). Where climb angles exceed the inclination of the stoss sides, stoss-side laminae are preserved with no erosion between sets.

In three dimensions, the geometry of ripple cross-lamination most commonly occurs as a series of intersecting troughs, each filled with curved cross-laminae that are concave both upwards and downstream (Figure 4). The troughs are the curved erosion surfaces cut by the migration of the scour pits and the laminae record their filling by the migration of the succeeding ripples. Usually, only the lower parts of lee-side laminae are preserved. In plan view, trough cross-lamination appears as a pattern of flow-parallel zones of curved laminae, known as 'rib and furrow', which is an important palaeocurrent indicator. Palaeocurrents are most accurately measured from the axes of the troughs. Rib and furrow is a more

common record of current ripples than the preservation of ripple forms on bedding surfaces. Where ripple forms are preserved, they are usually overlain by a drape of finer grained sediment due to a rapid reduction in current strength.

Dunes, Sand Waves, and Cross-Bedding

As current velocities increase above those appropriate for ripples, sand beds deform into larger bedforms, termed 'dunes' or 'sand waves', provided that the water is deep enough (Figure 2). These have a similar asymmetry to current ripples, although the wavelengths are greater, seldom less than 1 m and extending to many tens of metres. Heights are in tens of centimetres or even metres. There is a clear hydrodynamic distinction between ripples and dunes, illustrated by the superimposition of ripples on the larger forms under equilibrium conditions. Dunes, therefore, are not just large ripples. The orientations of superimposed ripples reflect the direction of flow close to the bed over and around the dunes, recording patterns of eddy separation and reattachment, especially those associated with scour pits.

Dunes and sand waves occur in a wide range of plan forms, from straight crested through highly three dimensional, and also span a wide range of height to length ratios (Figures 5 and 6). Steep, strongly three-dimensional forms are mainly a response to strong and relatively deep flows, whilst straight-crested or low-relief forms, which tend to lack scour pits, are responses to less strong or more shallow flows. The dimensions of dunes and sand waves reflect the properties of the flow, rather than the sediment. They seem particularly susceptible to changes in flow depth. However, it is quite difficult to interpret large bedforms in terms of flow parameters as they are commonly out of equilibrium with the prevailing current. Large volumes of sand must be moved to remould large forms and, in rivers where discharge varies quickly or in tidal settings, large-scale bedforms are often in a state of disequilibrium. In intertidal settings or on emergent river beds, larger bedforms are commonly modified by the process of emergence. Changing flow patterns over and around the forms and the action of waves both rework ripple patterns and reduce the angle of the lee-side slipfaces. In subtidal settings, sand waves often are present on the seabed where they are susceptible to semi-diurnal reversals of flow. Asymmetrical profiles may reflect quite a small asymmetry in strengths of ebb and flood tides.

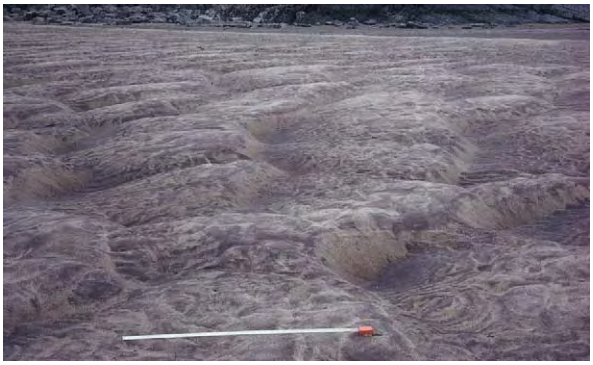

Figure 5 Small, three dimensional dunes with well developed scour pits in their lee side areas. Note how the superimposed ripples fan out to reflect the pattern of eddying over the dunes close to the bed. Note also the difference in scale of the dunes and the ripples. Tana River Delta, Norway.

Figure 6 A wide sandy braided bed of the Tana River, Norway, showing large, low relief sand wave bedforms. These examples have curved crest lines (convex downstream), superimposed ripples, and, locally, smaller dunes on their upper surfaces. Whilst their spacing is in hundreds of metres, the heights of their lee faces seldom exceed 1 m. The larger areas of sand, which separate the river into discrete channels, are compound bedforms or bars. Tana River Delta, Norway.

As with ripples, internal lamination produced by dune-scale bedforms is dominated by inclined lamination, generally referred to as 'cross-bedding' (Figure 7). The individual dipping laminae are termed 'foresets', whilst packages of foresets produced by the migration of individual dunes are 'sets'. Sets range in thickness from around 10 cm up to several metres, and foresets are generally defined by slight differences in grain size, related to avalanches of grains (grain flows) on the lee side and to fluctuating turbulence in that area. In vertical section, some foresets are straight with an angular basal contact (termed 'planar'), whilst others have a tangential or asymptotic contact. The sets fall into one of two classes depending on the shape of the set boundaries. Where these are broadly subparallel and flat-lying, the sets are described as 'tabular'. Where set boundaries are concave-upwards erosion surfaces, they compare, except in scale, with ripple cross-lamination, and the term 'trough cross-bedding' is used. The foresets of trough sets are predominantly concave upwards and tangential, whilst the foresets of

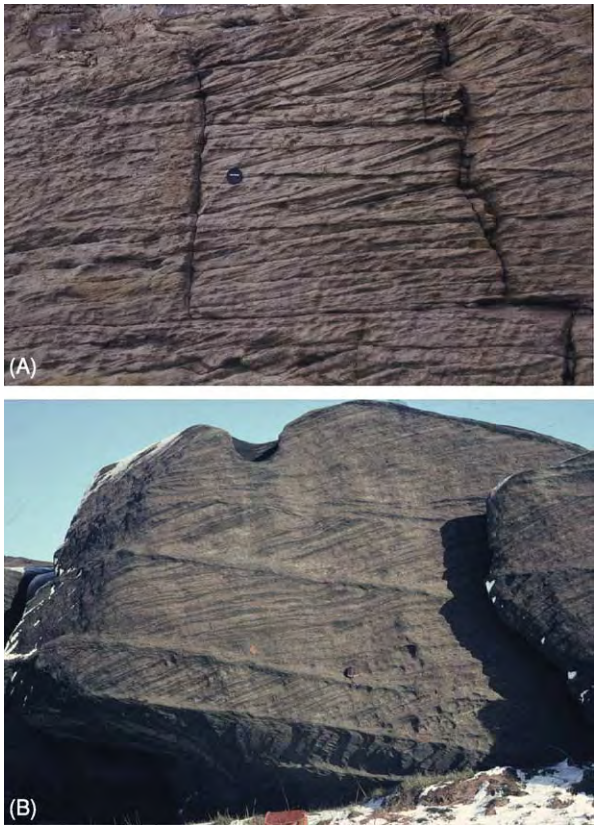

Figure 7 Examples of cross bedding in sandstones. (A) Coset of small sets with slightly asymptotic foresets. The bounding surfaces between sets are themselves inclined downstream, sug gesting deposition on the downstream side of a larger compound bar form. Westphalian, Northumberland, England. (B) Tabular sets with thin units of ripple lamination between sets. The foresets are essentially planar. Namurian, Staffordshire, England.

tabular sets vary in shape. This reflects the association between trough sets and lee-side scour pits and the fact that steep, three-dimensional dunes, which commonly have such pits, are associated with stronger currents. Tabular sets record the migration of dunes or sand waves without scour pits, probably with straight or only gently curved crest lines.

Changes in the shape of foresets along a set record changes in flow strength during the life of the bedform. They are a particular feature of tidal sediments and the deposits of rivers with large discharge variations. Wave action on emergence during the falling stage may create low-angle erosion surfaces, truncating the foresets. Succeeding foresets re-establish the higher angle dips above these 'reactivation surfaces' (Figure 8). Flow reversals in subtidal settings produce similar structures and tidal slack water can cause mud drapes to be interbedded with the foresets. In exceptional cases, the spacing of drapes can be interpreted in terms of spring-neap tidal cycles ('tidal bundles').

Figure 8 Reactivation surface within a tabular cross bedded set produced by the migration of a low relief sand wave. The discontinuity reflects modification of the lee side of the bedform during emergence during falling water discharge. Tana River, Norway.

Compound Bedforms and Bars

In many wide, sandy rivers, the large repetitive bedforms described above are organized into compound forms, which commonly appear to scale with the channel itself. Some of these features are attached to channel banks, whilst others are located in mid-channel. Some examples have a clear asymmetry to their stream-parallel profile with a slipface at the downstream end. In other cases, dunes descend a more gently inclined lee side. These compound features are commonly referred to as 'bars', of which there are many types. The important point, in terms of internal structure and its interpretation, is the relative movement directions of dunes and of the accretion of the bar. Where the bar advances downstream, in the same direction as the dunes, either a large, cross-bedded set will be present beneath smaller cross-beds, or the bounding surfaces between sets will be inclined downstream. Where bars move laterally as a result of dunes migrating along their flanks, bounding surfaces dip in a direction highly divergent from that of the cross-bedding (lateral accretion surfaces).

Upper Flow Regime Bedforms and Lamination

In situations in which water flow is very rapid and/or very shallow, saltating sand close to the bed moves continuously over an essentially flat surface. This phase of movement is known as 'plane bed transport' with the moving grain layer termed a 'traction carpet'. When the flow is particularly strong, the bed develops gentle undulations, forming ridges transverse to flow or three-dimensional domes. When this happens, the water surface also takes on a wave form which parallels that on the sediment surface. These undulations are 'standing waves' (Figure 9). Where the standing waves on the water

surface grow beyond a critical height, they move rapidly upstream and break, a case described as 'antidunes'. Breaking antidunes temporarily wipe out the undulations and the cycle of growth and breaking is repeated. This whole family of transport mechanisms is referred to as 'upper flow regime' transport.

Standing waves and antidunes are highly ephemeral features and preservation of their deposits is rare. However, where plane bed conditions coincide with bed aggradation, distinctive parallel and horizontal lamination forms. This may be accentuated by mica and gives rise to flaggy sandstones that split easily parallel to bedding. The bedding surfaces themselves show a distinctive lineation ('parting lineation') (Figure 10) parallel to the current, which is a useful palaeocurrent indicator. Rarely, parting lineation occurs on the bedding surfaces of undulatory lamination, indicating the chance preservation of standing waves.

Figure 9 Standing waves on the surface of a shallow, rapidly flowing stream. In phase undulations on the underlying, rapidly moving sand bed may produce undulating lamination with low preservation potential.

Figure 10 Upper bedding surface of parallel laminated sand stone showing a clear parting lineation or primary current linea tion. This lies parallel to the direction of the shallow, rapid flow that produced it. Middle Jurassic, Yorkshire Coast, England.

Wave Ripples and their Lamination

The to-and-fro movement of water associated with waves is able to move sediment, both on its own and in conjunction with unidirectional currents. Sand moved by waves is readily moulded into ripples, which are distinguished in several ways from current ripples. Wave ripples, most distinctively, have straight crests, which may be rounded or quite cuspate in profile (Figure 11). Their profile is also commonly symmetrical, although not always so. Where the strength of the wave surge is stronger in one direction than in the other, or where waves coexist with currents, asymmetry results. Wave ripples vary quite widely in spacing, depending on the grain size, the strength of the waves, and the water depth. Less common are ripples produced by coexisting wave trains with differing propagation directions. These show interference patterns, reflecting the wave sets responsible.

As well as producing ripples in their own right, waves also modify pre-existing bedforms, particularly under emergent or near-emergent conditions. Wave-modified current ripples are particularly common on tidal flats.

Internally, wave ripples produce small-scale cross-lamination which is not always easy to distinguish from that of current ripples. Interfingering bundles of laminae with opposed dips, draping laminae over symmetrical ripple crests, and discordances between internal lamination and ripple forms all suggest wave influence, but many cases are difficult to fully diagnose (Figure 12).

As well as producing ripples, waves also create plane bed conditions. This occurs most readily in the swash zone of beaches where the run-up and backwash of waves produce the shallow, rapid flows

Figure 11 Small, straight crested wave ripples with symmet rical, rather rounded crest lines. The straightness of the crest lines and the tuning fork junctions along the crests are most characteristic of wave influence. Tana River Delta, Norway.

This assemblage of hummocky and swaley cross stratification is typical of deposition from storms under conditions of coexisting, intense current and wave activity. Upper Jurassic, Dorset, England.

needed. Parallel lamination and parting lineations result if the sand is preserved.

Wave–Current Interaction

During storms, shallow-water shelf or nearshore areas are commonly subjected to energy regimes involving a combination of waves and currents. Under such conditions, sand falling from suspension may be reworked into low-relief, rounded forms and may be re-eroded by higher energy surges. The result is an undulatory lamination, characterized by gentle convex-upwards patterns and gentle scours. Where the convex-upwards laminae dominate, the structure is called 'hummocky cross-stratification', and where the scours dominate, it is termed 'swaley cross-stratification' (Figure 13).

Heterolithic Lamination

In settings in which energy levels fluctuate and in which there is a significant amount of sediment in suspension, it is common for mixed sand–mud sediments to be deposited. These record the alternation of suspended and bedload sediment deposition and are a particular, although not exclusive, feature of tidal settings. The sandy components are often ripple laminated with ripple profiles commonly preserved, so that current and wave forms can be distinguished. Collectively, these interlaminated sediments are termed 'heterolithic' (Figure 14) and are subdivided using the proportions of sandy and muddy components. Where mud dominates and sand forms isolated ripple lenses, the term 'lenticular bedding' is applied, whilst ripple-laminated sand with discrete mud drapes is called 'flaser bedding'. More or less equal components are referred to as 'wavy bedding'. Some confusion surrounds the application of these terms. Laminae rich in mica and carbonaceous debris in normal ripple cross-laminated sand can look superficially like flaser bedding, but the term is best reserved for cases with a clear separation of sand and mud.

Aeolian Bedforms and Internal Bedding

Wind, blowing over dry sand, initiates movement in much the same way as water. Above a certain critical velocity or shear stress, grains begin to move as bedload. However, in comparison with water, wind moves a much narrower range of grain sizes in this way. The buoyant effect of water is much greater than that of air and, in addition, the viscosity of water dampens collision impacts between grains in saltation. The result is that sands moved by air tend to be very well sorted and also well rounded. The first bedforms to develop on dry sand are ripples. These have low relief compared with aqueous current

ripples and are less clearly asymmetrical. They are commonly straight crested with the bifurcation of crest lines.

The vigorous saltation leads to grains following asymmetrical trajectories: a steep uplift from the bed, and a lower angle approach and impact. The impact throws other grains into motion, but the extent of this depends on the inclination of the bed at the point of impact. If the bed slopes upwind, the impact is steep and energy is dissipated strongly into grains near the impact point, throwing some into saltation and advancing others by a process of creep. If the bed slopes downwind, energy is dissipated more gently and grains accumulate. Wind ripples reflect this behaviour and their wavelength scales to the saltation path length and, hence, to the wind strength. Where wind blows dry sand across a surface that is immobile, such as a rock surface, a gravel bed, or a damp surface, wind ripples may be widely spaced and may begin to cluster together into larger forms that are incipient dunes. Where the surface is damp, saltating grains may adhere on impact through surface tension and patterns of wind 'adhesion ripples' or 'adhesion warts' may form. These irregular warty forms have steeper sides pointing upwind. All wind ripples have quite a low preservation potential, but examples do occur in the rock record. Wind ripples commonly produce subparallel lamination, 'pinstripe' lamination with inverse grading, and rare cross-lamination. It is an important component in the cross-bedding produced by aeolian dunes.

Vigorous wind transport commonly leads to the development of larger bedforms, 'aeolian dunes' (*see* **Sedimentary Processes:** Aeolian Processes), which occur in isolation on hard substrates or as parts of larger accumulations of sand. Dunes vary greatly in both scale and shape, and it is quite common for dunes of several scales to occur superimposed upon one another. An important distinction is between dunes with their own slipfaces and those without such surfaces. Slipfaces occur downwind of crest lines where sand accumulates through grain flow avalanches. Such processes commonly occur in conjunction with grainfall, whereby grains are thrown over the dune crest and accumulate on the lee side. Where grainfall dominates, the inclination of the surfaces may be lower and reworking by wind ripples may occur, particularly in the lower, more gently inclined parts of the dunes ('plinths').

Where sand supply is insufficient for the substrate to be fully covered, 'barchan dunes' or, more rarely, 'linear (seif) dunes' occur. In sand seas, a variety of more complex forms occurs. These include transverse dunes, barchanoid forms, and star-shaped dunes. The largest forms, termed 'draa', commonly have superimposed smaller dunes, which leads to complex morphologies. The size of the largest forms means that they change shape only over long periods of time and thus reflect a wind regime rather than a particular wind episode. Some are out of phase with the current regime as a result of lag effects.

Internally, dune sands show complex cross-bedding at scales up to many metres thick. The inclined laminae are commonly well defined and it may be possible to differentiate grainfall, grain-flow and wind-ripple laminae. Wind-ripple laminae generally occur in more gently inclined intervals, whilst grain flow is commonly close to the angle of rest (*ca*. 30°). Aeolian dune cross-bedding is characterized by discordances or bounding surfaces at several scales. Individual cross-bedded sets are separated from one another by erosion surfaces, and internally they may also be punctuated by low-angle erosion surfaces similar to the reactivation surfaces of aqueous cross-beds. These record the complexity of the wind regime whereby the lee sides of dunes become sites of erosion during particular wind episodes. They may also result from the migration of dunes over slipfaceless draas or the oblique migration of scour pits along the flanks of dunes.

Structureless Sand and Sandstone

Not all sand and sandstone has visible internal lamination. This happens for several reasons. First, it may have been deposited in that way. The dumping of sediment from suspension from, for example, a decelerating current, may have been so rapid that there was no time for the sand to be reworked into bedforms and laminae. On the other hand, sand that was initially laminated may have lost its lamination through later remobilization, perhaps due to liquefaction. Finally, lamination may be lost through the activities of burrowing organisms, which have the ability to totally homogenize laminated sediments (*see* **Trace Fossils**).

Decelerating Flows and the Bouma Sequence

Many sandstone beds in interbedded sandstone–mudstone successions show an internal vertical sequence of lamination types that are diagnostic of decelerating flows. The sandstones are sharp based and may have erosional sole marks (*see* **Sedimentary Processes:** Erosional Sedimentary Structures). Above their bases, they show one or more intervals of five different lamination types that occur in a constant relative order even though they are rarely all present in the same bed. These five types are: A, structureless

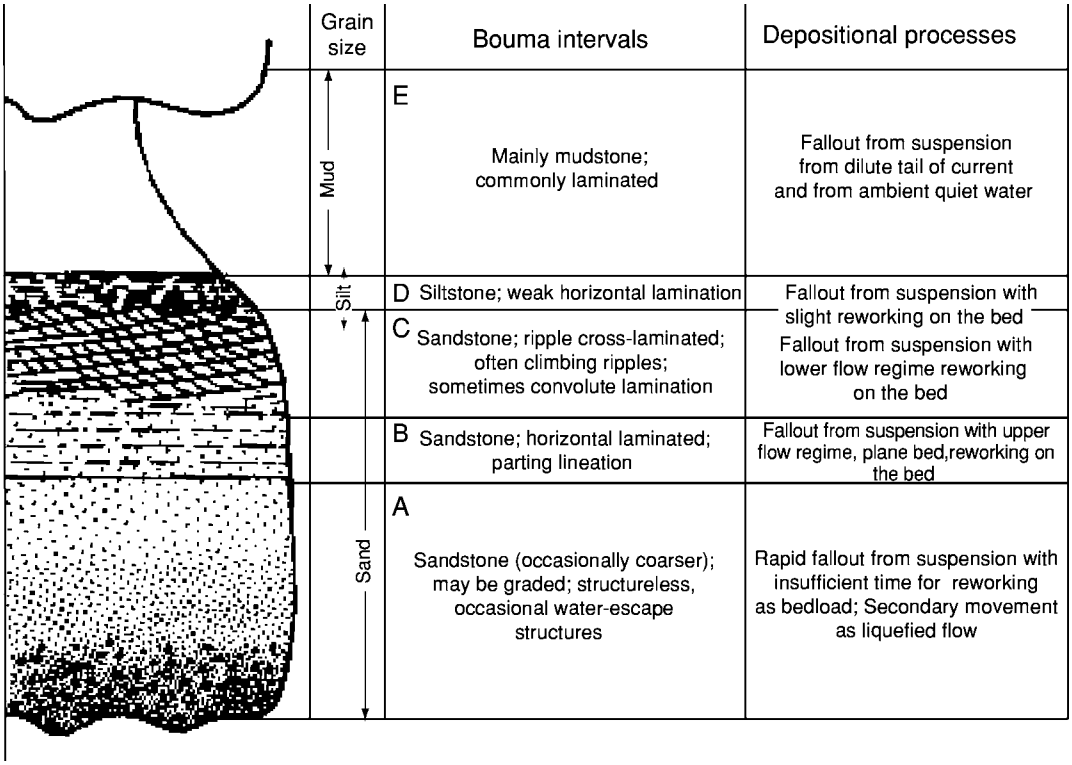

Figure 15 A schematic profile through a turbidite sandstone bed showing a complete sequence of Bouma intervals and their hydrodynamic interpretation.

(commonly graded) sandstone; B, parallel laminated sandstone; C, ripple cross-laminated sandstone; D, horizontally laminated (commonly silty) sandstone; E, mudstone. The complete succession of lamination types is known as the 'Bouma sequence' (Figure 15). The A interval records rapid deposition from suspension, with graded bedding reflecting sorting within the flow of a mixed grain size population. The B interval records upper flow regime plane bed transport, whilst the C interval records ripples moving in the lower flow regime. Climbing ripple lamination is quite common, recording rapid rates of bed aggradation, and convolute lamination may also result from rapid deposition. The D interval, often poorly displayed in weathered exposures, records fallout from suspension with weak reworking on the bed, whilst the E interval grades into the background sedimentation from suspension.

The overall succession, however complete or incomplete, records an episodic current, possibly erosional in its early stages, and progressively decelerating thereafter. Most commonly, the Bouma sequence is associated with deep-water settings where the episodic flows are turbidity currents (*see* **Sedimentary Processes:** Particle-Driven Subaqueous Gravity Processes), but similar decelerating flows occur in shallow-water settings of floodplains, shallow lagoons, and lakes due to crevassing of river banks during floods. Similar sands also occur in shallow marine settings as a result of storms, although the Bouma sequence may then be modified to include hummocky cross-stratification and wave ripples.

Figure 16 Coarse fluvial gravels showing clear pebble imbrication. The flat surfaces of the clasts dip upstream, indicating that flow, in this case, was from left to right. Holocene, Pyrenees, Spain.

Gravel Forms and Fabric

Whilst the preceding section deals mainly with sands and finer grained sediments, powerful water currents also transport gravel, and its deposition can lead to distinctive structures and fabrics (*see* **Sedimentary**

Rocks: Rudaceous Rocks). Where gravel moves as a traction load, on a stream bed or on a beach, it may become lodged on the bed, particularly where clasts land amongst similar sized clasts. If the clasts are flattened, they will tend to be deposited in an imbricated fabric with an upstream dip. This is the most stable position beneath the prevailing flow and, when seen in the rock record, 'imbrication' (**Figure 16**) is a valuable palaeocurrent indicator.

Gravel is also deposited in bars on river beds and these commonly have slipfaces at their downstream ends. Cross-bedding results from the avalanching that takes place there. Depending on the overall sediment population, sandy and gravel-rich foresets may be intermixed.

Post-Depositional Sedimentary Structures

J Collinson, John Collinson Consulting, Beech, UK

Introduction

Primary sedimentary structures and lamination in clastic sediments result from deposition under different hydrodynamic regimes. However, there are other secondary structures, which originate during or very soon after deposition as a result of sediment instability, extreme climatic effects, or chemical changes during burial. The last group involves the precipitation of mineral cements within the sediment. Some of the early physical structures deform primary depositional structures and lamination, whilst others originate entirely as a result of the deformation processes. Those associated with cementation often help to preserve original lamination and other delicate features, particularly in fine-grained sediment, that would otherwise have been destroyed by compaction.

Soft-Sediment Deformation Processes

Early formed soft-sediment deformation structures are typically features of sandstones and finer sediment. Deformation in gravels and conglomerates is rare, except in glacial and periglacial settings, or where there is abundant muddy matrix. The structures have an entirely physical origin and must be distinguished from organic deformation structures, such as burrows and trails of animals and disturbance by plant roots (*see* **Trace Fossils**). In addition, tectonic structures are often geometrically identical with syndepositional structures, and the boundaries between widespread tectonic deformation and more local, sediment-induced deformation may be blurred.

Deformation structures are quite difficult to classify as they result from rather diverse processes. However, all attempts at interpreting physical soft-sediment deformation structures must consider two discrete questions. First, why did the sediment lose its strength and become susceptible to deformation? Second, what forces operated on the weakened sediment to cause the deformation?

In most cases, the sediment loses frictional shear strength and behaves, briefly, as a plastic or a fluid. In other cases, a loss of tensile strength can lead to brittle deformation as soft-sediment faults. Loss of frictional shear strength may result in total remobilization of the sediment and transformation into a gravitational

mass movement, leading to a phase of resedimentation. However, this article deals only with situations in which the loss of strength was short-lived and the sediment regained its strength before it moved downslope, thus preserving structures that record more or less *in situ* deformation.

Deformation occurs within sediment when intergranular forces are unable to resist applied stresses, which are usually, but not exclusively, gravitational. The shear strength of sediment is normally expressed by the equation:

$$\tau = C + (\sigma - p)\tan\varphi$$

where τ is the shear strength, C is the grain cohesion, σ is the pressure normal to shear, p is the excess pore fluid pressure, and φ is the angle of internal friction. This means that sediment will fail when the applied stress exceeds τ; such a condition will be favoured by a lower cohesive strength C, by changes in grain packing to reduce $\tan\varphi$, or by an increase in pore fluid pressure p beyond a certain critical value. Such conditions can occur for several reasons, discussed below. Strain, when it occurs, may be isotropic, dispersed throughout the body of sediment, or concentrated on discrete slip surfaces.

Loss of Strength

In the shear strength equation set out above, the presence of fine-grained, especially muddy sediment tends to increase the role of the cohesive strength, which is largely a function of grain size, whilst in better sorted, mud-free sediment, frictional forces dominate. In both cohesive and non-cohesive sediments, high pore water pressure commonly leads to a loss of shear strength, but this condition can have different causes and durations in different sediments.

In fine-grained, muddy sediments, excess pore fluid pressure is often caused by relatively rapid deposition. Low permeability inhibits the escape of pore water and hence retards sediment compaction, giving overpressured conditions. In addition, the decay of organic matter within the sediment can generate gases, which, if unable to escape, also contribute to pore pressure. Such overpressured conditions occur close to the sediment surface where highly mobile mud may be susceptible to deformation or flowage. They also develop at a larger scale, and in a longer time frame, within thick piles of sediment, such as those deposited by prograding deltas or deltaic margins (e.g., Mississippi, Niger). In such cases, increasing pore water pressure with burial may eventually exceed lithostatic pressure, leading to failure. This results in plastic flowage of a thick, overpressured layer. These movements set up extensional stresses in the overburden, which can lead to the development of discrete slip surfaces that cut up-section as listric faults when the tensile strength of the sediments is exceeded. Such surfaces may also become the bounding surfaces of sediment gravity slides. These conditions, and the resultant movements, develop and persist over long intervals of time; in the case of the largest deltaic margins, over millions of years.

Rapidly deposited sands, lacking significant fine-grained sediment, commonly have rather loose grain packing. They are particularly susceptible to shock, such as by an earthquake, heavy wave action, further rapid deposition, or a sudden rise in water level. Shock breaks grain contacts and induces tighter packing and, as a result, excess pore water is present, raising the pore water pressure and causing temporary liquefaction, which will last until the extra pore water escapes. In the case of sands, the high permeability usually means that liquefaction is short-lived. Whilst liquefied, the sediment–water mixture deforms readily as a Newtonian fluid in response to gravitational and other applied stresses. As pore fluid escapes, usually upwards to the sediment surface, grain contacts are re-established and a rising front of reconsolidation 'freezes' the deformed sediment. Deformation is usually identified through the distortion of depositional lamination but, with extreme or sustained liquefaction and deformation, depositional lamination is totally obliterated and structureless sand or slurried textures are produced. The upwards movement of escaping pore water may also create deformation, both by distorting depositional laminae and by creating new vertical structures, such as dishes, pipes, and sheets, within which sediment–water mixtures move as fluidized flows.

Deforming Forces

Virtually all the forces that act upon sediment weakened by the above processes are gravitational. These can be divided into two major classes: a down-slope component of gravity and the action of gravity on inverted density gradients. In addition, shear at the sediment surface due to flowing water or ice, or to sediment gravity flows, may also deform the sediment.

The down-slope gravitational component may be sufficient to overcome the cohesive strength of muddy sediment on a slope. This can lead to the detachment of a slab of sediment on a basal shear surface and to internal deformation within the moving layer. The style of deformation varies depending upon the position within the moving sheet. Stretching, particularly at the up-slope end, may lead to tensile failure and to the development of brittle extensional structures, whilst compression, commonly in a down-slope setting, causes plastic folds. These styles of deformation are associated with a family of mass

movements dealt with in detail elsewhere (*see* **Sedimentary Processes:** Particle-Driven Subaqueous Gravity Processes). Also partly driven by down-slope gravitational components are sedimentary growth faults. These are related to failures in deeply buried overpressured muds. Extension on the faults is also driven by lateral flowage of these muds due to vertical loading by the overlying sediment pile.

Density inversions occur as a result of both depositional processes and the early loss of pore water. A sand layer, deposited on mud, will commonly have a higher density than the mud and, if the mud is weak, the instability may lead to loading of sand into the mud. Where the sand is of uneven thickness, as with ripple lenses or erosional sole marks, loading may be concentrated where the sand is thickest. Extreme cases of loading show detached balls of sand, usually encased in slurried mud or silt: so-called ball and pillow structures.

Within liquefied sand layers, which commonly result from shock, patterns of density inversion may be more subtle. Internal depositional lamination may be contorted in convolute lamination, some of which reflects the upward escape of water or low-density sediment–water mixtures. Very rapidly deposited sands may lack depositional lamination and experience liquefaction during the depositional process. The dewatering of such sands and the elutriation of fines by escaping water can produce subtle features, such as dish structures and water-escape pillars and pipes.

Deeper burial and associated differential compaction lead to the deformation of larger scale depositional geometries. The cross-sections of channel sand bodies, in particular, are susceptible to change from planar-convex forms to concavo-convex patterns where encased in muds. Where channel sands are encased in mud, as in some deep-water depositional settings, dewatering of the muds during burial can lead to high pore water pressures in the sands. This can eventually lead to rupture of the mud seal and to the injection of liquefied sands into the muds as sills and dykes. When such processes occur near the sediment surface, liquefied sand may be extruded as slurry flows or as sand volcanoes.

Where sands are deposited in large bedforms, such as dunes and sand waves, they may be liquefied through rapid deposition on the lee slope. If this happens whilst the current is still active, the cross-bedded sands, developed by lee-side deposition, may be sheared and the foresets dragged into folds, giving overturned cross-bedding.

The movement of ice over unconsolidated sediment also generates large-scale and intense deformation. This occurs near the front of a glacier, where glacial advance operates as a bulldozer to fold and thrust proglacial deposits. In addition, the basal layers of a mobile glacier may be rich in sediment. Shearing across the basal layers can lead to intense deformation, although the rheology mainly involves plastic deformation of ice rather than sediment liquefaction or cohesion.

Soft-Sediment Deformation Structures

This section deals with the descriptive aspects of soft-sediment deformation and relates the structures to the deforming processes. The structures themselves do not fall naturally into well-defined classes, but Figure 1 shows a scheme which relates all soft-sediment structures to processes. This diagram illustrates the possible interactions between different causes of a loss of strength and deforming forces, and shows that processes are gradational with tectonic deformation and with resedimentation. It also shows the wide range of scales across which deformation occurs, from microloading to growth faults at the scale of continental slopes, and highlights the differences in timing and duration of deformation. Structures formed during deposition, such as overturned cross-bedding, contrast with structures that require significant later burial, such as growth faults. Commonly occurring deformation structures are described below, in order of increasing scale, but moderated by considerations of process.

Load Casts and Pseudonodules

These usually occur at the interface between a mud layer and an overlying sand layer. Downward-facing bulbous load casts of sand are separated by upward-pointing flame structures of mud (Figure 2). Some occur on otherwise flat bedding surfaces, whilst others accentuate erosional or depositional irregularities. In extreme cases, sand may be detached from its source bed and occur as isolated load balls, or pseudonodules, within highly disturbed muds or silts, a features sometimes referred to as a 'ball and pillow' structure. Internal lamination within both sand and mud is highly contorted. Loading is caused by gravity acting on unstable density stratification where the sand layer is denser than the muds and where both layers are weakened by excess pore fluid.

Convolute Lamination

This commonly occurs within sands or silts and involves the distortion of depositional lamination by folding of variable intensity (Figure 3). In some cases, the folding is chaotic, whilst in others upward movement of escaping water has dragged lamination into upright folds. Cuspate folds with sharp anticlines and

more rounded synclines are typical. In many cases, depositional lamination can still be identified, commonly cross-bedding or cross-lamination. The good sorting and high porosities of aeolian sands make them particularly susceptible to liquefaction when the water table rises rapidly through them, giving convolute lamination on a large scale. Convolute lamination is common in turbidite sandstones, often

Figure 3 Convolute bedding developed in coarse cross bedded fluvial sandstones as a result of the sediment experiencing a short lived period of liquefaction shortly after deposition. Namurian, Yorkshire, England.

associated with the ripple laminated (Bouma C) interval (*see* **Sedimentary Processes:** Depositional Sedimentary Structures; Deep Water Processes and Deposits).

All examples reflect liquefaction of the sand, which can happen for a variety of reasons, including seismic shock, rapid sedimentation, breaking waves, or a shift in water table. Where seismic shock caused liquefaction, deformed layers may be very widespread and have stratigraphical significance. Upward escape of excess pore water, internal density inversions, and down-slope components of gravity may all contribute to deformation. Dewatering leads to reconsolidation of the sediment from the bottom up, 'freezing' the deforming laminae. Protracted liquefaction may lead to total homogenization.

Overturned Cross-Bedding

This is a special case of convolute lamination in which liquefaction occurred in an actively migrating bedform (Figure 4). Current shear on the sediment–water interface dragged the liquefied sand in a down-current direction in an essentially laminar style. An upward-migrating front of reconsolidation allowed higher parts of the sediment to be sheared longer, giving down-current-facing recumbent folds.

Figure 4 Overturned cross bedding in two small sets within a shallow marine sandstone. This was caused by ongoing bed shear by a current during a short lived loss of strength. The deformed sand was progressively 'frozen' as a front of reconsoli dation moved upwards through the sediment. Late Precambrian, north east Greenland.

Dish and Pillar Structures

These are most common in thick, otherwise massive sands and result from dewatering following rapid

Figure 5 A thick bed of sandstone in a turbidite setting showing intense development of dish structures due to rapid escape of pore water shortly after rapid deposition. Eocene, Fuenterrabia, Spain.

deposition. Dish and pillar structures are direct products of dewatering and are not distortions of pre-existing lamination. Dish structures are thin concave-upward, subhorizontal zones of slight clay enrichment produced by local filtering out of the elutriated fines (Figure 5). Their upturned edges merge with pillar structures, which are vertical conduits of water escape and record fluidized or near-fluidized conditions.

Sand Injection Structures

Where a sand body is encased in mud and progressively buried, compaction and dewatering of the muds can lead to overpressure in the sands. If the fluid pressure exceeds the tensile strength of the overlying mud, rupturing occurs and complex networks of dykes and sills of liquefied sand are intruded into the muds. This appears to be quite common in subsurface channel sand bodies in deep-water and slope settings, although outcrop examples are rare.

Small-scale injection dykes occur in mudstones of interbedded sandstone and mudstone successions. These may be folded ptygmatically because of differential compaction. Sand within dykes is typically structureless, although some examples show foliation parallel with dyke margins. Remobilized sands are increasingly being recognized as important petroleum reservoirs in the North Sea and elsewhere in the world.

Sand Volcanoes and Extruded Sheets

Sometimes upward-intruding liquefied sand, both dykes and pipes, penetrates to the free sediment surface where the sand is extruded. Where the escape conduits are pipes, sand volcanoes form, at scales from a few centimetres to a few metres (Figure 6). If the intrusions are dykes, fissure extrusion occurs and liquefied sand may flow as sheets before dewatering and 'freezing'. Where sand dykes penetrate muddy debris flows, extruded sand may be interfolded with the upper levels of the debris flow.

Mud Diapirs

Overpressure develops where muds are buried quite rapidly, as in a prograding delta. The resultant loss of strength and the significant overburden lead to both vertical and horizontal flowage of the muds. Where the overlying sediment is denser than the mud, as in an upward-coarsening deltaic succession, mud may rise vertically as a diapir or mudlump, pushing aside or penetrating mouth bar sands. In the Mississippi delta, mudlumps rise to sea-level and create short-lived islands offshore from distributary mouths. Mud diapirism may lead to great variability in the thickness of mouth bar sands, which thicken into withdrawal synclines between diapirs (Figure 7).

Horizontal flowage of overpressured muds leads to the extrusion of muds at the base of the prograding slope as imbricate thrusts and folds. The same motion is partly responsible for extensional stresses that drive extensional sedimentary growth faults in deltaic successions. Mud diapirs are widespread in Tertiary deltas around the world and may help to trap petroleum.

Slumps and Slides

Gravitational body forces acting on sediments lying on a slope lead to slumps and slides when cohesive (plastic) and tensile (brittle) strengths are exceeded. In both types, shearing is concentrated on discrete basal surfaces. They differ principally in their internal deformation. Slides are largely undeformed, but may have internal faults, whilst slumps show plastic folding. The two styles may coexist in the same deformed unit. The fold orientation may indicate palaeoslope direction, but analysis must be carried out with caution. Gravitational mass movements are dealt with more fully in (*see* **Sedimentary Processes:** Particle-Driven Subaqueous Gravity Processes).

Figure 6 Sand volcanoes on top of a slump sheet. Dewatering of the slump led to rapid upwards injection of a sand slurry which was extruded at a point vent to give the volcano. Namurian, County Clare, Ireland.

Figure 7 Mud diapir penetrating delta front mouth bar sands. Overpressuring of the buried muds led to a loss of strength which, combined with a density inversion, led to the upwards flow of mud. Namurian, County Clare, Ireland.

Sedimentary Growth Faults

These occur in deltaic successions. They are large-scale features and require exceptional exposures to be identified at outcrop (Figure 8). In small exposures, they may be confused with later tectonic faults. They are caused by shear failure at discrete dislocations within the sedimentary pile, and they commonly occur as listric surfaces that sole out on a basal '*décollement*'. In small examples, within a single progradational unit, the basal surface may be within particularly fine-grained mudstone directly above a basal flooding surface. In larger examples, penetrating several progradational units, the *décollement* may be within a thick interval of overpressured muds, whose lateral flowage towards the free surface slope combines with gravitational forces on the hanging wall block to drive that block down-slope. Growth faults are characterized by slow and continual movement

Figure 8 Small, synsedimentary growth fault within deltaic sediment. Note the thickening of sands into the hanging wall of the fault and the roll over within these sands. The synsedimentary nature of the fault is shown by the fact that the uppermost beds pass over the fault without disturbance. Namurian, County Clare, Ireland.

and are aided by progressive sediment loading. Their hanging wall areas act as local depocentres in which thickened delta-front sediments are deposited and preserved. Continued progradation of individual deltas or of the continental slope causes the active faulting to shift progressively basinwards. Large growth faults are important traps for petroleum in deltas such as the Mississippi and the Niger.

Climatically Induced Structures

In addition to the soft-sediment structures described above, in which a temporary loss of strength causes the disturbance, there are some rather diverse structures which result from climatic effects.

Desiccation and Other Cracks

When surface layers of mud or silt dry out, they contract and create isotropic horizontal tension. If this exceeds the tensile strength of the mud, polygonal (commonly hexagonal) cracks develop which may be filled with wind-blown or water-lain sand (Figure 9). The dimensions of the polygons are a function of the mud layer thickness, and several scales may coexist. Subaqueous shrinkage (synaeresis) of surface mud layers also leads to cracks, although these often form less regular patterns. They are thought to result from volume changes of clays within the surface layer. Synaeresis cracks may commonly be differentiated from subaerial desiccation cracks because they are infilled with mud, not sand. Large-scale polygonal cracks also develop through protracted freeze–thaw processes in periglacial settings.

Figure 9 Desiccation cracks on an upper bedding surface in ephemeral lacustrine sediments. Carboniferous, New Brunswick, Canada.

Evaporite Pseudomorphs

Evaporation of bodies of saline water leads to saturated solutions and to the precipitation of minerals on the floor of the lake or lagoon. If saturated conditions persist, large, euhedral crystals may grow at or just below the muddy sediment surface. When a subsequent flood or storm introduces both fresher water and coarse sediment, the crystals may be dissolved and their forms buried and cast by the coarser material. The bases of sandstone interbeds in playa lake sequences are often decorated by cubic pseudomorphs of halite, commonly with hopper faces (Figure 10), whilst in marine or lagoonal settings, gypsum pseudomorphs may occur.

Figure 10 Halite pseudomorphs on the base of a fine grained sandstone bed. Triassic, Cheshire, England.

Raindrop Impressions

These occur as small circular or elliptical depressions on the upper surfaces of beds of fine sediment. They record the impact of raindrops or hailstones and their preservation depends on the cohesive strength of the sediment. They are quite often associated with desiccation cracks.

Periglacial Deformation

This results mainly from the expansion of water on freezing and the contraction of frozen sediment during extreme freezing. This takes place on a seasonal basis in an active layer close to the surface and creates metre-scale patterns of polygonal cracks. Open cracks are filled with wind-blown sediment and material collapsing from the crack sides during periods of thaw. Expansion on freezing leads to the pushing up of ramparts on the edges of the cracks. In vertical section, frost polygons appear as sharply tapering wedges with complex, poly-phase fills. Convolute

bedding also occurs in periglacial sediment due to freeze–thaw action termed cryoturbation.

Concretions

During the burial of sediment, pore water may precipitate minerals in the pore spaces. In some cases, this is as pervasive cement, but, in other cases, it occurs in discrete patches around nuclei (Figure 11). In some cases, these cemented concretions or nodules occur apparently at random, whilst others follow bedding or are nucleated on obvious earlier inhomogeneities, such as fossils, burrows, or root traces. Some concretions, which form at shallow burial depths in fine-grained sediment, predate major compaction and, by resisting compaction, help to preserve lamination and delicate fossils that would otherwise be flattened beyond recognition. Other early concretions (e.g., calcrete nodules) are an integral part of soil textures and are discussed elsewhere (*see* **Soils:** Modern; Palaeosols). Most concretions occur during deeper burial and many have distinctive internal features. 'Septarian nodules' have internal cracks filled with calcite, reflecting shrinkage during their development (Figure 12). Other concretions have complex nested conical fractures, termed 'cone-in-cone structure'.

Aeolian Processes

N Lancaster, Desert Research Institute, Reno, NV, and United States Geological Survey, Reston, VA, USA

Introduction

Aeolian processes, involving erosion, transportation, and deposition of sediment by the wind, occur in a variety of environments, including beaches, semi-arid and arid regions (e.g., cold and hot deserts), agricultural fields, and some terrestrial planets, notably Mars and possibly Venus. Common features of these environments are a sparse or non-existent vegetation cover, a supply of fine sediment (clay, silt, and sand size), and strong winds. Aeolian processes are responsible for the emission and/or mobilization of dust and formation of areas of sand dunes. They largely depend on other geological agents (e.g., rivers, waves) to supply sediment for transport. Despite assertions by many early workers, erosion of bedrock by the wind is not a significant process in most regions.

Sediment Movement by the Wind

Most naturally occurring airflow is turbulent. Mixing of turbulent eddies, each with a different velocity and direction, together with the effect of friction at the surface, results in a wind profile with a logarithmic increase in velocity with height above the aerodynamic roughness length (z_o) (Figure 1). The aerodynamic roughness length is determined by the particle size and roughness of the surface. For sand surface, z_o is typically 1/30th of the mean particle size. For surfaces with scattered isolated roughness elements such as plants or rocks, aerodynamic roughness scales with the roughness density (the volume of roughness elements per unit area). The existence of roughness elements plays an important role in the interaction of the wind with the surface because the available wind shear stress is partitioned between the roughness elements and the intervening surface. A high density of roughness elements will therefore reduce the wind shear stress on the surface so that sediment mobilization and transport may be reduced or eliminated.

Particle movement is achieved via a combination of direct wind shear stress on the surface and atmospheric turbulence. There are three modes of sediment transport by wind: creep or reptation, saltation, and suspension (Figure 2). The mode of transport depends primarily on the ratio between particle settling velocity, and hence particle size, and wind shear stress and turbulence intensity. Very small particles (<20 μm) are transported in suspension (tens of kilometres or greater) and are kept aloft by turbulent eddies in the wind. True suspension occurs when the particle settling velocity is very small compared to the turbulence intensity of the wind. Larger particles (20–63 μm) undergo short-term suspension for distances of tens to hundreds of metres; material of sand size (63–1000 μm) is transported mainly in a series of short hops (saltation), in which the vertical component of wind velocity (turbulence) has no effect on particle trajectories. Material coarser than 500 μm diameter is transported in contact with the surface by reptation and creep. The modes of transport are interdependent: saltating sand particles eject silt- and

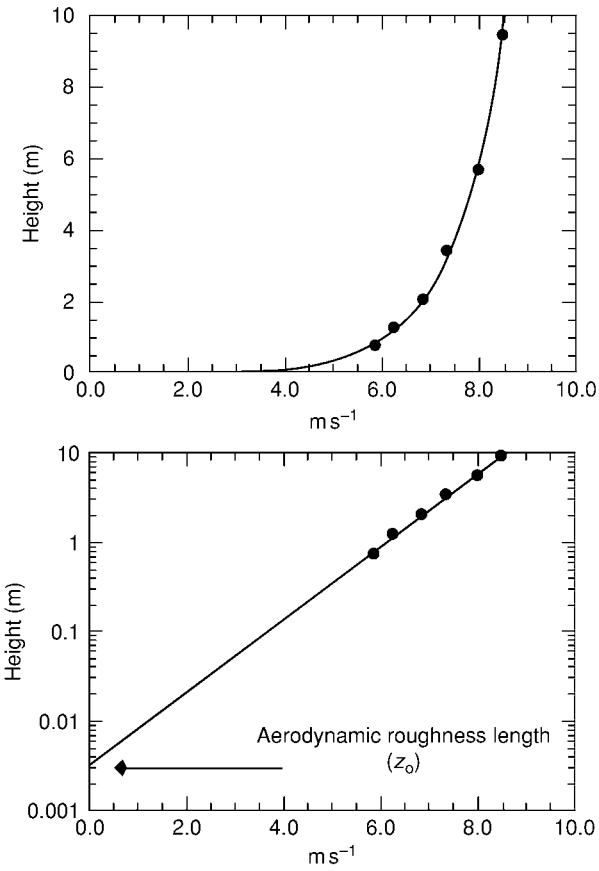

Figure 1 Development of wind profiles. The wind profile equation is $u_* \quad u/\kappa \ln(z/z_o)$, where u_* is wind shear velocity, u_* is wind speed at height z, and κ is the von Karman constant (~0.4). Data from field experiments.

clay-size particles into the wind and impact coarse grains that are rolled along the bed.

Grains begin to move and sediment is entrained by the wind when fluid forces (lift, drag, and moment) exceed the effects of the weight of the particle and any cohesion between adjacent particles as a result of moisture, salts, or soil crusts. There is a cascading effect as the first particles to move dislodge or impact other grains, so that the number of particles in transport increases exponentially. These particles extract momentum from the wind, reducing its near-bed velocity, so that the transport rate reaches a dynamic equilibrium state over a period of 1 to 2 s. The threshold wind speed at which grains begin to move is strongly dependent on particle size (**Figure 3A**). As in water, there is a particle size at which the transport threshold is at a minimum. For quartz sand in air, the minimum threshold velocity is associated with fine sand (approximately 100 μm diameter).

Most sand particles are moved by saltation in a layer close to the bed, with an exponential decay in the number of particles moved with height above the bed. Particles in saltation move in a parabolic path with a steep ejection limb and a gradual return to the bed. The impacting grains may rebound directly (successive saltation), deform the bed, eject fine particles, or move coarse grains a short distance by reptation or surface creep. The mass flux of sand has been determined by numerous laboratory wind tunnel and field studies to be proportional to the cube of wind shear velocity above a threshold value (**Figure 3B**). For any wind shear velocity, there is a potential rate of sand transport or transport capacity; this is reached only when the availability of sediment is unrestricted (e.g., most loose sand surfaces). In these conditions, the wind is saturated with respect to transport capacity. If the actual transport rate is less than the potential rate, then the wind is undersaturated. Very fine grains (silt and clay size) are inherently resistant to entrainment, yet are readily transported by the wind. Studies have shown the critical role of impacting sand grains in the mobilization of silt- and clay-size particles and have demonstrated the close relations between the horizontal flux of sand-size particles and the vertical flux of fine particles. In these situations, the horizontal mass transport rate is directly related to shear velocity (**Figure 3B**), so dust emissions scale to the fourth power of wind shear velocity (u_*^4; **Figure 3C**). Where there is a limited supply of particles able to abrade soil clods or playa crusts, dust emissions are limited by the supply of particles rather than by the wind shear velocity, and the vertical flux of dust is almost independent of wind shear velocity.

Based on the principle of sediment continuity, winds are erosional if transport rate (or wind shear velocity) increases downwind; deposition occurs when transport rates decrease in the direction of transport, and sediment bypass occurs when there is no

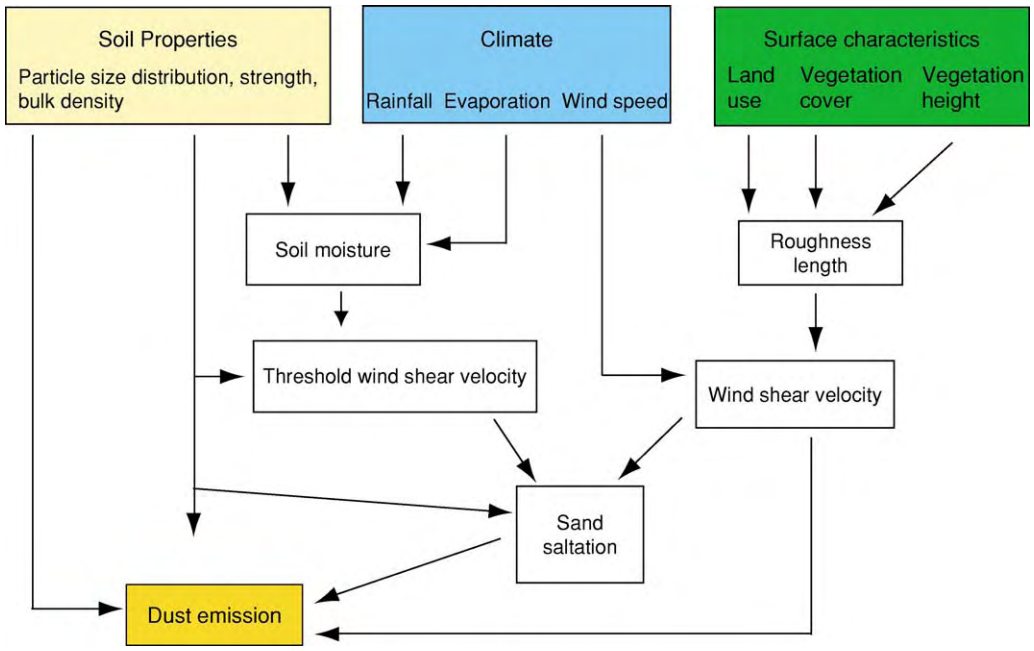

Figure 4 Controls of wind erosion processes on agricultural lands. Reproduced with permission from Leys JF (1999) Wind erosion on agricultural land. In: Goudie AS, Livingstone I, and Stokes S (eds.) *Aeolian Environments, Sediments, and Landforms*, pp. 143 166. Chichester and New York: Wiley.

change in transport rates. These principles are of vital importance to understanding of the dynamics of dunes and sand seas.

Wind Erosion

Erosion by wind involves two linked processes: abrasion (mechanical wearing of coherent materials, including playa crusts and clods created by tillage) and deflation (removal of loose material). Considerable attention has been devoted to the processes and rates of wind erosion because of their impact on agriculture, especially in semi-arid regions, and the implications of dust emissions for air quality. Wind erosion abrades crops, removes organic matter, nutrients, and fertilizer, and changes soil texture. The products of wind erosion (especially dust particles) impact air quality, atmospheric radiative properties, and human health, causing respiratory illnesses and transporting pathogens. Rates of wind erosion vary widely and for a given wind shear velocity are dependent on soil or sediment texture and the degree of crusting and cohesion. The highest emission rates for fine-grained sediment are associated with soils of loamy texture, especially those that have been disturbed by vehicular traffic and/or animals.

Empirical studies of wind erosion rates in relation to environmental conditions and agricultural practices have resulted in the development of predictive models, including the widely used wind erosion equation (WEQ) and the new Wind Erosion Prediction System (WEPS) developed by the United States Department of Agriculture (USDA). The considerable uncertainties associated with such empirically derived models have stimulated development of physically based models of wind erosion in which relations between the physical parameters of the wind and the surface are used to predict dust emissions (Figure 4).

Wind Erosion Landforms

Wind erosion landforms have not received the same level of research attention as have those associated with aeolian deposition. Landforms created by wind erosion can occur on several scales. Large-scale landforms include yardangs (Figure 5A), some of which may occur in systems of ridges and swales aligned with the wind. Yardangs are streamlined forms, with a blunt upwind face and a tapering leeward projection that appears to have evolved to minimize drag. Many yardangs are formed in Quaternary lacustrine deposits; others occur in bedrock, including Precambrian dolomite, Cambrian sandstone, and Mesozoic limestone. Large-scale systems of yardangs are also observed in several areas of Mars. Formation of yardangs appears to involve winds from a very limited range of directions and, at least for bedrock examples, long-term erosion. In some areas (e.g., Kalahari, West Texas), wind erosion has created enclosed depressions with their depth controlled by the water table or resistant strata (Figure 5B). Small-scale aeolian erosional landforms involve wind abrasion of clasts

Figure 5 Wind erosion landforms. (A) Yardangs in Dahkla Oasis, Egypt; (B) Kalahari pans; (C) Ventifacts in the Namib Desert.

and bedrock outcrops to form ventifacts (Figure 5C). Smoothing and polishing, faceting, fluting, and grooving of rock surfaces occur in areas of high-intensity sand transport and affect a variety of lithologies, including granite, marble, and basalt.

Dust Storms

Dust storms are defined as events in which visibility is reduced to 1 km or less as a result of blowing dust (Figure 6). Interest in air quality and in the impact of aerosols on atmospheric properties has promoted intensive study of dust storms and their occurrence in space using meteorological records and satellite images. The Advanced Very High Resolution Radiometer (AVHRR) and the Moderate Resolution Imaging Spectroradiometer (MODIS) satellite images and the Total Ozone Monitoring Sensor(TOMS) have been used to identify major dust source areas and to track the dispersion of particulate matter (Figure 7). Major dust source areas include the Bodelé Depression in Tchad, the Aral Sea area, south-east Iran, and the loess plateau of China. These areas are characterized by seasonally strong winds and areas of fine-grained sediments (including those of playa lakes or previously deposited aeolian materials). The interannual frequency and magnitude of dust storms are strongly linked to climatic variability, so that in many areas dust emissions are inversely correlated to rainfall. Although dust storm intensity in some areas is affected by human impacts, including water diversion for irrigated agriculture and poor land use practices, the largest sources of dust emissions in the Sahara are in uninhabited regions.

Aeolian Deposits

Aeolian deposits include sand seas and dune fields, deposits of silt (loess), and fine-grained material that forms a significant component of desert margin and other soils. Many marine deposits, especially those downwind of major desert areas, also include significant proportions of wind-transported material.

Silt and Clay Size

Terrestrial deposits of wind-transported silt-sized quartz particles, termed loess, cover as much as 10% of Earth's land surface. Loess deposits are widespread in areas of northern China, central Russia, the Ukraine, Kazakhstan, central Europe, Argentina, Alaska, and the central United States. Much of the material was thought to be derived from silt particles produced by glacial grinding and supplied to aeolian processes by glacial outwash ('glacial loess'), but aeolian abrasion and other processes, including frost shattering, salt weathering, and fluvial comminution, are important, especially in the formation of 'desert loess'. At least some loess (e.g., in Colorado and Nebraska) has its origins in weathered bedrock (e.g., siltstones, volcaniclastic deposits). Loess deposits and their interstratified buried palaeosols provide a long record of Quaternary climate change (Figure 8). In these sequences, the rate of loess deposition varies

Figure 6 Reduced visibility from major dust storm in West Texas, 15 December 2003. Compare with clear day (inset). Photographs by J Lee, Texas Tech University.

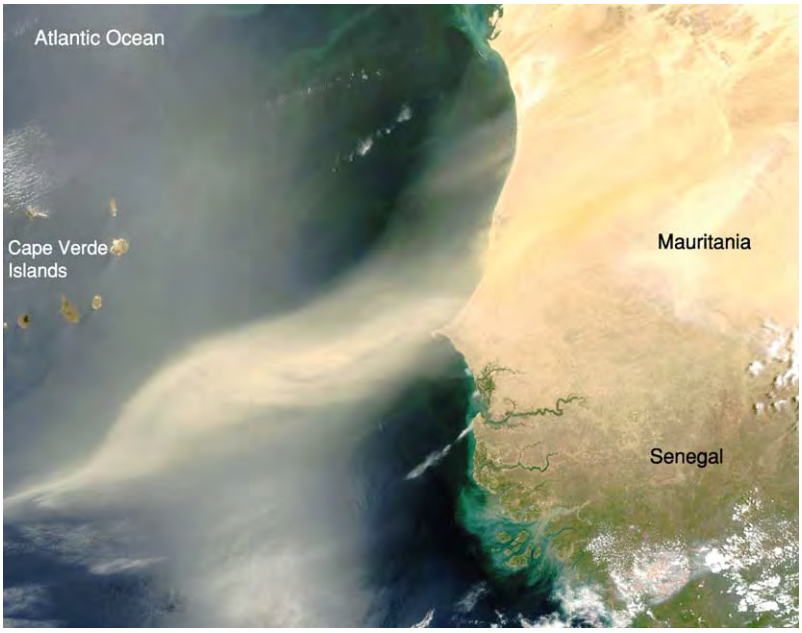

Figure 7 Dust plumes extend up to 200 km offshore from the western Sahara in Senegal and Mauritania, 30 April 2003. This was the fourth day of the storm. Figure 8 Loess deposits in Nebraska. Photograph and annotations by D Muhs, USGS.

over time, being greater in glacial periods (more arid, windier, less vegetation) compared to interglacial periods (less arid and windy, more vegetation), when the influx of particles was low enough to allow soils to form.

Silt- and clay-sized material of aeolian origin is also an important component of many desert margin soils. Deposition of silt plays a role in the formation of many stone pavement surfaces in desert regions (desert pavement, or 'reg'). These surfaces are characterized by a surface layer of gravel or larger clasts that overlie fine-grained materials. Older work argued that desert pavement surfaces were deflationary and that the mantle of coarse clasts resulted from winnowing and removal of fine material. Detailed studies of these surfaces now show, however, that the surface layer of gravel-sized clasts rests on an accretionary mantle of soil-modified dust that may be a metre or more thick. The dust is trapped by the clasts and deposited between them. The fine material is incorporated into the mantle by pedogenic processes (e.g., shrinking and swelling of clay minerals), so that the clasts remain at the surface as it inflates over periods of thousands of years. Thus desert pavement surfaces developed on bedrock and alluvial surfaces are actually depositional features.

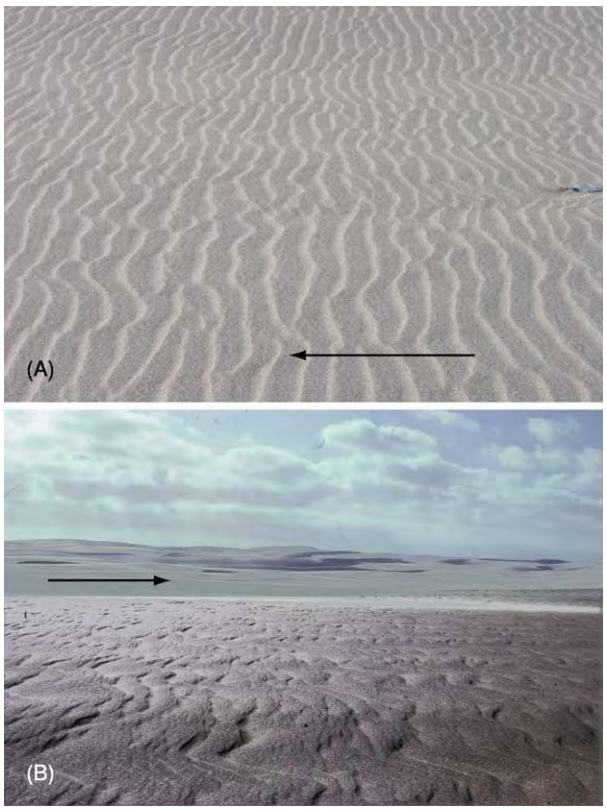

Figure 9 (A) Wind ripples in the Victoria Valley, Antarctica; (B) granule ripples (megaripples) at Skeleton Coast, Namibia. Arrows indicate formative wind direction.

Sand Dunes

Aeolian dunes form part of a hierarchical system of self-organizing bedforms developed in wind-transported sand; this system comprises wind ripples (spacing 0.05–2 m), individual simple dunes or superimposed compound and complex dunes (spacing 50–500 m), and compound and complex megadunes, or draa (spacing >500 m). Dunes occur wherever there is a sufficient supply of sand-sized sediment, winds to transport that sediment, and conditions that promote deposition of the transported sediment. These requirements are satisfied in two main environments: coastal areas with sandy beaches and onshore winds, and desert areas. Most dunes occur in contiguous areas of aeolian deposits termed 'sand seas' (>100 km^2) or 'dune fields'.

Wind ripples (Figure 9) typically have a wavelength of 0.05–0.2 m and an amplitude of 0.005–0.010 m. They are ubiquitous on sand surfaces except for those undergoing very rapid erosion or deposition, and form because a flat sand surface over which sand transport by saltation and reptation occurs is dynamically unstable. Field and laboratory wind tunnel experiments and numerical modelling suggest that ripple wavelength is a function of grain transport distance and that ripples develop as a result of stochastic variations in the flux of reptating coarser grains driven by the impacts of finer saltating grains. Once the initial variation in bed topography develops, variations in microtopography influence the intensity of saltation impacts and therefore the local mass flux of reptating grains, and the pattern becomes self-organizing by the merging and growth of a characteristic wind ripple wavelength and amplitude.

Aeolian dunes occur in a self-organized pattern that develops as sand surfaces respond to the wind regime (especially its directional variability) and the supply of sand. Sand dunes occur in four main morphological types (Figure 10): crescentic (transverse), linear, star, and parabolic. The simplest dune types and patterns form in areas characterized by a narrow range of wind directions (unidirectional wind regime). In the absence of vegetation, crescentic dunes will be the dominant form. Isolated crescentic dunes, or barchans, occur in areas of limited sand supply; they coalesce laterally to form crescentic (barchanoid) ridges as sand supply increases (Figure 10A and B). Linear dunes, which form in areas of bimodal or wide unimodal wind regimes, are characterized by their length (often more than 20 km), sinuous crestline, parallelism, and regular spacing (Figure 10C and D). The essential mechanism for linear dune formation is

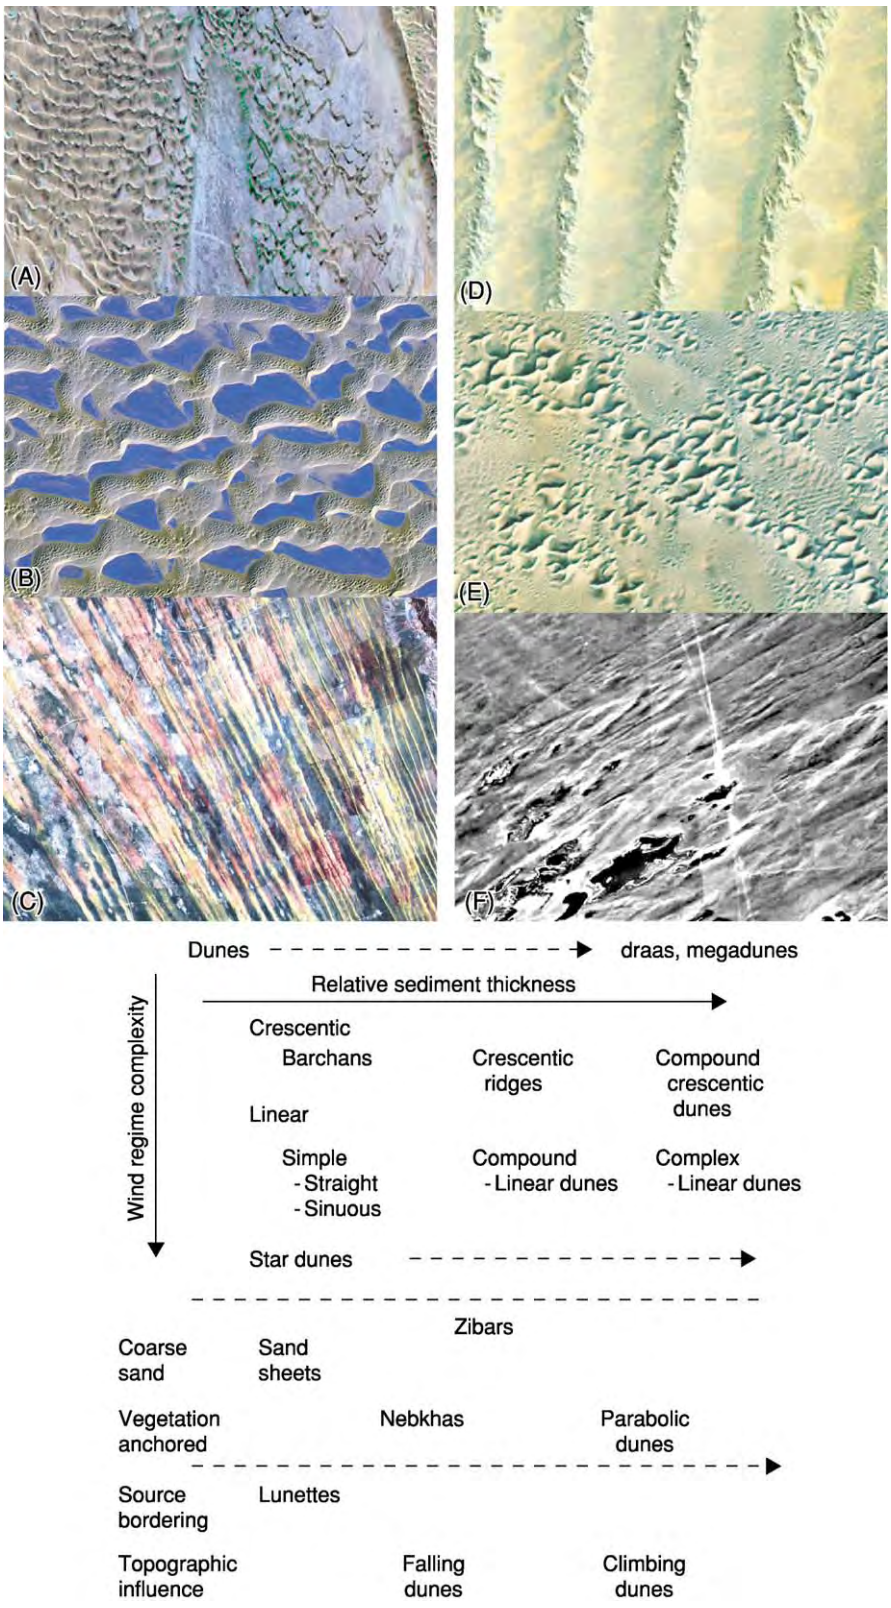

Figure 10 Morphological classification of aeolian sand dunes, and satellite images and aerial photographs of major dune types: (A) barchans and crescentic dunes, Namib Sand Sea; (B) compound crescentic dunes, Liwa, United Arab Emirates; (C) simple linear dunes, Kalahari Desert; (D) complex linear dunes, Namib Sand Sea; (E) star dunes, Gran Desierto, Mexico; (F) parabolic dunes, Casper, Wyoming.

the deflection of winds that approach the crest at an oblique angle, then parallel wind flow to the lee side and transport of sand along the dune, so elongating it. Star dunes have a pyramidal shape, with three or four sinuous sharp-crested arms radiating from a central peak and multiple avalanche faces (Figure 10E). Star dunes occur in multidirectional or complex wind regimes and are the largest dunes in many sand seas, reaching heights of more than 300 m. The development of star dunes is strongly influenced by the high degree of form–flow interaction, which occurs as a result of seasonal changes in wind direction, and the existence of a major lee-side secondary circulation. Parabolic dunes (Figure 10F) are characterized by a U or V shape with a 'nose' of active sand and two partly vegetated arms that trail upwind. They are common in many coastal dunefields and semi-arid inland areas and often develop from localized blowouts in vegetated sand surfaces. Other important dune types include zibars (low-relief dunes lacking discernible slip faces; commonly occur on sand sheets), nebkhas (hummock dunes; anchored by vegetation; common in may coastal dunefields), lunettes (form downwind of small playas; often composed of sand-sized clay pellets), and a variety of topographically controlled dunes (climbing and falling dunes, echo dunes).

Relations between dune types and wind regimes indicate that the main control of dune type is the directional variability of the wind regime (Figure 11). Grain size, vegetation cover, and sediment supply play subordinate roles.

Dune Processes and Dynamics

The development and morphology of all dunes are determined by a complex series of interactions between dune morphology, airflow, vegetation cover, and sediment transport rates. As dunes grow, they project into the atmospheric boundary layer so that streamlines are compressed and winds are accelerated up the stoss (windward) slope by up to 2.5 times, depending on the size and steepness of the dune. Flow acceleration results in an exponential increase in sediment transport rates towards the dune crest, resulting in erosion of the stoss slope. In the lee of the crest of dunes, wind velocities and transport rates decrease rapidly as a result of flow expansion between the crest and brink of the lee or avalanche face and flow separation on the avalanche face. Flow separation causes fallout of previously saltating sand grains and development of avalanche (slip) faces. Secondary flows, including lee-side flow diversion, are also important when winds approach the dune obliquely, and are an important process on linear and many star dunes. Migration of crescentic dunes occurs as a result of erosion of the stoss slope and deposition on the lee. Their movement can be described by $c = Q/yh$, where c is the migration rate, Q is the bulk volumetric sand transport rate, y is the bulk density of sand, and h is dune height. Linear dunes

migrate laterally at a very slow rate and also extend downwind. Star dunes are essentially stationary forms.

Dune Sediments

Dunes are composed of moderately to well-sorted sands (63–1000 μm), with a mean grain size in the range 160–300 μm. Most dune sands are composed of quartz, but may include significant quantities of feldspar. Dunes composed of volcaniclastic materials occur in some areas. Carbonate-rich dune sands are found adjacent to many subtropical coastlines and gypsum dunes occur close to some playas.

Three primary modes of deposition occur on dunes: migration of wind ripples, fallout from temporary suspension of grains in the flow separation zone (grainfall), and avalanching of grains initially deposited by grainfall (grainflow). These deposition modes create three basic types of aeolian sedimentary structures: wind ripple laminae, grainfall laminae, and grainflow cross-strata. The packages of laminae may be separated by a hierarchy of bounding surfaces representing episodes of reactivation, dune growth, and migration of dunes in conditions of bedform climbing.

Crescentic dunes are dominated by grainfall and grainflow cross-strata (Figure 12A). Linear dune structures imaged using ground-penetrating radar show a change in the dominant type of sedimentary structures as the dune develops. Small dunes are dominated by stacked sets of cross-strata that dip in opposite directions and are formed by the migration of the elements of a sinuous crestline up the dune. The structures of larger dunes are dominated by trough cross-strata created by the migration of superimposed bedforms (Figure 12B). Sedimentary structures of star dunes are not well known, but are likely complex.

Sand Seas

Desert sand seas are major depositional landforms that comprise dunes of varying size, spacing, and morphological type; sand seas also have areas of sand sheets as well as interdune deposits (e.g., playas, lacustrine deposits) and extradune fluvial, lacustrine, and marine sediments. Major areas of sand seas lie in

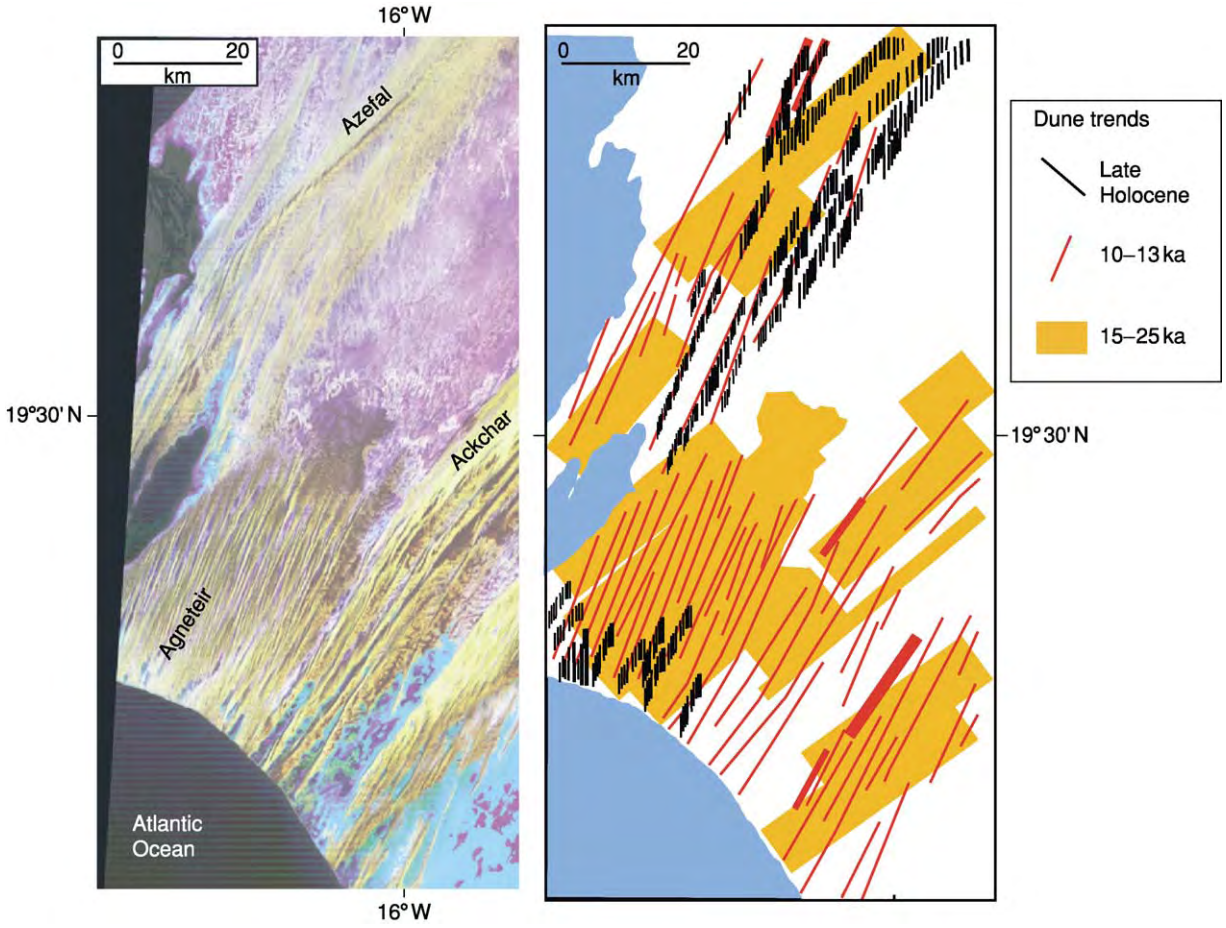

Figure 14 Linear dune generations in western Mauritania; LANDSAT image (left) and interpreted dune trends (right).

the tectonically stable desert regions of the Sahara, Arabian Peninsula, Australia, and southern Africa and in the enclosed basins of central Asia (Figure 13). Sand seas and dune fields form part of well-defined regional- and local-scale sediment transport systems in which sand is moved by wind from source areas (e.g., distal fluvial deposits, sandy beaches) via transport pathways to depositional sinks. Sand seas accumulate downwind of source zones wherever sand transport rates decrease as a result of regional and/or local changes in wind speed and directional variability, so that the influx of sand exceeds outflux.

Most sand seas exhibit significant spatial variations in dune type and sediment characteristics. These may be the result of regional changes in wind regime, but can also be the product of multiple periods of sand influx and stabilization, controlled by changes in climate and sea-level. Areas of different dune types therefore often represent distinct generations of dunes. Advances in dating techniques (e.g., optically stimulated luminescence) are beginning to provide absolute chronologies of dune generations in sand seas (Figure 14).

Preservation of Aeolian Deposits in the Rock Record

Formation of an aeolian rock record requires three sets of processes: sand sea construction, accumulation of aeolian strata, and preservation of the

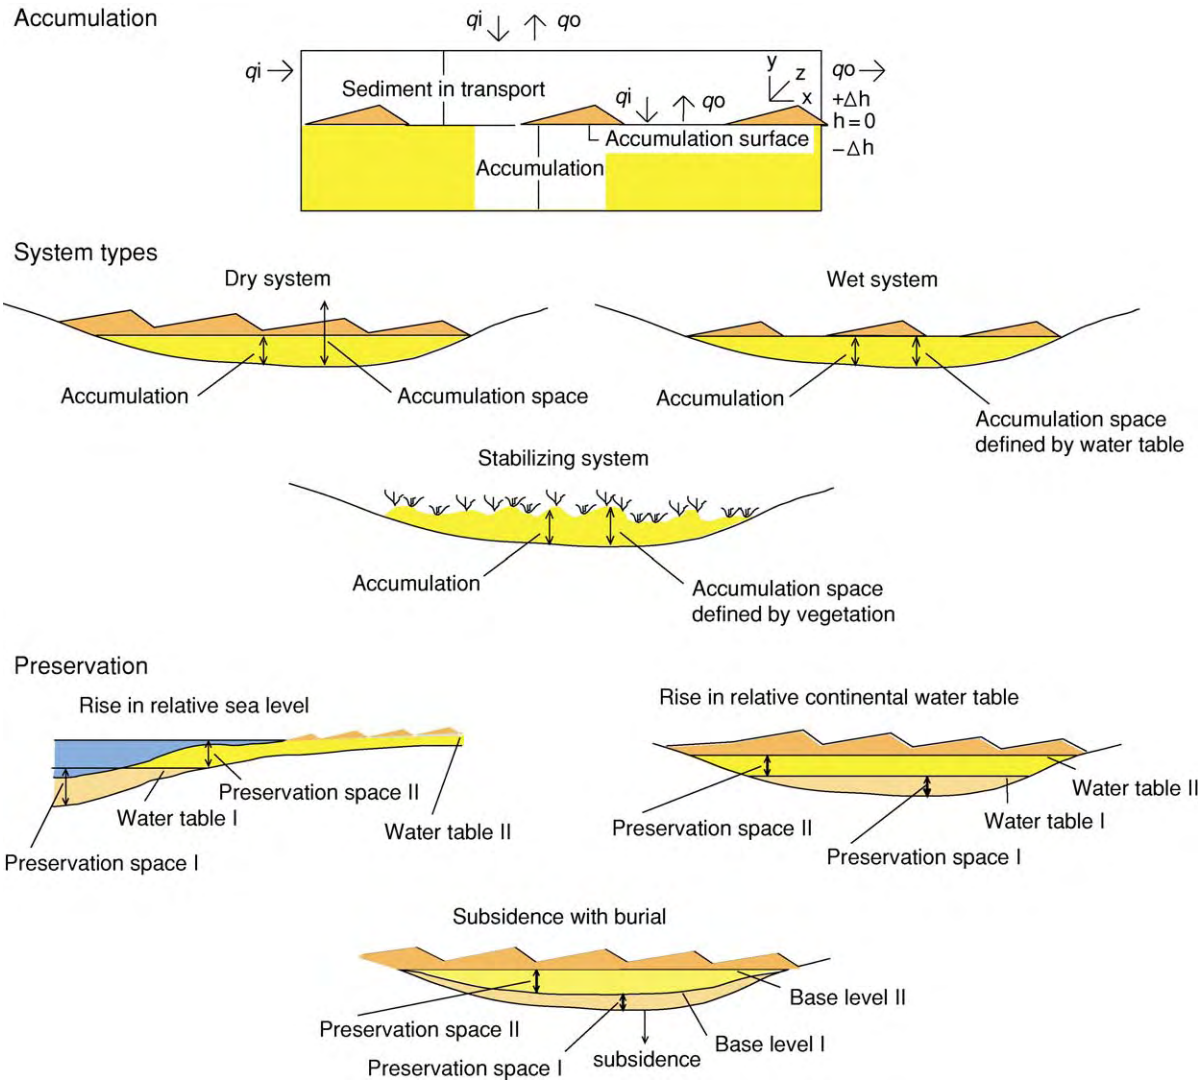

Figure 15 Accumulation and preservation of aeolian sands. Accumulation depends on the transport rate *qi* into and *qo* out of the system. Reproduced with permission from Kocurek G (1998) Aeolian system response to external forcing factors a sequence stratigraphic view of the Saharan region. accumulation. Accumulation of aeolian deposits occurs when that sediment is transferred from bedforms to the accumulation such that its surface rises over time (Figure 15). In dry aeolian systems, the water table is sufficiently far below the surface that it plays no role in the dynamics of the accumulation, which is instead dominated by the wind. In wet aeolian systems, the water table is at or near the surface and so controls accumulation dynamics. Where vegetation controls accumulation dynamics, the system is known as a stabilizing aeolian system. In all cases, accumulation occurs when sediment transport rates decrease downwind and the excess sediment is deposited; and/or when the concentration of sediment in transport (approximately indicated by dune size) decreases over time. In dry systems, spatial or temporal decreases in wind strength give rise to accumulation of sediment by bedform climbing; in wet systems, transport rates

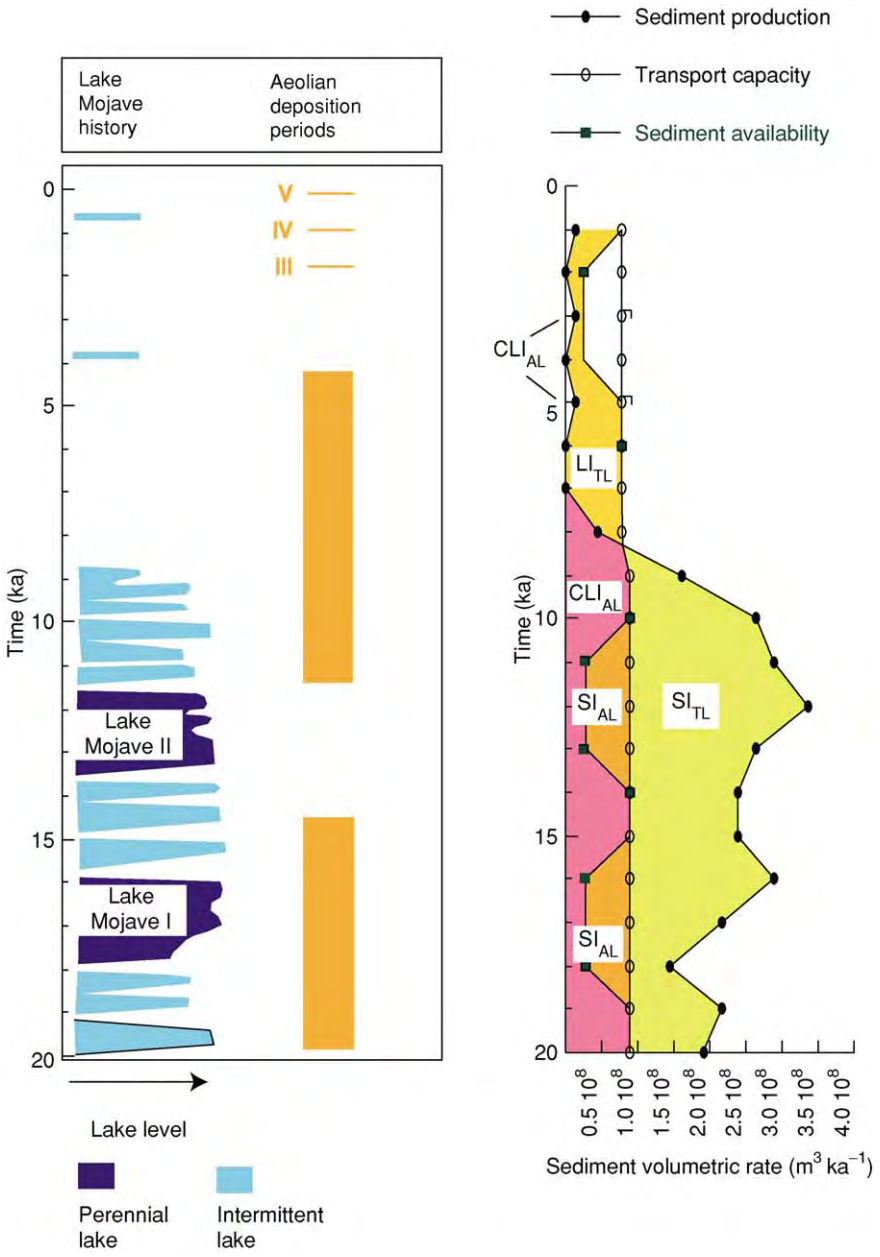

Figure 16 Example of controls on an aeolian system state in the Mojave Desert, both transport limited (TL) and availability limited (AL). decrease downwind because sediment is trapped by dunes migrating into a wet area, resulting in a decrease in dune size, or dunes shrink because the water table rises under the whole system.

For these accumulations to be preserved, there must be subsidence and burial and/or a rise of the water table through the accumulation. Because wind has the potential to erode any sand accumulation above the water table if it is undersaturated with respect to transport capacity, exhaustion of sediment supply may promote erosion unless the accumulation is buried by non-aeolian strata or the water table is at

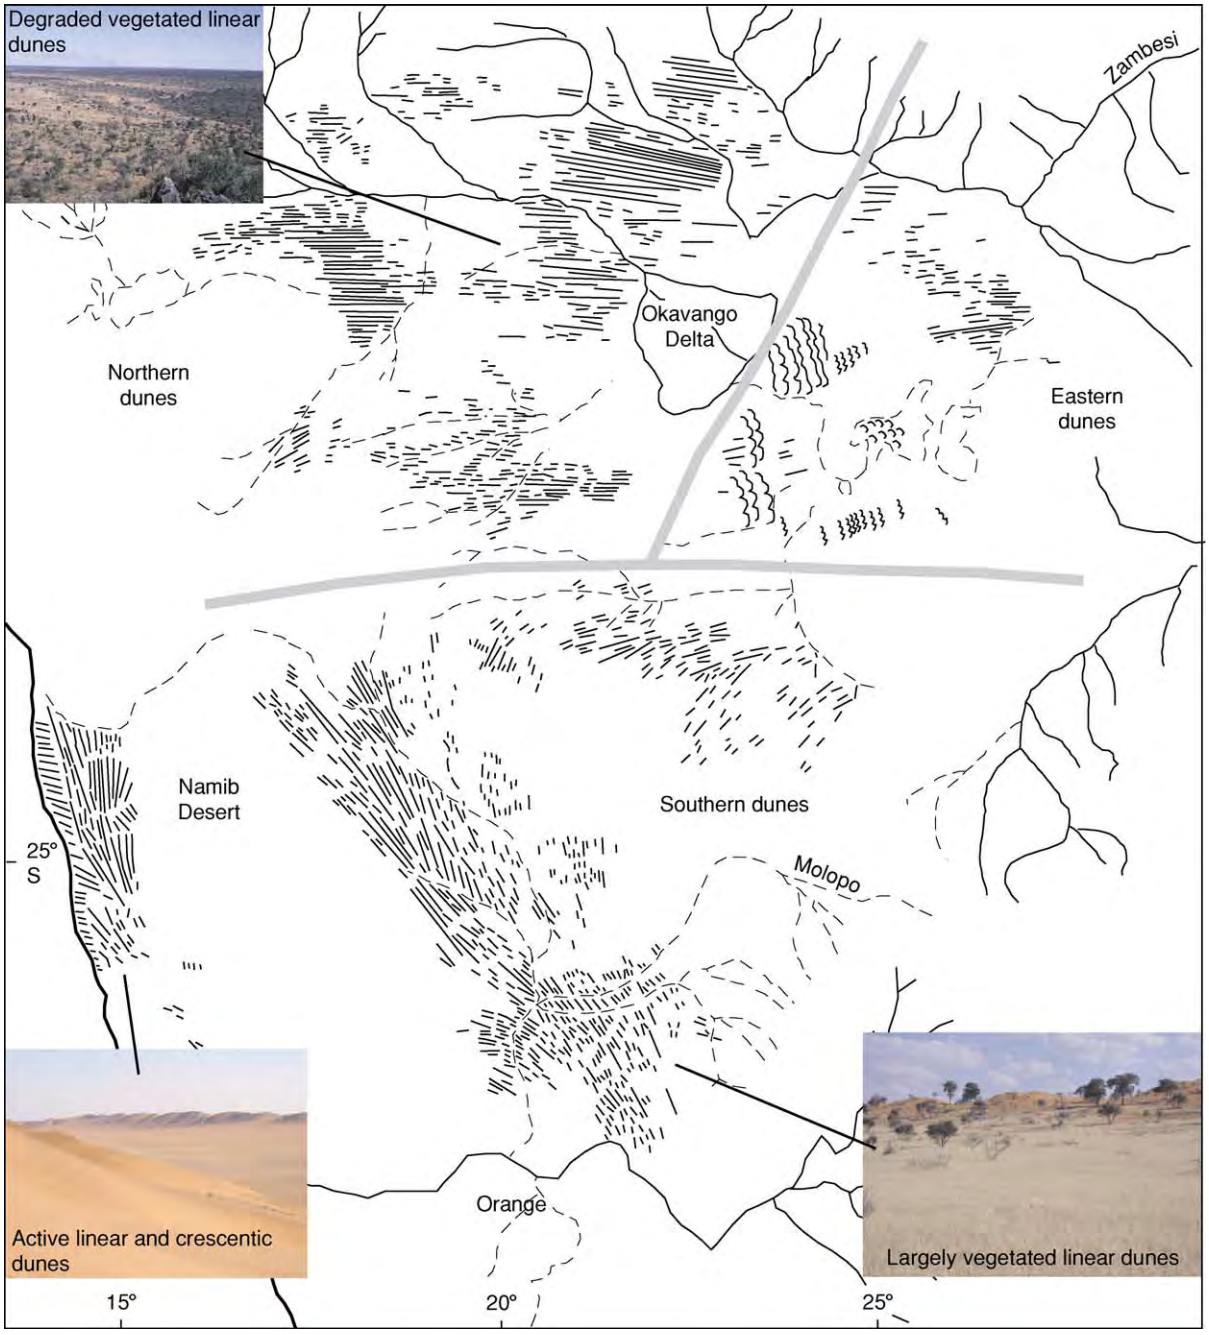

Figure 17 Relict dune systems in the Kalahari Desert of southern Africa. Dune patterns reproduced with permission from Lancaster N (2000) Eolian deposits. In: Partridge TC and Maud RR (eds.) The Cenozoic of Southern Africa, pp. 73 87. Cape Town, South Africa: Oxford University Press.

or near the surface. Preservation of aeolian accumulations is favoured in tectonic basins subject to a long history of sediment influx and subsidence, in coastal areas in which marine transgressions can bury aeolian accumulations or cause a rise in the regional water table, and in continental areas in which the water table rises permanently because of tectonism or climate. These conditions were satisfied during the formation of the extensive Jurassic aeolian sandstones of the western United States, which were deposited in a subsiding foreland basin supplied with large amounts of sediment from the North American Craton. Marine transgressions from the west preserved parts of the record via sabkha and marine strata. By contrast, most aeolian accumulations in the Sahara and many other deserts are unfavorably located with respect to preservation. One exception is that along the coast of Mauritania and its continental shelf, where aeolian sands sourced from inland craton areas are preserved by the postglacial rise in sea-level and the associated rise in water tables.

Effects of Climate and Sea-Level Change on Aeolian Systems

Many aeolian deposits and landforms formed during the Quaternary Era, thus they have been affected by climatic and sea-level changes associated with glacial–interglacial cycles. The effects of changes in external forcing factors are manifested by changes in the supply of sediment of a size suitable for transport by the wind, the availability of this sediment for transport (determined by vegetation cover and soil moisture), and the mobility of this sediment (controlled by wind strength). The interactions between these variables can be evaluated in terms of the state of the aeolian system and the limiting factors

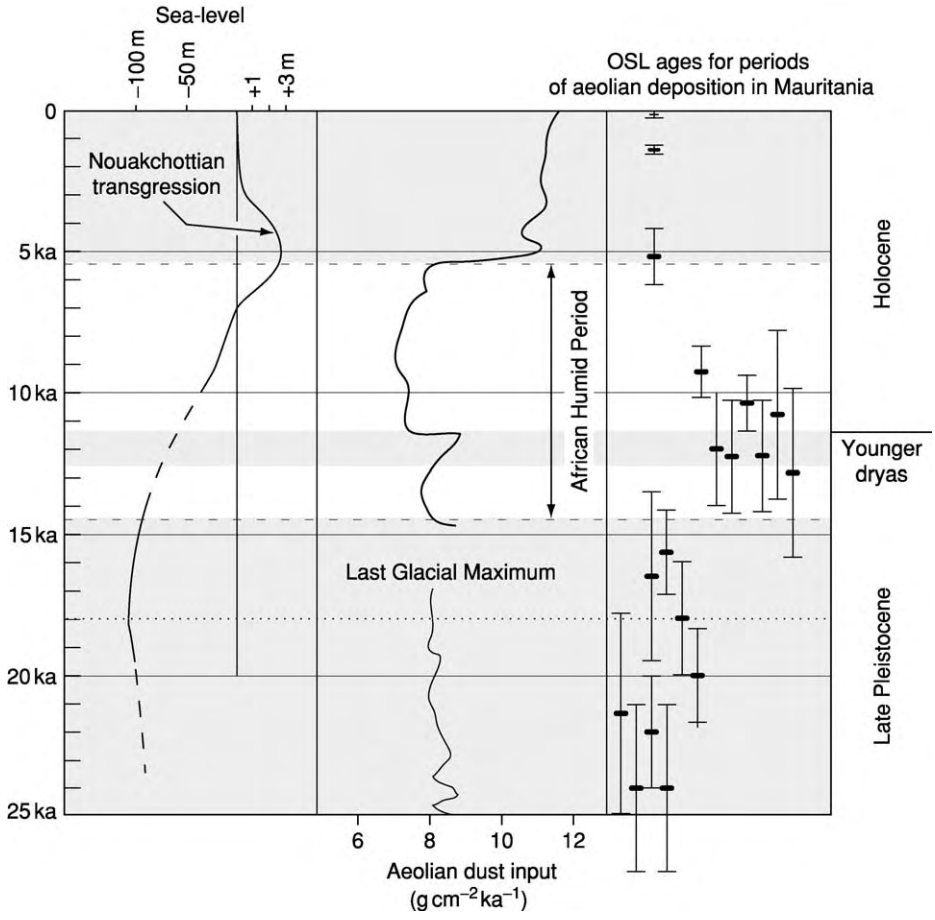

Figure 18 Relations between periods of dune construction, sea level, and dust flux to the Atlantic Ocean (dust flux after deMenocal P, *et al.* (2000) Abrupt onset and termination of the African Humid Period: rapid climate responses to gradual insolation forcing. *Quaternary Science Reviews* 19(1 5): 347 361). identified (Figure 16). The changes in system state are manifested as episodic accumulation of aeolian deposits, resulting, for example, in sequences of loess accumulation interspersed by palaeosols (Figure 8), or formation of different dune generations in aeolian sand seas and dune fields (Figure 14). Consideration of variations in the supply of sediment for dune construction or loess accumulation, together with changes in the availability and mobility of this sediment, has prompted new explanations of regional variations in loess stratigraphy in North America and periods of aeolian accumulation in the Mojave and Arabian deserts. For example, loess accumulation was low during the last glacial maximum in Alaska, despite high rates of sediment supply and mobility, because tundra vegetation is ineffective at trapping sediment. This is in contrast to areas in the Great Plains and Central Lowlands, where accumulations of thick sequences of loess during the last glacial period were favoured by high rates of sediment supply from glacial outwash and high rates of accumulation in the boreal forest that then covered these areas. In the Mojave Desert, high rates of aeolian accumulation and dune construction took place during times when palaeolake systems were drying out seasonally or annually. Sediment deposited in these basins during wetter periods was mobilized during periods of drier climates. Aeolian construction ceased when these supplies of sediment were exhausted (Figure 16).

In addition to being influenced by climate and sea-level change, aeolian sediments and landforms may also provide evidence for past climate changes. Examples include loess–palaeosol sequences, as well as dune systems, now vegetated and inactive, indicating the former extent of arid conditions and past wind regimes in what are today areas of semi-arid or sub-humid climates (Figure 17), and increased rates of aeolian dust deposition in ocean sediments and ice cores (Figure 18).

Catastrophic Floods

A J Russell, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

Introduction

At present there is no widely recognized definition of a flood other than a 'notable flow of water'. Since the diluvial theory of the biblical flood, cataclysms and catastrophic flooding have drawn the attention of geologists throughout the development of the subject and to the present day. Catastrophic floods occur worldwide within a wide range of depositional environments and hydroclimatic settings. Catastrophic floods represent a major natural hazard within riverine environments, generating substantial loss of life and infrastructure. As a surface process, catastrophic floods are capable of generating immense landscape change and the transfer of huge sediment volumes. Large meltwater outbursts associated with continental deglaciation have recently been invoked as a trigger mechanism for changes in ocean circulation and consequent climate changes.

Catastrophic floods have been defined in a number of ways. From an applied perspective, catastrophic floods can be defined in terms of human and monetary loss. Floods can also be judged truly catastrophic, depending upon their impact on channel morphology and sedimentology or the work they do in transporting sediment. The extent to which a flood is catastrophic also depends upon the time-scale over which one wishes to consider its impacts. Preservation of erosional landforms and sedimentary successions associated with floods over geological time-scales are likely to reflect truly catastrophic events and the presence of appropriate depositional environments for preserving evidence of high-magnitude floods. Over shorter time-scales, a flood may be judged catastrophic if its impacts result in an irreversible change in fluvial geomorphology. High-energy flows are known to result in a suite of 'catastrophic processes', which do not operate under non-flood conditions and which achieve substantial and distinctive impacts. Catastrophic processes can, however, also occur under nonflood flow conditions within, for example, steep bedrock fluvial systems and subglacial drainage systems characterized by high stream powers.

Causes of Catastrophic Floods

Catastrophic floods require the sudden input of large volumes of water to a flood routeway. Flood generation mechanisms provide a major control on flood magnitude, frequency, and characteristics (Figure 1). Traditional classification schemes of flood causes examine the relationship between floods and climatological variables. More recently, attention has focussed on identifying the physical limits on the magnitude of floods generated by various mechanisms.

Rainfall is the most common cause of flooding in rivers around the globe. Rainwater is a major input to the fluvial system, often having travelled through hillslopes or more rapidly as overland flow. Rainfall intensities tend to be high over short time periods and on a relatively local scale. Meteorological and climatological controls on flood-producing precipitation events can be identified over a range of spatial and temporal scales (Figure 2). This hydroclimatological approach uses understanding of the controls on flood-generating precipitation events to characterize the distribution of floods in space and time. Other approaches have considered maximum flood discharges, which can be yielded from a certain catchment area. Empirically derived 'envelope curves' illustrate major differences in rainfall–runoff relationships between different climatic regions. Envelope curves do not, however, consider the relative role of specific drainage basin characteristics in generating flood flows (Figure 3).

Snowfall generally reduces the immediate potential for flooding by putting water into storage for more gradual release upon melting. However, the progressive or rapid melt of a snow-pack can generate substantial floods, especially as a 'nival' flood in springtime. Nival floods commonly affect rivers with large catchments, which allow synchronous water input from all parts of the catchment area. Snowmelt rates are controlled by the amount of available energy. Heavy rainfall onto a snow-pack will enhance peak flood discharges from a catchment, although modest precipitation onto a snow-pack may delay flows, resulting in lower peak discharges. Nival flows are also associated with secondary storage-release floods resulting from the failure of temporary snow dams or river ice jams.

Melt of glacier ice is a major control on discharge within proglacial river channels. Although melt-induced flows commonly exhibit discharge variations on diurnal and synoptic time-scales, they are not normally considered floods unless associated with unusually high ablation. This may occur, for example, during subglacial volcanic eruptions or where there are enhanced levels of geothermal activity. More commonly, however, glacial meltwater is stored

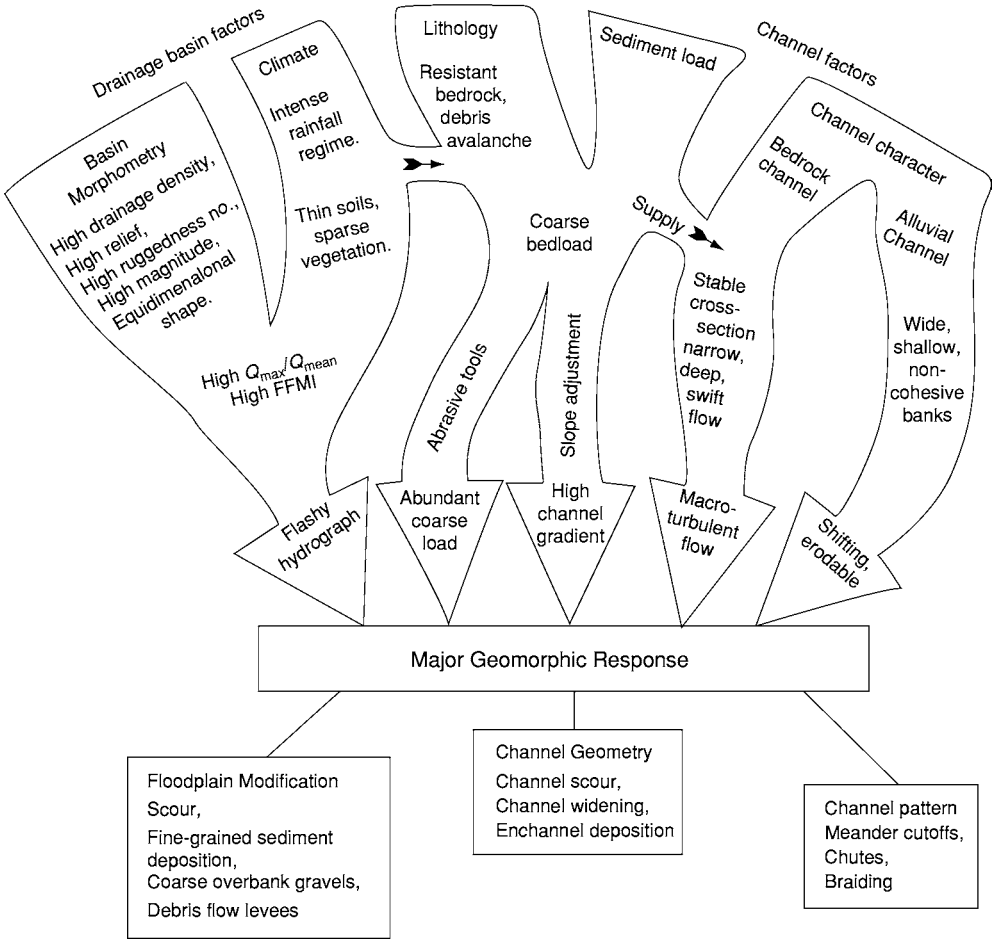

Figure 1 Controls on flood magnitude, frequency, and characteristics. After Kochel RC (1988) Geomorphic impact of large floods: review and new perspectives on magnitude and frequency. In: Baker VR, Kochel RC, and Patton PC (eds.) *Flood Geomorphology*, pp. 169 187. London: Wiley.

on top of, against, within, and underneath glaciers, providing the potential for storage-release events (Figure 4).

Natural or man-made dam failures can release outbursts of large volumes of water over relatively short time-spans. Natural dams commonly comprise vegetation debris, river ice, glacier ice, or sediment. Dam formation mechanism, composition, and geographic setting control dam longevity, failure mechanisms, and flood magnitude. The world's largest floods have resulted from the failure of glacier dams during the Late Quaternary. Man-made dams are also subject to failure, with the capability of releasing catastrophic floods many times greater in magnitude than could physically be generated by natural processes within the same catchment (Figure 5).

Accumulations of vegetation debris or coarse woody debris within river channels can obstruct flood flows, temporarily and partially damming floodwater. Infrequent high-magnitude flows within ephemeral rivers, for example, would allow sufficient time for coarse woody debris to accumulate within the channel between the highest magnitude events. Sudden dam failure commonly generates an enhanced flood peak as water released from storage is superimposed on the main flood hydrograph.

Although snow accumulation with river channels is a common occurrence in many parts of the world, there are relatively few reports of flooding produced by snow-dam failure. Outburst floods have been described from snow-dammed lakes in Antarctica and nival flood peaks enhanced by small snow-dammed lake outbursts in Canada. Snow damming mainly affects small low-order streams and can only pond water for very short time periods.

River ice break-up during the spring melt can lead to ice-jams at flow constrictions, resulting in considerable upstream inundation as well as downstream flooding on ice-jam failure. Unlike the snow-dammed lake bursts, ice-jam-related flooding occurs on major

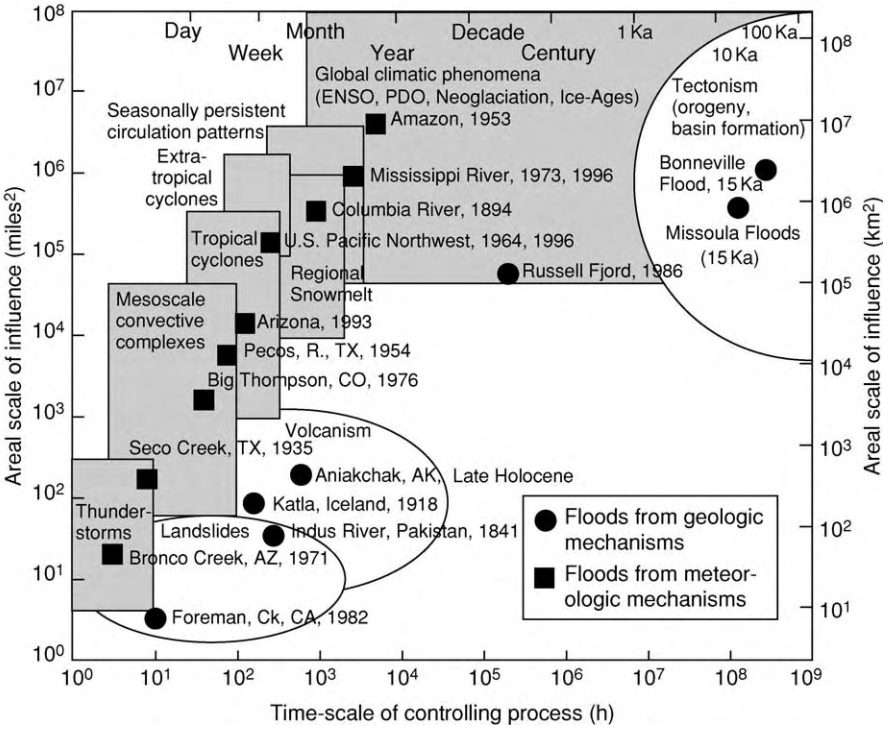

Figure 2 Space and time domain for flood producing hydroclimatological conditions and flooding. After Hirschboeck (1988) Flood hydroclimatology. Figure 3 Envelope curve for maximum discharge generation in relation to catchment area. After Hirschboeck KK (1987) Cata strophic flooding and atmospheric circulation anomolies. In: Mayer LD and Nasch D (eds.) *Catastrophic Flooding* pp. 23 56. Allen & Unwin.

river systems. Within the northern hemisphere, northward draining rivers are particularly prone to ice-jams as the spring melt is initiated within the catchment headwaters before the lower reaches have thawed.

Within glaciated catchments, ice-cliff or subglacial tunnel collapse can temporarily dam meltwater rivers with a breccia of ice blocks. Damming commonly lasts only for periods of up to one hour, as meltwater flows are easily able to penetrate, float, and bulldoze

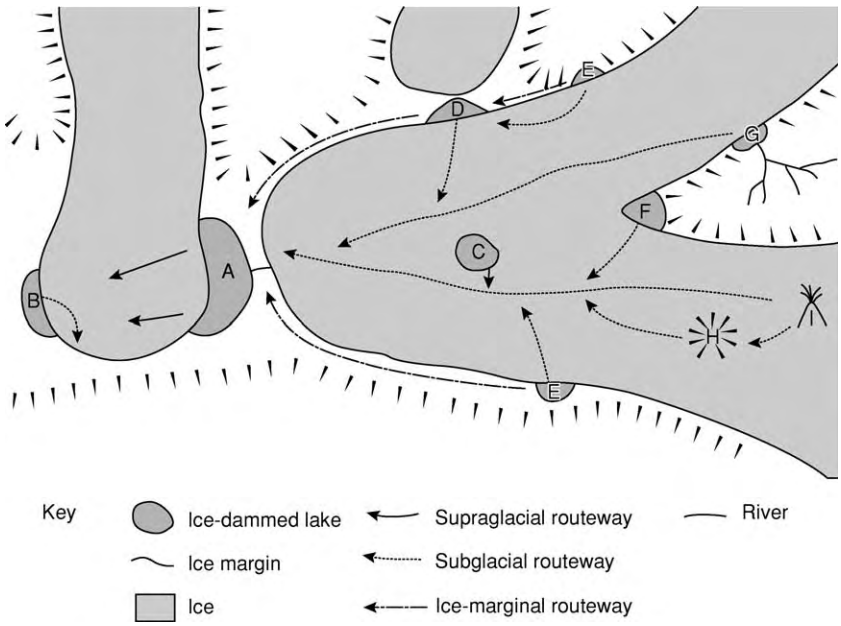

Figure 4 Ice dammed lake storage locations. Letters A I represent different meltwater storage locations, each associated with characteristic lake drainage triggers and jokulhlaup routing characterics. 'A' represents a tributary glacier which dams a trunk valley and which is subject to subaerial breach widenin. 'B' 'D' 'E' 'F' and 'G' represent proglacial and ice marginal ice dammed lakes in a variety of settings where drainage is triggered by mechanisms such as lake overspill, ice dam flotation, syphoning and subglacial cavity formation. 'C' represents a supraglacial lake which taps through the entire thickness of the glacier. 'H' is a subglacial lake within either a suitable storage location such as a volcanic caldera, or as an up turned bowl shaped lake often associated with locations with high geothermal acitivity. Drainage triggers postulated for subglacial lakes include ice dam flotation as well as Darcian flow through the glacier substrate. 'I' represents a subglacial eruption site, which may result in little or short lived meltwater storage during the course of an eruption. High meltwater temperatures associated with the drainage of geothermal and volcanic events characteristically result in jokulhlaups with rapid rising stages. Jokulhlaup hydrographs have a longer rising stage and lower peak discharge the further the ice dammed lake is from the glacier snout. After Tweed and Russell (1999) Controls on the formation and sudden drainage of glacier impounded lakes: implications for jokulhlaup characteristics. *Progress in Physical Geography* 23: 79 110.

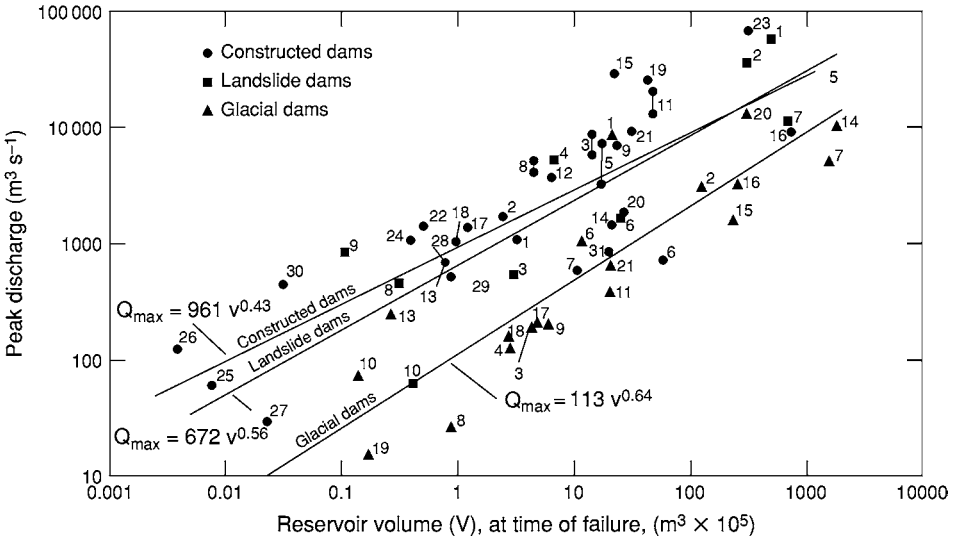

Figure 5 Relationships between lake volume and peak discharge for the failure of different dam types. After Costa (1988) Rheologic, geomorphic and sedimentological differentiation of water floods, hyperconcentrated flows, and debris flows. In: Baker VR, Kochel RC, and Patton PC (eds.) *Flood Geomorphology*, pp. 113 122. London: Wiley.

the breccia dam. Such events have been reported from locations such as the Alps, Greenland, and the Canadian Arctic and commonly result in floods with peak discharges up to an order of magnitude higher than 'normal' diurnal meltwater flows. These floods occur within either ice-marginal river systems or englacial tunnels, and they are more frequent earlier in the melt season when increasing meltwater discharges undermine and remove glacier ice from winter advance positions.

Glaciers are able to store water within ice-dammed lakes over time-periods of 10^1–10^2 years, generating glacier outburst floods or 'jökulhlaups' when they drain. Lakes can form in a number of locations: beneath, within, on top of, and at the edge of glaciers (**Figure 4**). Subglacial lakes can exist either within pre-existing topographic depressions, such as volcanic calderas and valleys, or within up-turned bowl-shaped lakes protruding upwards into the glacier. Such subglacial lakes are common in Iceland where high geothermal heat fluxes and frequent volcanic activity are common. In Iceland, subglacial Lake Grímsvötn drains every few years as meltwater takes time to accumulate, raising the lake to a level where drainage will occur. In 1996, rapid influx of meltwater from the nearby Gjálp subglacial eruption site resulted in the filling of Grímsvötn within one month. Approximately 3.4 km^3 of meltwater drained subglacially from the lake as a jökulhlaup, which lasted for three days.

Although Grímsvötn is one of the largest modern subglacial lakes known to drain, it is dwarfed by Late Quaternary jökulhlaups from glacial Lake Missoula, which drained over 2000 km^3 of water within just a few days. The release of water from sub- or englacial pockets has also been invoked as an explanation for sudden outburst floods or 'debacles' from Alpine glaciers. Large supraglacial lakes are also known from modern glaciers and ice-sheets and can involve the drainage of up to ~0.1 km^3 of meltwater subglacially over distances of tens of kilometres. Ice-marginal, ice-dammed lakes are relatively common at modern glaciers, and the presence of shorelines, deltas, and lacustrine deposits provide widespread evidence for the existence of large ice-marginal lakes associated with Palaeo ice-margins. Large proglacial lakes formed during the deglaciation of North America, and drained to the North Atlantic and Arctic oceans via a series of enormous spillway channels. For example, glacial Lake Agassiz is known to have drained 160 000 km^3 of meltwater within only a few years.

Although ice-dammed lakes occupy a variety of locations relative to the impounding glacier, the most significant control on jökulhlaup characteristics is whether the glacier enters a main valley as an outlet and has the potential to pond a lake within the main valley upstream of the glacier dam. In this case, the ice-dammed lake volume would be much larger than that of ice-marginal, ice-dammed lakes relative to the glacier dam. A number of mechanisms to account for the drainage of ice-dammed lakes have been proposed. In general terms, lake drainage will take place if there is a hydraulic gradient allowing lake water to flow into the glacier. However, a connection must also exist between the lake and the glacier for drainage to commence. In most cases ice-dammed lake drainage leaves the glacier intact, but complete ice-dam removal may take place where the lake volume is large relative to ice dam volume. The timing of ice-dammed lake drainage is frequently controlled by the retreat and advance of glaciers. Glacier thinning and retreat often allow the initiation of cycles of lake drainage (**Figure 6**). Jökulhlaup magnitude decreases during each cycle as impounded lake volume decreases during glacier retreat (**Figure 6**).

Glacier retreat within high mountain regions often creates highly unstable moraine-dammed lakes, which are prone to sudden failure and flood generation. Calving of glacier ice into these lakes can generate waves, which overtop and then incise the moraine dam, allowing the extremely rapid development of a breach, facilitating catastrophic evacuation of lake water. Melt out of buried ice within moraine dams may take decades, and it is common for moraine-dammed lakes to exist for considerable periods before drainage. Once a moraine dam has been breached, only a subsequent glacier advance can reinstate the dam.

Landslides can generate floods in two ways. Firstly, rapid input of landslide debris to lakes can generate displacement waves. The best-known example of such a flood was at the Vaiont reservoir in Italy, where a landslide generated a large displacement wave that washed up a hillside and over the dam. In Iceland, a rockfall generated a displacement wave known as the Steinholtshlaup, which constituted one of the most rapid flood-rising stages experienced in Iceland. Landslides frequently dam major valleys allowing the formation of large lakes. Dam failure may occur immediately after formation, or may be delayed, possibly for decades, until reservoir volume has built up to a sufficient level for drainage to occur.

Bedrock and sediment dams are also known to fail via catastrophic enlargement of their spillways, leading to large outbursts. The drainage of Lake Bonneville in the USA during the Late Quaternary generated an outburst with a peak discharge of approximately 1×10^6 m^3 s^{-1}, whilst draining 4800 km^3 of water over several months. In New Zealand the

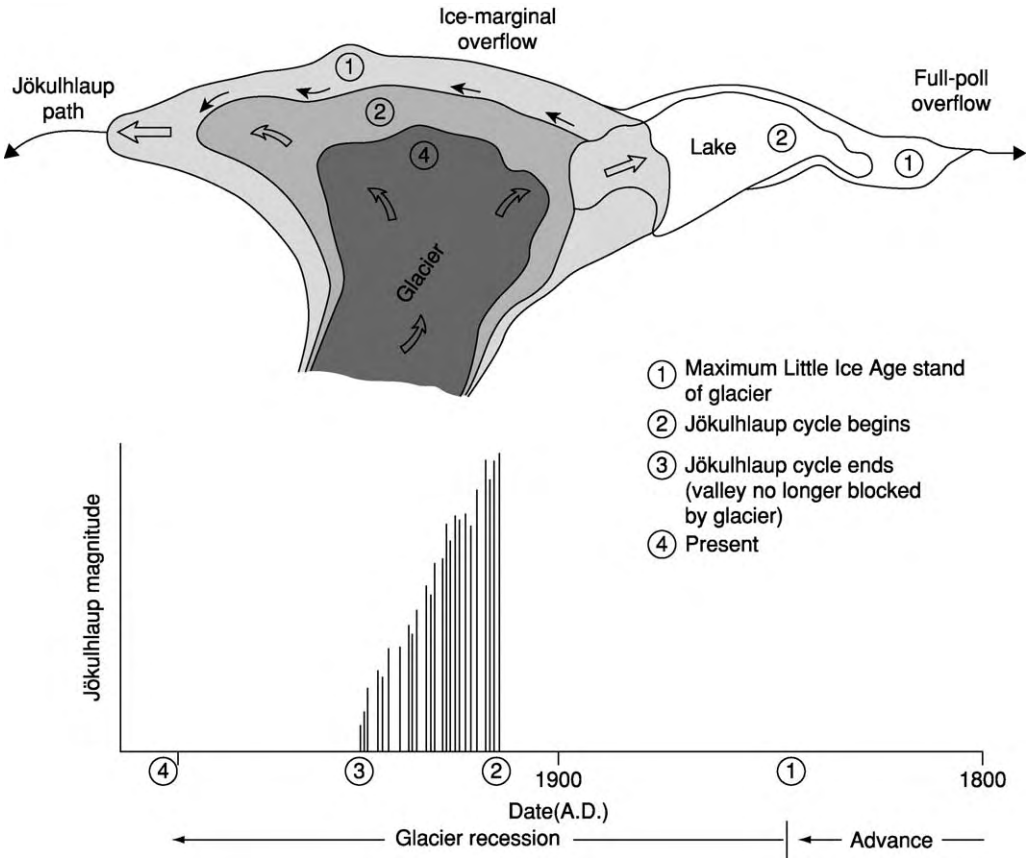

Figure 6 The jokulhlaup cycle. The upper diagram illustrates the advance and retreat of a glacier during the Little Ice Age. Ice positions 17 4 in the upper diagram correspond with the timescale illustrates in the lower diagram. The cycle of jokulhlaup drainage occurs as the glacier is thinning and retreating from its advance. Jokulhlaup magnitude within the cycle decreases as ice dammed lake volumes decrease progressively during glacier retreat. After Evans SG and Clague JJ (1994) Recent climatic change and catastrophic geomorphic processes in mountain environments. *Geomorphology* 10: 107 128.

failure of caldera Lake Taupo generated a peak discharge of $1.7–3.5 \times 10^5\,m^3\,s^{-1}$, draining a total of $20\,km^3$ of water. The failure in Alaska of Aniakchak caldera ($3.7\,km^3$) generated a peak discharge of $1 \times 10^6\,m^3\,s^{-1}$. Deposition of alluvial fans at tributary junctions within ephemeral systems can block subsequent flood flows, resulting in enhanced flood peaks due to sudden dam failure.

Catastrophic Flood Characteristics

The discharge hydrograph is the most important characteristic of any flood as it defines flood duration and magnitude. Flood magnitude can be described by the peak discharge and total flood volume. Hydrograph shape reflects flood generation mechanisms and drainage basin characteristics. Different flood generation mechanisms result in different hydrograph types (Figure 7). Dam failure due to rapid breach development generates very rapid rises to peak discharge (Figure 7A). Volcanically generated (volcanoglacial) jökulhlaups also produce extremely rapid rises to peak discharge due to extremely high ice melt rates and glacier hydrofracturing. Rainfall-generated floods in ephemeral river-systems also display rapid rises to peak discharge followed by more sedate waning flow stages. Many jökulhlaup hydrographs exhibit gradual rising stages characterized by an exponential shape (Figure 7B). These jökulhlaup hydrographs are controlled by a positive feedback between meltwater flow and tunnel enlargement (Figure 7B and 7E). The rate of exponential discharge increase is controlled by ice-dammed lake water temperature, the length of the tunnel routeway, and height difference between the lake surface and the outlet. Flood hydrographs with multiple peaks can represent either nonsynchronous response of various subcatchments, complex channel networks to runoff, or temporary channel blockage and subsequent release. For volcanoglacial jökulhlaups, multiple peaks may be generated by peaks in volcanic activity. Similarly 'heartbeat' events associated with temporary tunnel blockage are characterized by a sudden fall and then rise in discharge (Figure 7C). Sudden onset

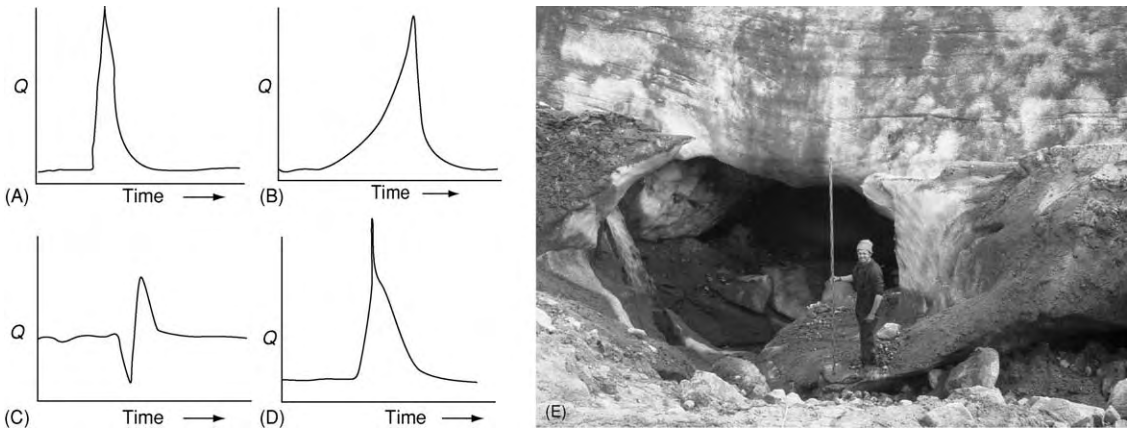

Figure 7 Flood hydrographs with contrasting shapes. (A) Rapid rise to peak discharge associated with sudden dam failure and glacier outburst floods associated with sheet flow and hydrofracturing. (B) Exponential rise to peak discharge is typical of floods where rising stage is controlled by progressive enlargement of ice tunnels. (C) 'Heartbeat' event where temporary channel blockage results in a reduction in discharge followed immediately by a flood peak associated with dam failure. (D) Composite flood hydrograph characterized by the superimposition of one flood wave on top of another. (E) Jokulhlaup tunnel inlet generated by the drainage of a small ice dammed lake in West Greenland.

jökulhlaups may fill ice-marginal basins within minutes, creating short-lived ice-dammed lakes, which in turn drain to produce a composite flood hydrograph where one flood peak is superimposed upon another (Figure 7D).

Catastrophic floods are often characterized by a dearth of direct process measurements. Most hydraulic variables are extrapolated from geomorphological and sedimentary evidence using hydraulic modelling techniques developed for lower magnitude flows. Calculated velocities are often extremely high ($<40\,m\,s^{-1}$), often an order of magnitude greater than that for nonflood flows. Flow depths in excess of 500 m have been reconstructed for the largest floods on earth. Flood flows commonly vary between sub- and supercritical states. Shear stress and unit stream power provide useful indicators of a flood's capacity to erode channel boundaries and to transport sediment. Flows are commonly macroturbulent, and involve considerable aeration of the flow (Figure 8A). Large-scale roughness generates tornado-like vortices known as 'kolks', which have the capability to pluck large fragments from the bedrock surface. High-flow velocities and violent flow separation can generate local instantaneous reductions in the vapour pressure of water, allowing the formation of water vapour bubbles within the flow. Violent collapse of the vapour bubbles releases large amounts of energy, enabling the pitting of bedrock surfaces. Flood flows commonly superelevate towards the outside of channel bends and exhibit cambered surface profiles (Figure 8B). In many cases it is very difficult to define the flood surface due to unsteady and macroturbulent flow conditions (Figure 8A and 8B). Flood peak discharges commonly attenuate downstream due to resistance effects and transmission losses within some systems. Floods and displacement waves with high peak discharges and relatively modest volumes show the highest rates of downstream attenuation.

High flood powers and bed shear stresses allow grain sizes that would normally be transported as bed load to be transported as either suspended or

wash load within the flow. A jökulhlaup in Greenland with a discharge of 1100 $m^3 s^{-1}$ and powers of 3000 $W m^{-2}$ transported sediment of up to 10 cm in diameter in suspension, whilst the November 1996 jökulhlaup in Iceland with a peak discharge of 45–53 000 $m^3 s^{-1}$ and a power of 40 000 $W m^{-2}$ was capable of moving 2-m-diameter boulders in suspension. These modern jökulhlaups only maintained such high stream powers locally and for a short duration. Giant Quaternary outbursts in the Altai Mountains of Siberia and from glacial Lake Missoula have generated flood powers of 10^5–10^6 $W m^{-2}$ over larger areas.

As erosional and sediment transport capacities are so high during floods, large amounts of sediment can alter flow conditions. Typical alterations include reduction of resistance to flow as sediment in transport blankets roughness elements, reductions of fall velocities of sediment in transport, and transition to upper flow regime bed conditions.

Sediment concentrations often exceed the values normally associated with fluidal flow conditions and become hyperconcentrated. Sediment bulking during floods may transform floods into debris flows, which have their own strength. Debris flow deposits directly reflect the entire flow thickness in contrast to water flood deposits, which only represent what was deposited at the bed of the flow. Sediment concentrations within catastrophic floods may also increase towards the base of the flow, leading to hyperconcentrated near-bed conditions, often referred to as a traction carpet. This may account for the deposition of units more typical of hyperconcentrated flow conditions by seemingly turbulent high-energy fluvial flows.

High sediment concentrations within floods can only be achieved if there is sufficient sediment readily available for entrainment. Sediment availability to catastrophic floods varies, depending upon flood generation mechanism, lithology, and weathering environment. Sediment bulking is usually most efficient within catchment headwaters, where precipitation inputs are high and stream and hillslope systems are

Figure 11 Subglacially eroded rip up clast deposited by the November 1996 jokulhlaup near to the glacier margin.

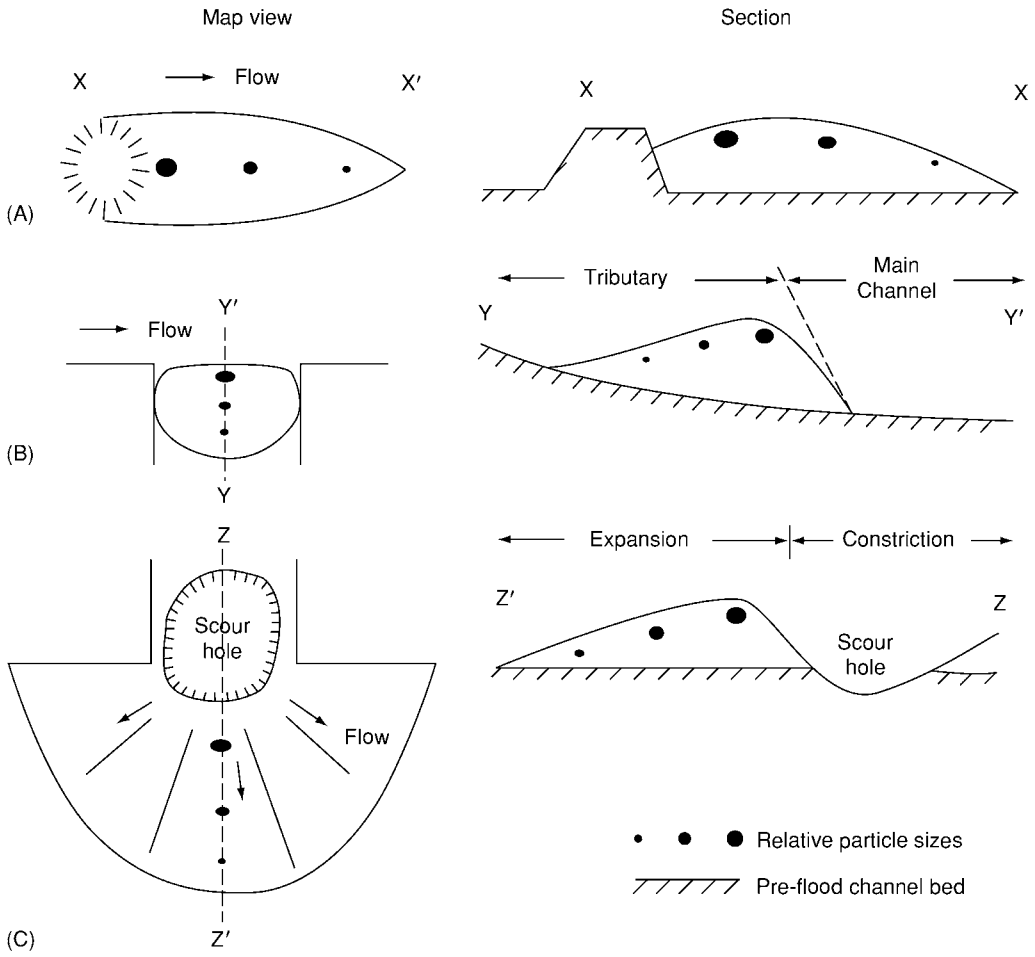

Figure 12 Role of channel geometry in controlling the morphology and sedimentology of flood deposits. Adapted from Baker (1984) Flood sediments in bedrock fluvial systems. In: Koster EH and Steel RJ (eds.) *Sedimentology of Gravels and Conglomerates*. Canadian Society of Petroleum Geologists Memoir 10, pp. 87 98.

coupled. In many cases, hillslope failure may transform directly into debris flows. Some floods may acquire large volumes of sediment at source. Jökulhlaups associated with subglacial volcanic eruptions contain large volumes of primary eruption products, and dam-failure outbursts are often heavily freighted with sediment eroded from the dam breach. Sediment concentration during nonvolcanic glacier outburst floods is usually supply limited, as large volumes of water dilute a finite volume of available sediment. Catastrophic floods can also bulk-up by eroding their channel boundaries.

Sediment transport during catastrophic floods exceeds nonflood transport rates by orders of magnitude. Such flows are able to access sediment sources beyond the reach of lower magnitude flows and are capable of exceeding thresholds for bedrock erosion. However, infrequent high-magnitude events may not be the dominant transport mechanism in catchments dominated by high productivity of fine-grained sediment.

Geomorphic and Sedimentary Impact

Flood impacts can be either erosional or depositional, with the occurrence, distribution, and character of specific impacts controlled by the spatial and temporal distribution of stream power. Erosional landforms are generated when flood power exceeds channel resistance to erosion. Flood flows not only have to exceed local erosional thresholds, but must persist long enough to generate distinctive suites of erosional landforms. Repeated Late Quaternary outburst floods from glacial Lake Missoula have created the world's most spectacular erosional landscape. Within the Columbia gorge system erosional landforms have been associated with various stream power ranges. Only the largest of the Missoula floods had sufficient power and duration to develop the entire suite of erosional features: streamlined hills, stripped basalt, butte and basin scabland, and inner channels, in order of ascending stream power (Figure 9). Although landscapes of flood erosion owe their detailed morphology to the interaction between hydraulic processes and local bedrock strength and structure, bedrock channels exhibit numerous common characteristics. Cataracts are common where flood flows excavate a more resistant cap-rock, allowing for rapid headward migration of a plunge pool (Figure 10A). Large-scale potholes are common where deep flood flows allow kolks to form. Where bedrock surfaces are stable, they can be abraded by sediment in transport to produce a range of erosional bedforms (Figure 10B). The widespread distribution of bedrock bedforms in parts of North America has been interpreted as the product of catastrophic subglacial sheet floods. Large channels and lake overspills containing large-scale and widespread erosional evidence are common in many

Figure 13 (A) Oblique aerial photograph of valley confined outwash plain subject to jokulhlaups showing proximal expansion bars. (B) Photograph of 1987 jokulhlaup flows across a outwash plain in West Greenland 1987. Note high energy proximal flows expanding from a flow constriction and relatively tranquil flows in the distal area related to backwater ponding upstream of a flow constriction.

parts of the world subject to catastrophic floods. As well as eroding bedrock, floods have the potential to incise unconsolidated sediment. The November 1996 jökulhlaup in Iceland excavated large volumes of subglacial sediment, providing enormous numbers of rip-up clasts to the ice proximal outwash plain (**Figures 11** and **15B**). Large buried tunnel valleys in former glaciated regions have been attributed to Quaternary catastrophic floods. Large tracts of the channelled scablands inundated by the Late Quaternary Missoula outburst floods have eroded into loess, generating large-scale streamlined islands.

Catastrophic flood deposition is controlled by spatial and temporal variations in stream power. Downstream variations in flood channel morphology control stream power variations, resulting in zones of erosion, nondeposition, or deposition. Flood deposition within confined bedrock channels is limited either to the flood-waning stage or to specific locations such as the mouths of tributary channels, embayments, or the lee of obstacles to flow (**Figure 12**). Large bars radiate downstream from flow expansions and commonly surround a scour hollow or zone of nondeposition. Boulder ridges or 'berms' are also frequently deposited at sudden flow expansions at the boundary between the main and secondary flows (**Figures 12** and **13A**). Flow constrictions commonly generate considerable backwater effects, which build up progressively during the rising stage and subside during the waning stage (**Figure 13B**). Deposition takes place into the backwater zone under progressively lower energy flow conditions (**Figure 13A** and **13B**). High-stage backwater deposits are reworked by higher energy waning stage flows. If during the flood the channel constriction is widened by erosion, the backwater effect will reduce substantially and subsequent backwater effects will be reduced. Unconfined flood flows tend to be shallower with high rates of flow dissipation consequently, resulting in thinner flood units.

Although catastrophic flood deposits are commonly identified by the presence of anomalously large clasts, indicative of high sediment transport capacities, this only applies where coarse-grained sediment is available for entrainment. However, for many fluvial systems coarse-grained sediment is supply limited. Other criteria are therefore needed to characterize flood deposits. Landforms and deposits may be interpreted to be of flood in origin if they are sufficiently large in scale relative to those associated with normal flows within the same fluvial system. Giant flood bars often display large-scale cross-stratification, which could easily be misinterpreted as delta foreset beds. Flood units are usually laterally extensive and contain a relatively uniform suite of clast lithologies compared with nonflood units. Flood deposits often contain rip-up clasts composed of blocks of sediment eroded from the river bed or banks (**Figures 11** and **15B**). Mud clasts are common within ephemeral river systems where silts and clays are ripped up during the flood-rising stage. Glacier proximal jökulhlaup deposits commonly contain rip-ups derived from subglacial fluvial excavation, which comprise sheared and folded subglacial diamicton or older outwash sediments (**Figures 11** and **15B**). Large-scale ice block obstacle marks and their associated secondary melt-out structures are diagnostic of high-magnitude glacier outburst floods (**Figure 14**). Simultaneous progradation, aggradation, and backfilling within the ice-marginal zone are

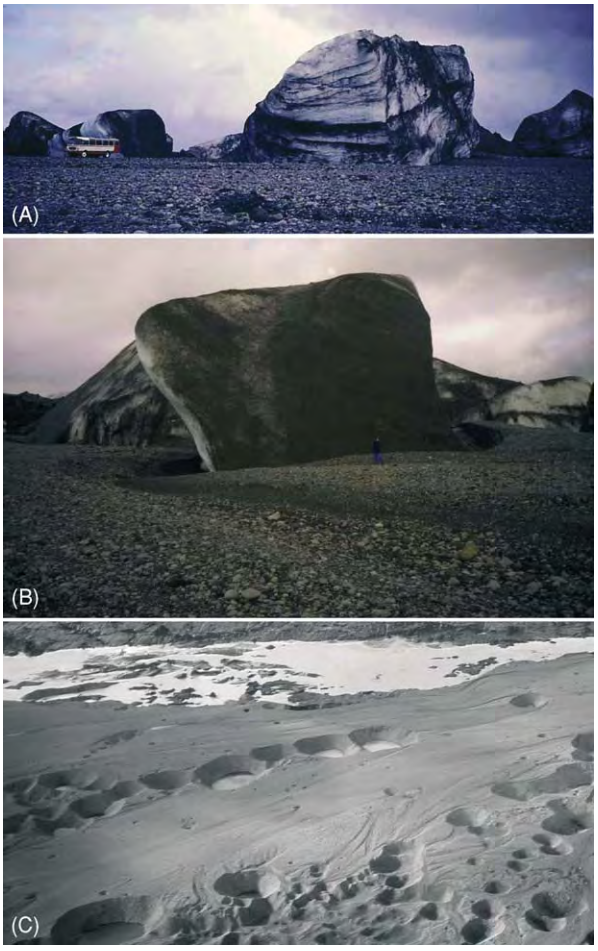

Figure 14 (A) Large ice block transported over 1 km by the November 1996 jokulhlaup on Skeiðarársandur, Iceland. (C) Aerial view of kettle holes and obstacle marks four years after the jokulhlaup.

characteristic of high-magnitude events, capable of simultaneous channel erosion and infill.

Catastrophic flood units vary in sorting, texture, and matrix content, depending upon the size distribution of available sediment as well as its rate and mode of emplacement. Traction deposition generally results in very poorly sorted, cohesionless, clast-supported deposits, which commonly display poorly defined imbrication (Figure 15A). Stream powers calculated for many catastrophic floods are high enough to carry boulder-sized sediment in suspension. Rapid rainout and deposition from suspension at the mouth of tributary valleys commonly results in more matrix-rich deposits, which are typical of proximal eddy bar deposition (Figure 15B). More distal suspension sedimentation forms stacked upward-fining sequences similar to turbidites within lacustrine and marine environments (Figure 15C). Coarsening-upward successions are commonly deposited on the rising flood stage, reflecting deposition from transport-limited flood flows (Figure 15D).

Floods commonly access large volumes of sediment, allowing their transformation from water flood to hyperconcentrated flows (Figure 16). The presence of laterally extensive deposits consistent with deposition from hyperconcentrated flows indicates catastrophic floods. Although debris-rich floods may be commonplace within alluvial fan and ephemeral systems, within most river systems only exceptional floods have the capacity to generate hyperconcentrated flow conditions. Bedforms within fluvial systems dominated by repeated floods contain reactivation surfaces, which indicate progressive deposition during a series of high-magnitude floods interrupted by interflood pauses. Reactivation surfaces can also be identified by dateable palaeosols and tephra horizons, which can help in the reconstruction of Palaeo flood magnitude and frequency.

Figure 16 Massive fine grained unit on Sólheimasandur, Iceland interpreted as the product of a hyperconcentrated jokulhlaup.

Catastrophic floods deliver large volumes of sediment to the marine environment where they generate turbidity currents capable of transporting sediment offshore for up to 10^3 km. Turbidite units of up to 60 m in thickness identified in the offshore sedimentary record of the north-eastern Pacific Ocean have been attributed to outbursts from glacial Lake Missoula. In Iceland, volcanogenic jökulhlaups play an important role in the supply and transport of sediment to southern Iceland shelf and adjacent marine basins. Giant, sediment-rich jökulhlaups from Katla subglacial volcano dominate the offshore sedimentary record along most of Iceland's southern coast.

Controls on Catastrophic Flood Impact

Flood generation mechanisms, sediment availability, and routeway characteristics are the main controls on flood impact (Figure 1). The long-term impact of any flood may, however, depend upon the ability of more frequent, lower magnitude events to rework flood deposits, thereby allowing channel recovery. If flood recurrence interval is greater than the time required for recovery, then floods may be considered to have not had a long-term impact. Conversely, if flood recurrence interval is less than recovery time, then the channel will not be able to recover from the impact of one flood by the time the next flood occurs. Some flood impacts may, however, be regarded as being irreversible, in instances where high flood sediment calibre makes between-flood reworking impossible or where bedrock erosion occurs. Large-scale flood excavation of bedrock channels, such as those associated with glacial Lake Missoula outbursts, represent a long-lasting impact. Similarly, slackwater deposits associated with extremely high-magnitude flows will also have a high preservation potential if intervening flows with tributary streams are incapable of reworking flood deposits.

Conclusions

Catastrophic floods can be generated by a range of mechanisms within a number of hydroclimatic environments. Although the impacts of floods can be defined in a number of ways it is crucial that we assess carefully whether a flood is truly catastrophic. Continental-scale catastrophic flood landscapes can be identified in association with the growth and decay of ice-sheets during repeated glacial and interglacial cycles. Some floods were large enough to influence ocean circulation, thereby impacting on the climate system. Better understanding of the causes, characteristics, and impacts of catastrophic floods is crucial for the identification and mitigation of hazards and for interpretation of the sedimentary record.

Deep Water Processes and Deposits

D J W Piper, Geological Survey of Canada, Dartmouth, NS, Canada

Introduction

Deep water beyond the continental shelves covers 63% of the Earth's surface. About one-seventh of this deep-water area, on the continental margins, receives a direct supply of terrigenous sediment from the continents, and this accounts for the majority of deep-ocean sediment deposits, including the largest Quaternary sediment accumulations on the planet, which occur beneath continental slopes and on submarine fans (Figures 1 and 2). Beyond the continental margins, the pelagic realm slowly accumulates biogenic material and far-travelled clays (Figure 3). The deep oceans are primarily a depositional environment, and that deposition is strongly influenced by ocean-floor morphology. Deep trenches at subduction zones and deep abyssal plains at passive continental

margins trap terrigenous sediment, preventing turbidity currents from reaching the greater part of the ocean floor. The large-scale morphology of the ocean is controlled principally by tectonic processes: seafloor spreading and its associated thermal effects, faulting, and volcanism; the complex rifting of continents in the early stages of ocean formation; and the even more complex effects of subduction and eventual closure of oceans. This article reviews the processes that lead to sediment distribution in the ocean and the large-scale distribution of these sediment deposits.

Technological advances in swath bathymetry in the past decades have greatly improved our understanding of the morphology of the seafloor. Given the vastness of the ocean and the technological challenges involved in monitoring seafloor processes, morphology is an important guide to the processes acting on the seafloor. Seismic-reflection profiling is an essential tool for evaluating the distribution of seafloor facies and hence inferring processes: the growing availability of three-dimensional seismic has revolutionized our understanding of continental-margin sedimentation. Direct sampling of deep-water sediments is limited to piston cores, which rarely penetrate more than 20 m, and some 1000 scientific boreholes, which are hundreds of metres long, drilled by the Ocean Drilling Program and its predecessors.

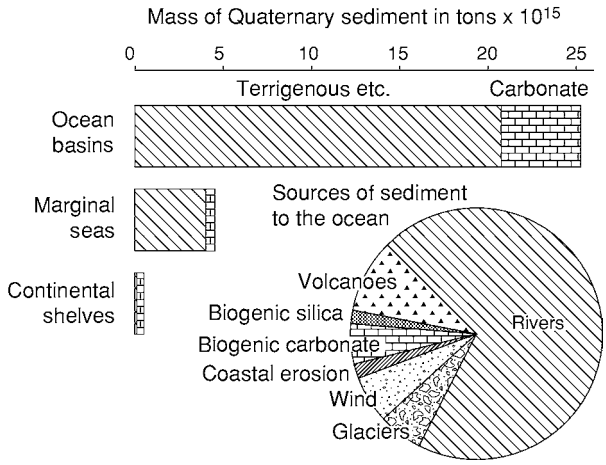

Figure 1 The volume of Quaternary sediment in the ocean, showing that the bulk of the deposition is in the deep ocean. The principal sediment sources are rivers, with volcanoes, glacial and wind transport, and biogenic carbonate also being important.

Sediment Sources

Rivers provide the principal input of sediment into the oceans (Figure 1). At high latitudes, terrigenous

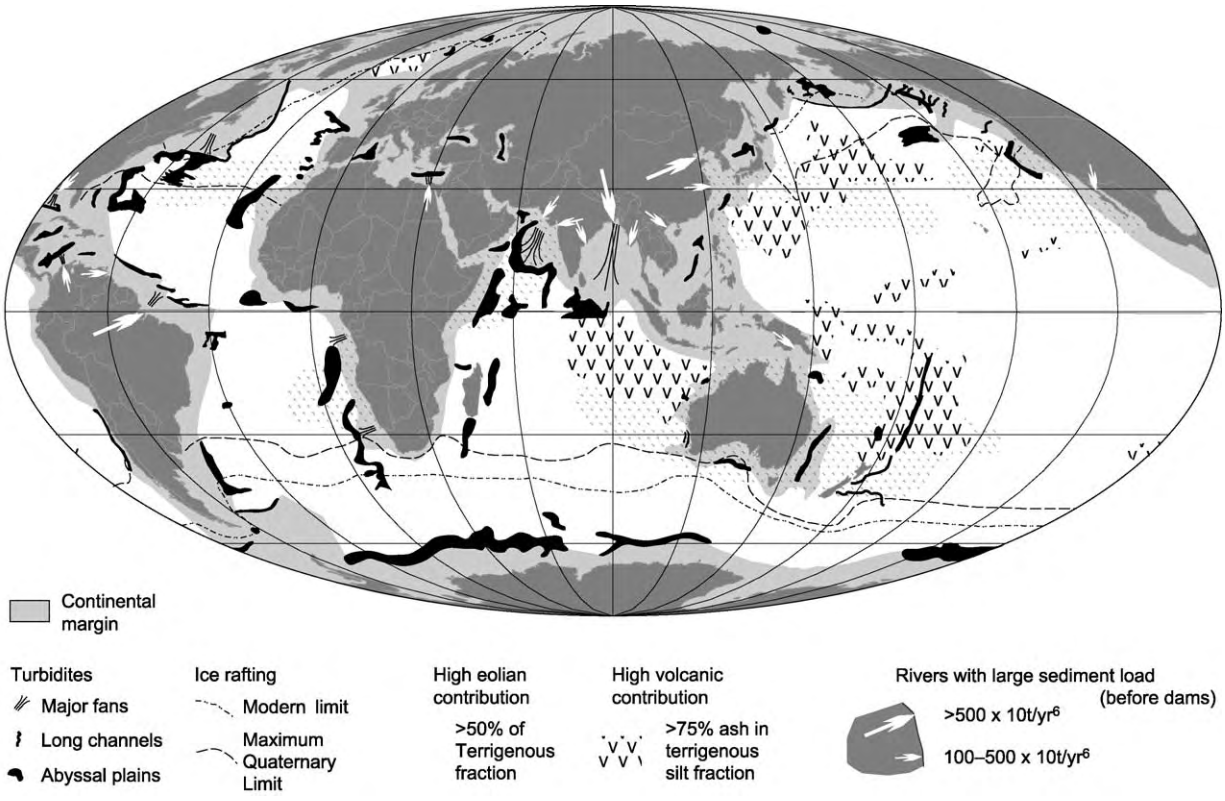

Figure 2 Terrigenous sediment in the deep ocean.

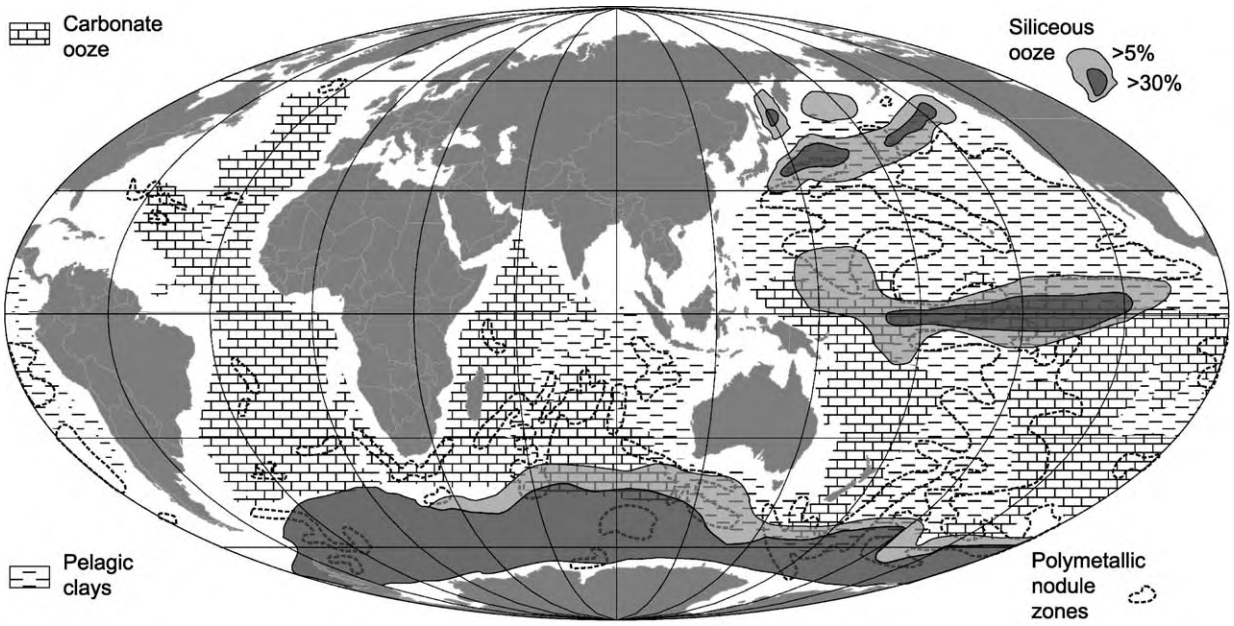

Figure 3 Distribution of the principal types of pelagic sediment.

sediment is supplied by sediment derived from subglacial melt water discharge and directly from ice, including meltout from icebergs thousands of kilometres from their source. In mid-latitudes, wind-blown dust (exceptionally including sand) is a significant component of deep-ocean sediment. Locally, volcanic material is a major component of seafloor sediment. Pelagic sediments (*see* **Sedimentary Rocks:** Deep Ocean Pelagic Oozes) consist principally of the skeletal material of pelagic organisms, notably calcium carbonate from Foraminifera, Coccolithophoridae (coccoliths or nannofossils), and pteropods, and opaline silica from Radiolaria, diatoms, and silicoflagellates. In oceanic areas with low sedimentation rates, various authigenic minerals form *in situ* in the sediments or on the ocean floor and may become significant components of the sediment. These include: phosphorites formed in slow-sedimentation environments in areas of active upwelling; metal-rich sediments and iron oxides associated with hydrothermal discharge in areas of active volcanism, particularly mid-ocean ridges (*see* **Tectonics:** Hydrothermal Vents At Mid-Ocean Ridges); manganese nodules and crusts of iron–manganese oxides, which precipitate in areas of slow sedimentation on the deep ocean floor (*see* **Sedimentary Rocks:** Oceanic Manganese Deposits); zeolites, which form principally from the alteration of volcanic ash and glass; and barite, which may be related to either hydrothermal activity or high organic productivity.

The dispersal of terrigenous sediment from various sources can be tracked by studying sediment petrology. The gross distribution of clay minerals within the ocean has long been used to infer sediment source and dispersion. In recent years, the signature of radiogenic isotopes (particularly lead and neodymium) and mineral geochronology in detrital terrigenous sediment have been used to understand further source and dispersion, including the tracking of ice-rafted detritus and aeolian dust. Tephra beds have been characterized geochemically and mineralogically, both to identify source and as stratigraphic markers.

Sediment Transport Processes in Deep Water

The transport of sediment to deep water involves both the normal processes of oceanic circulation and episodic sediment gravity flows. The resulting terrigenous deposits depend on the supply of sediment from the continent and shallow continental margin and on the complex interaction between flows and ocean morphology.

Surface currents in the ocean are primarily wind-driven, whereas overall circulation in the oceans is a consequence of density differences caused by temperature and salinity variations in the ocean water. Deep circulation is driven by the sinking of cold saline water in the North Atlantic Ocean and around Antarctica, with net upwelling in the North Pacific Ocean. The effect of the Coriolis force is to intensify ocean circulation on the western sides of oceans, where the thermohaline circulation generally

parallels the continental margin. Thus, for example, on the western side of the North Atlantic Ocean a powerful surface current (the Labrador Current) strongly influences the seafloor to water depths of 1500 m, and the deep Western Boundary Undercurrent of cold saline water derived from the Norwegian and Greenland Seas flows southwards at water depths of 3500–5000 m off the coast of Canada and the USA. Constricting topography results in the intensification of currents, for example around and over seamounts, through major fracture zones in the mid-ocean ridge system, and where microcontinental fragments such as Rockall Bank or the Campbell Plateau create constrictions.

The mean flow in both surface currents and the thermohaline circulation is generally a few centimetres per second, but locally the flow can be complex and energetic, for example in the large eddies in the Gulf Stream and Kuroshio, the former creating the 'abyssal storms' measured at the Hebble site in the Western Boundary Undercurrent of the North Atlantic, where velocities exceed $0.2\,m\,s^{-1}$. Similarly high velocities are found in topographical constrictions, for example in the Gulf of Cadiz, where Mediterranean Overflow Water exits the Straits of Gibraltar. Such flows are capable of eroding fine-grained seafloor sediment, may leave lag sands and gravels, and produce a variety of abyssal bedforms. Suspended sediment derived from the continental margin or suspended by ocean currents may be advected long distances as nepheloid layers – zones of higher amounts of particulate matter in the ocean circulation. In lower energy areas, this suspended matter settles to form sediment drifts. Boundaries between different thermohaline water masses are commonly marked by zones of higher turbulence and internal waves, which lead to higher amounts of suspended particulate matter and, in some cases, to erosion where they interact with the continental slope or with seamounts.

Organic matter sinking from the surface waters of the ocean is progressively oxidized, thereby depleting mid-level waters in oxygen and at the same time returning many nutrients to seawater. These nutrients become available in areas of upwelling. Deeper waters therefore have higher concentrations of dissolved carbon dioxide, with the highest concentrations being found in the older deep water of the Pacific Ocean. Deep waters of the Pacific Ocean are consequently undersaturated in calcium carbonate, leading to the dissolution of biogenic carbonate. Most dissolution of opaline silica occurs during oxidation of the protoplasm, but further dissolution takes place in undersaturated deep waters.

The wind-driven surface circulation is sedimentologically important in dispersing surface plumes derived from rivers and glacial margins. In addition, icebergs are transported in the surface circulation and, as they reach warmer waters and melt, they deposit ice-rafted detritus on the seabed. During Pleistocene Heinrich events in the North Atlantic Ocean, surface melt-water plumes were dispersed 2500 km south-eastwards from Hudson Strait and icebergs were dispersed even farther by the surface circulation.

Atmospheric circulation is a lesser agent of sediment transport to the deep ocean. Volcanic eruptions contribute fine volcanic ash through both troposphere plume transport, which may extend for thousands of kilometres, and worldwide distribution of fine ash that reaches the stratosphere. Dust derived from deserts is the principal source of terrigenous material in much of the mid-latitude pelagic realm.

Infrequent gravity-driven processes, including turbidity currents, debris flows, and submarine landslides, transport the largest volumes of sediment from the shallow continental margins to the deep sea (*see* **Sedimentary Processes:** Particle-Driven Subaqueous Gravity Processes). A turbidity current is a density current in which the denser fluid is a sediment suspension. Turbidity currents may be initiated by many processes: all that are needed are a mechanism to put sediment into suspension and a steep slope to maintain the flow. Thus, hyperpycnal flow of rivers, glacial outburst floods (jökulhlaups), storm resuspension of shelf or beach sediment (*see* **Sedimentary Environments:** Storms and Storm Deposits), and in-mixing of ambient water into a debris flow will all initiate turbidity currents on steep slopes. Potential energy is converted to kinetic energy as the flow accelerates down the continental slope, commonly eroding the seafloor and eventually depositing sediment on the deep ocean floor. Processes within an individual turbidity current may range from hyperconcentrated flow at the head and base of the flow to normal turbulent sediment suspension in the upper part and tail of the flow, ultimately producing a low-density suspension, which contributes to nepheloid-layer dispersion by the thermohaline circulation. Turbidity currents occur every 1–10 years in steep river-fed basins with narrow shelves and off large shelf-crossing rivers, but only every 100–1000 years on most continental margins and every 1000–10 000 years on distal abyssal plains.

The largest submarine landslides involve debris avalanches of blocks tens to hundreds of metres in size, which flow in a laminar fashion and scour deep grooves into the seafloor. Slide blocks overlying sands liquefied by seismic shaking and muddy rotational slumps may break up and in-mix water to evolve into debris flows. Large coherent slides may plough

into seafloor sediments, and outrunner blocks may extend far beyond the main slide; the movements of both are facilitated by hydroplaning.

Subaerial volcanic islands, most importantly in island arcs, contribute sediment to the marine realm by proximal fall-out of ash and by pyroclastic flows entering the sea and forming turbidity currents. Flank collapse of volcanoes, both subaerial and submarine, produces widespread and voluminous debris avalanches around volcanic islands, the largest exceeding 5000 km^3. Submarine volcanic eruptions may be effusive or explosive, producing lava flows, large quantities of hyaloclastite, and pumice. Loose material will tend to move downslope by mass-transport processes and may also be modified by bottom currents.

The biota plays an important role in deep-ocean sedimentology. The skeletons of planktonic organisms are the major component of pelagic sediments. Pelagic sediments are generally thoroughly bioturbated, as are hemipelagic muds. Microbial processes are important in controlling the chemistry of seawater and in the development of authigenic pelagic sediments. Coral reefs and both cold and hot vent communities create large biogenic rock masses in deep water.

Sediment Nomenclature

Different nomenclature schemes are applied to terrigenous sediments of the continental margin and to pelagic sediments of the open ocean. The standard nomenclature for terrigenous sediment is based on grain size, with the Shepard and Folk systems (Figure 4) being the most widely used. The term 'mud' is widely used for sediment comprising principally silt and clay. Standard pyroclastic terms are applied to submarine pyroclastic deposits, and terminology applicable to shallow-water limestones is generally also applied to deep-continental-margin limestones. For pelagic sediments, the Ocean Drilling Program scheme is widely used (Table 1). The term 'ooze' is applied to sediment with a biogenic component exceeding 60% and is preceded by the names of all components making up more than 30% of the sediment, for example foraminifer–nannofossil ooze (often abbreviated to foram–nanno ooze). Minor components (10–30%) are prefixed to the sediment name with the term rich, e.g. zeolite-rich radiolarian ooze. Where the biogenic content is between 30% and 60%, the name is based on the predominant fossil and the appropriate textural name for the siliciclastic component, e.g. foraminiferal clay.

Several genetic names are widely and loosely used to describe marine sediments. Hemipelagic muds are highly bioturbated muds with less than 30% biogenic material that accumulate slowly from suspension

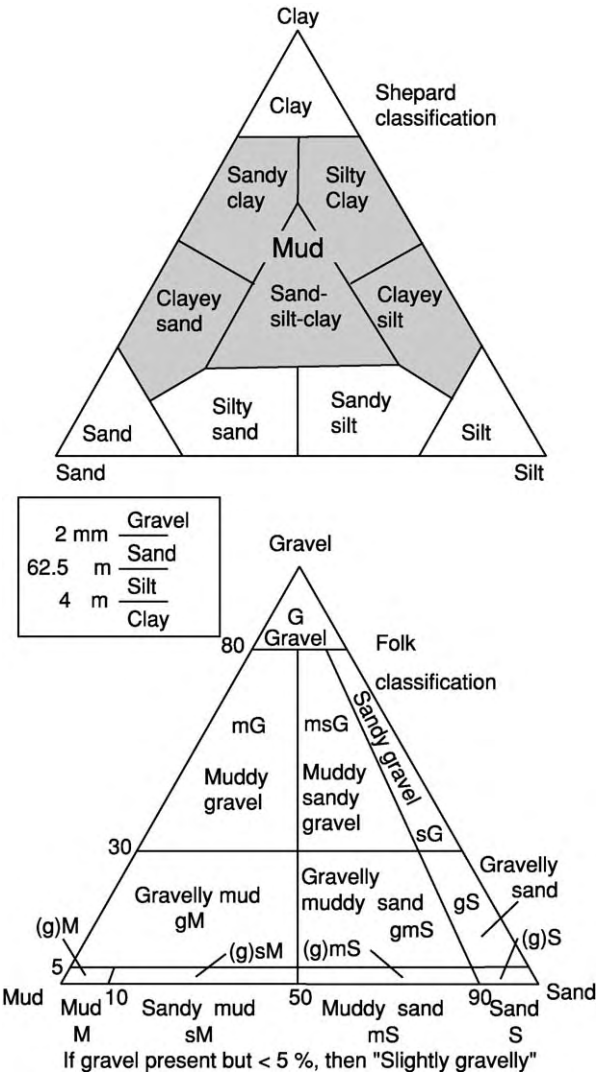

Figure 4 Shepard and Folk nomenclatures for terrigenous sediments.

fall-out of sediment that is either resuspended on the adjacent continental shelf or transported in nepheloid layers. The term turbidite is applied to sands, silts, and muds that are deposited principally from turbidity currents; their deposition is rapid, and bioturbation is sparse or absent. Sorted sands and gravels inferred to be deposited from hyperconcentrated flows are generally included in the term turbidite, although some authors have argued that the transport process resembles that of debris flows. Debrite is used for the blocky and poorly sorted deposits of debris flows, debris avalanches, and similar mass-transport processes. Deposits of contour-following bottom currents are generally called contourites (*see* **Sedimentary Environments:** Contourites); such deposits are most readily recognized from their morphological setting and from their character in seismic-reflection

Table 1 Nomenclature of pelagic sediments

EXAMPLES OF SEDIMENT NAMES					TYPE OF SEDIMENT		PRINCIPAL NAMED COMPONENTS
0	5	10	30	60	100 % biogenic material		
Silty clay, Clayey silt, Clayey sand, Clay (mud = silty clay and clayey silt)					TERRIGENOUS (continental margin)		Sand, silt clay
Clay	Zeolite-bearing clay	Nanno-rich clay			PELAGIC	Mainly abyssal brown clay	Clay, zeolite, ash, nannofossils, Radiolaria
	Foram-bearing clay	Foram-rich clay	Foram clay, nanno clay	Foram ooze, Foram-nanno ooze		Mainly biogenic carbonate	Foraminifera (forams), Nannofossils (nannos), Pteropods
	Diatom-bearing clay	Diatom-rich clay	Diatom clay	Diatom ooze, radiolarian ooze		Mainly biogenic silica	

profiles. The actual deposits are generally hemipelagic muds, although, in areas of strong current flow, coarser bioturbated winnowed deposits occur.

Continental Slopes

Continental slopes are regions of steeply sloping seafloor that lie between continental shelves and the deep ocean basins (Figure 2). Regional gradients are typically 2–5°, but locally slopes may be much steeper. Their large-scale morphology is a consequence of tectonic processes: the different elevations of continental crust and oceanic crust, the details of the original rift tectonics on passive continental margins, and the styles of subduction and accretion on convergent margins. This tectonic frame has been modified, most profoundly on older margins, by the deposition of continental-margin sediment, which locally may be more than 10 km thick over the basement. The position of the shelf break – the generally abrupt increase in gradient where the continental shelf passes into the continental slope – is in many places a direct consequence of sea-level lowering of around 110 m at the Last Glacial Maximum 21 000 years ago and marks the limit of progradation of shallow-marine sediments. In many cases the shelf break represents the seaward limit of delta-top progradation. In high latitudes, the shelf break may mark the seaward limit of continental ice-sheets. Where shelf-edge reefs are developed, the elevation of the shelf break is a consequence of a balance between sea-level rise and vertical reef accretion and is commonly close to present sea-level.

Continental slopes show a complex balance between erosional and depositional processes. The steep gradients promote sediment gravity processes, and the ocean-margin topography leads to strengthening of the oceanic circulation, particularly on the western sides of oceans. Deposition is principally of sediment that crosses the continental shelf and is therefore most important where shelves are narrow, shallow, and energetic and where sediment supply is high, notably seaward of major rivers and in areas of high carbonate productivity, including reefs. Regional deposition on the continental slopes off river mouths is from low-salinity surface plumes of fine-grained suspended sediment and from nepheloid layers developed from the settling of such sediment and resuspension of seafloor sediment. Storms and, on some shelves, tidal currents resuspend shelf sediment and advect it in suspension to the upper slope, where it is deposited as hemipelagic mud.

Slope morphology strongly influences sedimentological processes and products. Submarine canyons are widespread on many continental slopes, ranging in scale from the mighty Monterey Canyon, which is of similar dimensions to the Grand Canyon of the Colorado River, to small-scale slope gullies. Submarine canyons seaward of wide continental shelves are relatively inactive: the morphology appears to be a relict from sea-level lowstands. The canyons concentrate open-ocean water circulation, so that tidal flows may be sufficient to transport fine sands. These flows and the related upwelling also result in higher biogenic productivity than on the open slope. Sediment gravity flows, however initiated, will tend to flow within canyons, where they will accelerate on steep slopes.

Many canyons have their origins in river-mouth processes, both contemporary, as in the case of the Var Canyon in south-eastern France, and more generally at times of sea-level lowstands, when many rivers

discharged near the present shelf break. Direct hyperpycnal flow of sediment-laden floodwaters is the principal erosional process for smaller rivers with high bedload discharge; the role of hyperpycnal flows in very large rivers is uncertain. Glacial outburst floods erode particularly large submarine canyons, such as on the Laurentian Fan off south-eastern Canada. Studies of fjord deltas, a readily accessible modern analogue of shelf-edge rivers, suggest that failure of rapidly deposited river-mouth sediment may be equally important for initiating erosive turbidity-current flows. Canyons initiated by river-mouth processes at sea-level lowstands may undergo headward erosion as sea-level rises, as in the La Jolla Canyon off southern California and the Zaire/Congo Canyon of West Africa. In the La Jolla Canyon, beach sands accumulate in the canyon head under fair-weather conditions and are resuspended by storm waves that set up down-canyon turbidity flows that accelerate and erode canyon-filling sediment. Storm-wave transport of carbonate-platform sediment, especially through tidal passes in reefs, is important in initiating erosive turbidity-current flows on low-latitude carbonate margins. In general, turbidity currents will accelerate and erode on slopes of more than 2°, resulting in erosional undercutting of canyon walls, which promotes sediment failure. On some continental slopes, retrogressive sediment failure is an important process in the development of slope gullies. Slope gullies may also form as a result of density flows, derived from the fall-out of suspended sediment near river mouths and at ice margins, progressively coalescing to produce a badland-like drainage system.

The effects of sediment failure are widespread on many continental slopes, and failures are some of the most prominent morphological features on modern swath bathymetry of the continental slope. Many large-scale features, such as the 200 km wide Storegga Slide on the Norwegian margin, which failed 8000 years ago, are thought to have been triggered by earthquakes, by analogy with the 1929 Grand Banks failure on the Canadian Atlantic margin and the 1998 Papua New Guinea event. In many cases, including Storegga and the Cape Fear Slide on the US Atlantic margin, there is evidence that sediment strength was reduced by excess pore pressure due to the release of gas from gas hydrates. A particular type of large-scale sediment failure occurs on the slopes of oceanic volcanic islands, such as the Canary and Hawaiian islands, where progradation of steep volcanic edifices over weak deep-water sediments results in episodic catastrophic failure of the volcano flanks. Smaller-scale sediment failure is also widespread on continental slopes. On sediment-starved slopes, such as off New England (USA), failure may take place in Tertiary strata and principally involves slides. Retrogressive rotational slumps commonly evacuate many tens of metres of soft sediment on continental slopes producing blocky mass-transport deposits and debris flows. Sediment creep, such as that described from the South Korea Plateau, may eventually lead to failure along décollement zones tens to hundreds of metres below the seafloor.

Larger-scale gravity sliding of the upper few kilometres of the sediment column is the dominant feature of slope evolution seaward of some of the largest deltas in the world, notably those of the Niger and the Amazon, producing slope-parallel ridges and a prominent slope-toe escarpment. A similar large-scale morphology is produced on slopes with active salt tectonics, most spectacularly in the Gulf of Mexico, where the Sigsbee Escarpment is located at the toe of the slope and the slope morphology is dominated by salt diapirs and salt-withdrawal basins. Accretionary prisms at sediment-dominated convergent margins show large-scale morphological similarities to these complex passive-margin slopes, with thrust-controlled ridges and basins. In all of these complex slope settings, submarine canyons and valleys have irregular paths and variable degrees of incision. Slope failures are particularly common, as a result of tectonic oversteepening. Gas hydrates are particularly abundant on many accretionary margins, and fluctuations in the stability field with changes in bottom-water temperature or sea-level may trigger failures.

Overthrusting results in underconsolidated sediment with excess pore pressures, which commonly migrates to the surface to form mud volcanoes. Mud volcanoes are also common in prodeltaic environments with high sedimentation rates. Smaller-scale pockmarks – crater-like seafloor depressions a few tens of metres in diameter – indicate locations where gas or formation fluids are released, either catastrophically or quasi-continuously. In many areas, such pockmarks are developed along faults that leak formation fluids. Leaking hydrocarbons may also provide the energy source for biogenic 'cold-seep' communities on the continental slope.

Low-latitude carbonate platforms supply two main types of sediment to the continental slope. Where the platforms are fringed by rapidly growing reefs, collapse of the reef front results in debris avalanches. Storm transport of shelf sediment off a carbonate platform, particularly if it is focussed through passes in reefs, can produce turbidity currents, depositing well-sorted carbonate-rich sands and muds. At sea-level lowstands, with a narrow continental shelf, carbonate margins may behave like terrigenous margins, with the cutting of slope canyons that lead to small fan channels and lobes. At sea-level highstands,

carbonate production is generally much higher and may lead to progradation of the continental slope, channels on the lower slope, and turbidite deposition of carbonate sediment.

In contrast, the effect of lowered sea-level on mid-latitude continental margins was to increase sediment supply to the deep sea. In many cases, rivers discharged onto and prograded across a much narrower continental shelf, so that sediment was supplied directly to the high-gradient continental slope, down which it was transported by turbidity currents and mass-transport processes. At high latitudes, continental ice streams crossed many continental shelves, delivering glacial diamict directly to trough-mouth fans. Sediment delivery was particularly high during ice retreat in subarctic regions and was aided by abundant melt water. Sediment failures were triggered by glacio-isostatic earthquakes.

The Deep Continental Margin

The continental rise on a passive continental margin is a zone of sediment deposition on slopes that are typically between 1 : 50 and 1 : 500 and occurs beyond the steeper continental slope, which is commonly incised by canyons. The continental rise consists principally of submarine fans. An erosional submarine canyon leads to a submarine fan valley or channel, generally with depositional levees and a downslope decrease in channel depth. Depositional lobes are developed at the downslope termination of the channel and pass gradually into the flat abyssal plain, where the gradient of less than 1 : 1000 would be imperceptible to an observer on the ground. In more complex convergent continental margins there is generally more morphological control of deposition, but the same architectural elements are present: erosional canyons lead to leveed channels, channel-termination lobes, and, finally, basin or trench floors with more sheet-like stratigraphy. Channels may link two morphologically distinct basins, as in the case of the Biscay and Iberia abyssal plains. Indeed, these elements are also present on complex continental slopes with intraslope basins.

The channel systems are pathways for turbidity currents. Many channels are highly meandering; whether a channel is meandering or straight appears to be related to the gradient. On many passive-margin submarine fans, such as the Amazon, Zaire, and Bengal fans, channels change course abruptly through avulsion. Where channels are topographically constrained, for example Bounty Channel east of New Zealand, Surveyor Channel in the north-east Pacific, and the North-west Atlantic Mid-Ocean Channel in the Labrador Sea, an almost constant path has been maintained over thousands of kilometres. The lower parts of the turbidity currents transport sand through the channels and, owing to flow expansion, deposit it rapidly as channel-termination lobes. Only fine-grained sediment is transported to the distal parts of basins. The upper parts of the current entrain water, thicken, and spill over the levees, depositing overbank silts and muds. The cross-sectional areas of channels (kilometres wide, tens to hundreds of metres deep) and the velocities of turbidity currents estimated from cable breaks (2–19 m s ^{1}) testify to the size and power of the turbidity currents.

Sediment drifts are large sediment bodies constructed by deposition, generally of hemipelagic sediment, from the deep-water thermohaline circulation. The most powerful currents, in constrictions or adjacent to steep slopes, will commonly winnow or erode sediment, some of which may be of turbidite origin. This sediment, together with material introduced into nepheloid layers from the tails of turbidity currents or from resuspension on the shelf, is deposited slowly in areas of lesser current velocity. The North Atlantic Ocean, the Mediterranean Sea outlet, the eastern sides of the North and South American continents, the New Zealand margin, and the west side of the Antarctic Peninsula have particularly well-developed sediment drifts. Most have accumulated over many millions of years and have undergone alternating phases of deposition and winnowing or erosion as bottom-water circulation has fluctuated with changing climate. Many sediment drifts support mesoscale bedforms, including erosional furrows and sediment waves, with wavelengths of kilometres and heights of tens of metres.

Sediment Distribution in Pelagic Realms

Half of the Earth's surface is covered by pelagic sediment, yet study of its sedimentology is challenging because of its slow sedimentation rates and intense bioturbation. Some 47% of the pelagic realm is floored by foraminiferal ooze, 15% by siliceous ooze (mostly diatom ooze around Antarctica), and 38% by abyssal brown clay, in areas where there is total dissolution of biogenic material.

The distribution of biogenic oozes is a consequence of surface productivity, which is greatest in areas of upwelling, notably at the equator, on the western margins of continents, and at the Antarctic Convergence. Most biogenic material that reaches the

deep-sea floor does so through accelerated settling in the form of faecal pellets from zooplankton. Calcium carbonate is dissolved in deeper waters, particularly in the Pacific Ocean. The depth at which seafloor dissolution is complete is known as the carbonate compensation depth and fluctuates spatially and through time with changes in the thermohaline circulation.

Thus, foraminiferal and nannofossil oozes are widespread in the Atlantic and Indian oceans and on the East Pacific Rise but are absent over much of the northern and south-western Pacific Ocean (Figure 3). Sedimentation rates are generally 10–50 mm ka ^{1}. Diatom oozes occur beneath the high-productivity areas of the Antarctic Convergence and the extreme North Pacific Ocean, and radiolarian oozes occur beneath the Equatorial Divergence in the Pacific Ocean, with sedimentation rates of 2–10 mm ka ^{1}. Abyssal brown clays are most abundant in the Pacific Ocean, below the carbonate compensation depth, and have sedimentation rates of approximately 1 mm ka ^{1}. The authigenic components of pelagic sediments have been described above. Metalliferous sediments are generally restricted to small areas adjacent to sites of active volcanism but do cover a large area of the East Pacific Rise near the Galapagos Islands. Manganese nodules are particularly common in parts of the Indian and Pacific oceans with slow sedimentation rates. Poorly sorted ice-rafted detritus is an important component of pelagic sediment in the Arctic Ocean, the southern Ocean around Antarctica, and the northern North Atlantic Ocean.

The progressive subsidence of oceanic crust away from spreading centres results in a systematic stratigraphical succession in pelagic sediments. Thin metalliferous sediment and iron–manganese oxides may directly overlie oceanic crust. They are overlain by foraminiferal ooze deposited on the shallower seafloor of the mid-ocean ridge, with the sedimentation rate and the proportion of siliceous organisms depending on latitude. Eventually, subsidence of the oceanic crust may bring the seafloor below the carbonate compensation depth, and abyssal brown clays accumulate. Finally, subsidence and perhaps subduction will bring the ocean floor within reach of terrigenous sediment from the continent.

Fluvial Geomorphology

J Lewin and P A Brewer, University of Wales, Aberystwyth, UK

Introduction

Fluvial geomorphology is concerned with the creation of landforms by river processes through the removal and transfer of materials on Earth's surface. Process studies are rooted in a number of disciplines, the earliest identifying 'processes' as evolutionary time sequences in landforms. In later work, this has continued in such fields as the study of meander dynamics. Hydrology-based approaches have involved the identification of formative (generally high river flow) events and their frequency, together with empirical relationships between river channel dimensions and river flow parameters. Work in engineering hydraulics, including the need to design stable channels, has also been a source of process understanding. Such work has led on to detailed analysis of water flow structures in river channels and prediction of thresholds for, and amounts of, sediment entrainment, transport, and deposition. Physical modelling both of channel reaches and of the treelike networks of rivers in their drainage basins has also now been joined by numerical modelling at a number of scales: flow in meander bends and confluences, the development of channel patterns, the evolution of drainage networks, and simulation of alluvial stratigraphy and sediment transfers within catchments as a whole. All this is particularly helpful because landform development, responding perhaps to only a few formative events in a year or to a rare flood, is only fractionally observable. In effect, modelling allows both a 'speeding up' of processes and experimentation with presumed controlling factors such as gradient and sediment sizes and mixtures. Results may then be checked against field observations. On the other hand, some field circumstances (such as the effect of needle ice or animal trampling on river bank stability, or real-time discharge fluctuations and their effects on groundwater and sediment flux on floodplains) are less easily modelled.

Fluvial systems exist over a range of scales, from centimetre-wide intertidal channels and other drainage networks on a sandy beach, to the more than 6 million km^2 drainage basin of the Amazon. A fine-textured system is shown in Figure 1. All such systems are complex, self-organizing, and hierarchical in structure. At the microscale, processes involve the movement of individual particles. These may be arranged in bodies of sediment (as in increments of bank erosion, moving gravel sheets on a river bed, or as sedimentation layers following a large flood), and these in turn become part of 'form units' such as channels, bed material forms (dunes or bars), levees and the crevasse channels that may cut across them, and backswamps. These units are combined into what have been called 'architectural ensembles', or types of rivers and their floodplains. These have form units that are present to differing extents according to contrasting process environments, each with their differing hydrological regimes, stream

Figure 1 The Zabriskie Point badlands in Death Valley, California, USA. The landscape is dissected by a hierarchy of channel networks ranging in scale from rills a few centimetres wide to a braided channel belt over 10 m wide.

energies, vegetation, and sediment sizes and supply rates.

At the highest level, drainage basins incorporate a range of ensembles from head to mouth. Higher level dynamic behaviour includes the evolution of drainage networks in the context of changing sea-levels, climate, and tectonic activity. This can become very complex, with forms retaining a kind of 'memory' of past conditions, which in part may affect their active behaviour. For example, cold-climate weathering and erosion products of the last Ice Age make up a major part of channel bed materials in some present-day temperate environment rivers. Elsewhere, bedrock channels may be more apparent, and in fact bedrock erosion has recently been more closely studied, notably in headwater channels that may be the major source of transported catchment sediment, and in the rocky channels and gorges found in steeplands, some semiarid environments, and elsewhere.

Overall, fluvial geomorphology is therefore concerned with a wide range of time and space scales, ranging from rock particles to river catchments. At the lowest levels, studies may be concerned with equilibrium responses to quasi-instantaneous forces; with increasing level, however, response time increases to a length that may parallel global climate change. Even without a change in external factors of this kind, it is likely that there is a need to understand evolutionary (and technically chaotic) behaviour, as well as equilibrium behaviour (as in the response of a particle of given shape and mass to applied fluid force). However, modelling complex behaviour in hierarchical systems does commonly incorporate lower level 'process rules', and this underlies the need in fluvial geomorphology for improved understanding of process mechanisms at all levels. Catchment factors (varying the gradient, sediment, and discharge at individual sites) affect local processes, which in turn may operate to change the character and extent of catchments.

Material Transfer

Lower level material transfer in alluvial systems is illustrated diagrammatically in Figure 2A, which emphasizes that periods of storage and reactivation are involved. Coarser material moves incrementally in reach-length steps associated with flood events, whereas fine sediment may move long distances during single events. Solute transfer is continuous, if varying in concentration. Solutes constitute an extremely significant part of the total load carried by rivers, especially, of course, in catchments with soluble limestone and shale lithologies (Table 1). Weathering processes (surface and subsurface) are important both in the general reduction of land surfaces and for making possible the input and transport of rock materials in particulate or solute form. For rivers, cold-climate environments (including glacierized ones) may produce large quantities of coarse, physically weathered materials; low-relief and vegetated tropical environments may contribute clay-rich sediment and solutes to their river systems from weathered soils. Fine sand may dominate river loads in sandstone terrains. Generally speaking, sediment transfer is intermittent; thresholds for movement both in channel and related to sediment input from hillslopes are differentially achieved within catchments, leading to what is called 'complex response' to forcing events.

For submerged or partially submerged particles, it is possible to calculate the physical forces that must be exerted on the particles to move them on a river

Table 1 Suspended and solute load data for selected rivers[a]

River	*Drainage area (km^2)*	*Mean specific suspended sediment load ($t\,km^{-2}\,yr^{-1}$)*	*Mean specific dissolved load ($t\,km^{-2}\,yr^{-1}$)*	*Percentage of total load carried in solution*
Congo	4 000 000	13	12	48
Nile	3 000 000	0.7	4	86
Brahmaputra	580 000	1370	130	9

bed, but these forces are usually expressed in terms of mean flow parameters (which are more easily estimated) such as mean velocity, bed shear stress, or unit stream power for a given river level (see Figures 2B and 3).These can then be related to movement thresholds, for particles of given size, as bedload or suspension load. However, field data show great complexity because of factors such as the presence of mixed grain size and the packing and armouring (in which finer material at depth is protected by coarser material above) of bed materials (Figure 3). The actual entrainment of particles also involves eddy, sweep, and burst flow phenomena in flowing water. Nevertheless, in general, turbulent flow (turbulence being expressed in terms of the Reynolds number) is capable of transporting fine material in suspension, with amounts set by supply rates, whereas coarser materials (available to the river from its bed and banks) are more characteristically competence limited, such that a threshold of river flow has to be reached for coarser sediment entrainment and transport. For coarser load, it has proved possible to develop a range of bedload formulas (for example, relating transport rate to excess shear stress, discharge, or stream power, the 'excess' being the value above the threshold at which particle motion begins). For gravel rivers, such equations have not in general proved very successful when checked against the limited amount of direct bedload transport observations available. Equipment may be of the kind installed on the East Fork River, Wyoming, where moving sediment was trapped in a set of open slots on the river bed, moved to the bank on a conveyor belt to be weighed, and then returned to the river further downstream (Figure 4).

In general, suspended and solute loads have to be measured following water sampling, and yield measures are much more generally available. Data obtained during flow events over periods of years show results that may be complex in detail: for example, sediment concentrations may be higher as waters rise during a flood, compared to when waters recede, and there is no precise and unique relationship between discharge or water stage and concentration. However, it appears that events of moderate frequency (around annual) and stage (about bankfull or channel-full) achieve the most work, though for bed materials, large floods may be necessary both to generate slope failure and coarse-material input and to move the larger particles on a river bed. Floods that are extreme, compared to the annual average, occur every few years in some environments, whereas in other environments the flood expected, say, every 10 years is not that much larger than the annual one (Figure 5). Globally, sediment yields may vary greatly and are high particularly in high-relief/active tectonic

Figure 4 A field facility for bedload sampling and measurement installed by the United States Geological Survey on the East Fork River, Wyoming.

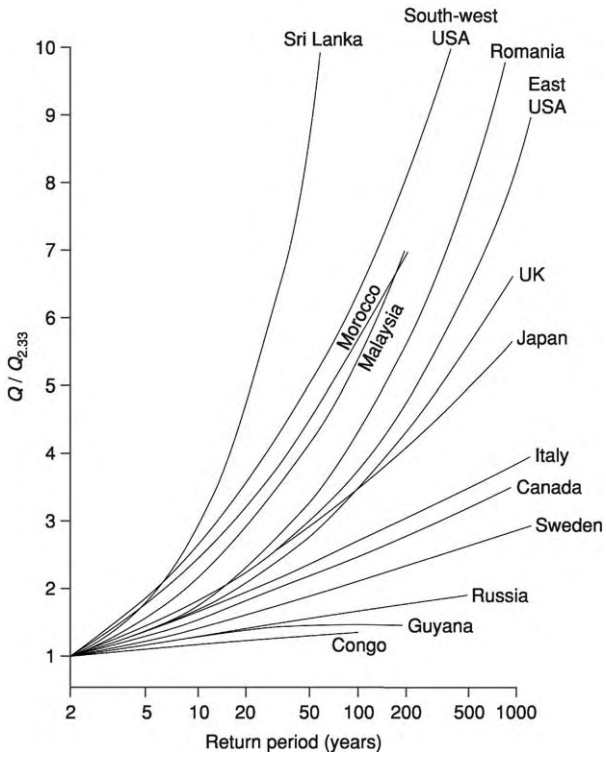

Figure 5 Curves showing flood frequency and magnitude relative to the mean annual flood ($Q_{2.33}$).

environments, on highly erodible terrains (including loess areas), and in regions of human disturbance.

Empirical relationships have also been established between channel measures and flow parameters. Flow velocity can be related to hydraulic radius (A/P; where A is the cross-sectional area of water flow and P is the wetted perimeter) and estimates of bed roughness, whereas river width and depth and velocity are differently related to variation in discharge, either as discharge rises or falls at a given cross-section ('at a station') or for constant flow conditions as discharge increases downstream (Figure 2B). These statistical average 'hydraulic geometry' relations (derived for single-thread rivers and so called because they are power function or 'geometrical' in form) are less apparent for downstream gradient and grain size, though both in general decrease, the former giving concave-up river 'long profiles', and the latter showing the effectiveness of in-channel size sorting and abrasion of particles as they move. In fact, research has rather moved away from detecting empirical relationships of this kind towards physically and theoretically underpinned modelling and field monitoring of bank erosion and channel shape processes. Field and laboratory studies of sorting and abrasion processes have explored topics such as abrupt discontinuities in channel bed grain sizes, and the nature of abrasion processes (see Figure 6).

Form Units

Alluvial rivers generally possess a set of landforms, self-formed in river-transported materials. There is a basic contrast between channels and their floodplains, the latter inundated only during flood flows producing a blanketing of flood deposits, which may

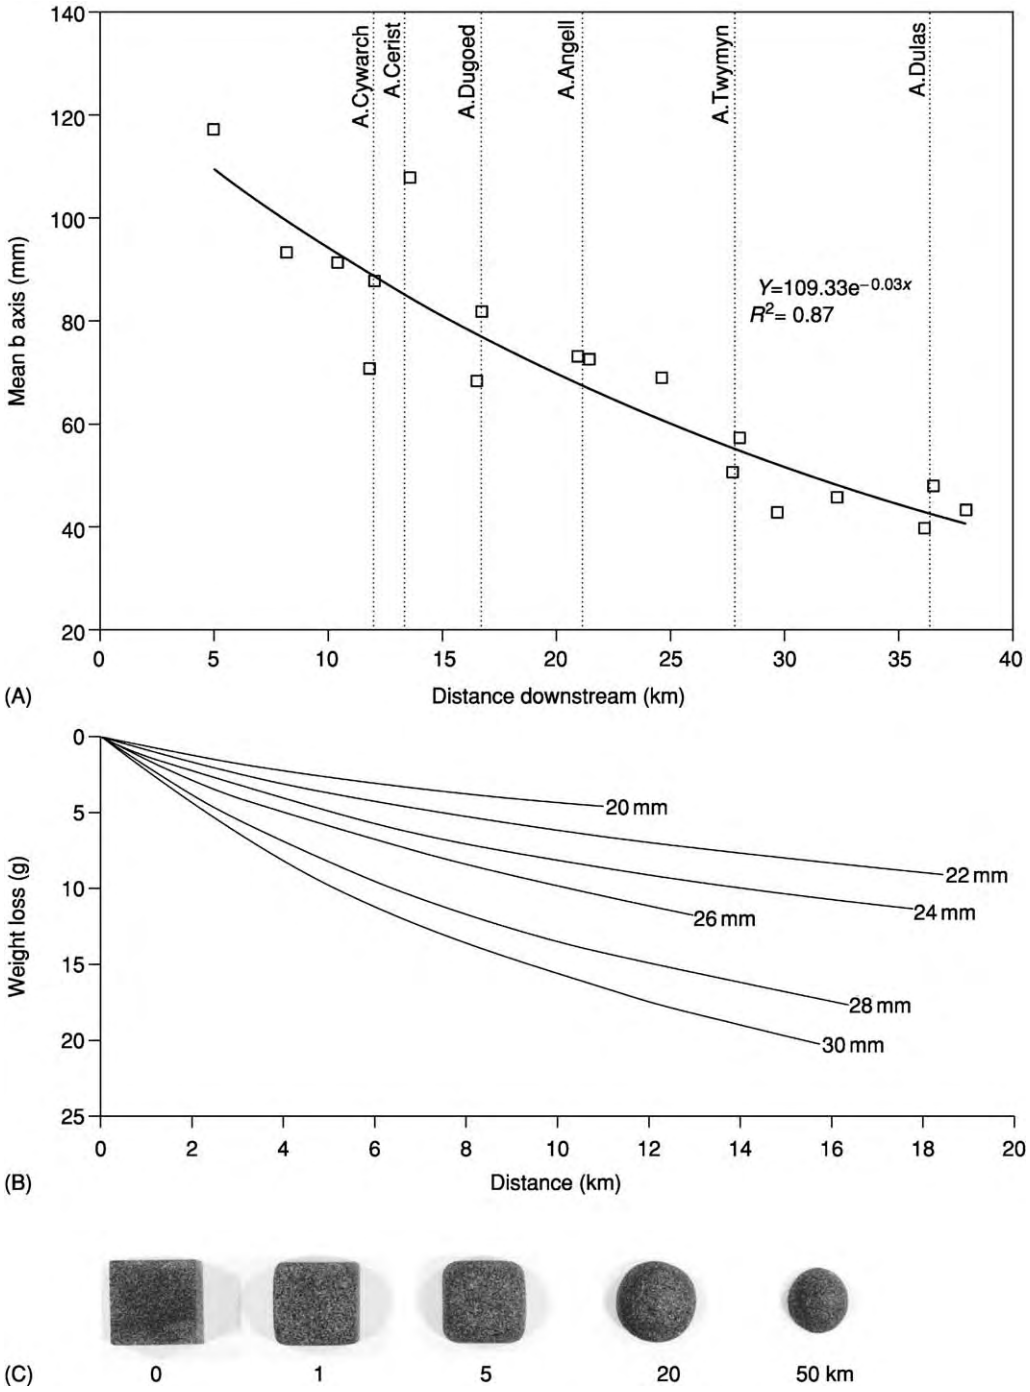

Figure 6 Field and laboratory data illustrating downstream fining and abrasion processes. (A) Downstream decrease in mean grain size on the Afon Dyfi, mid Wales, UK; abrupt, but generally localized, increases in grain size are attributed to relatively coarse sediment inputs from tributary channels. (B) Weight loss of rock cubes (ranging in size from 20 to 30 mm) in an abrasion tank; weight loss per unit distance is greater for larger cubes because of kinetic energy and surface area effects. (C) Progressive size reduction and roundness increase of a 20 mm chinastone cube during 50 km of travel in an abrasion tank.

be on top of coarser materials laid down in-channel by migrating streams. In more detail, the set of landforms includes channel bars of various types (point bars on the inside of meander bends, together with side- and mid-channel bars exposed at low flows); eroding banks characterized by various types of failure (including particulate removal or mass failure, or beam failure where overhanging banks are undercut); levees (channel-side ridges) and crevasses (dissecting channels) at the channel margin; abandoned channel fills; and backswamp-type floodplain environments in which organic processes may dominate. Each of these has been studied intensively in recent years, with documentation of the style and rate of deposition/erosion and the flow conditions responsible. This has, in the case of in-channel flow and sediment monitoring and modelling, involved painstaking field measurement (sometimes under hazardous flood conditions) and theory development. In other situations, historical records and maps have been used to reconstruct channel changes over a century and longer.

The series of case studies now available exemplifies the general point that hydraulic processes operating in contrasted energy (set by gradient and incident flows) and sedimentary (set by the type and supply volume of sediment of particular size) environments produce contrasted landform developments. For example, rivers with laterally stable courses and high sand load may generate large levees and ponded backswamps behind them, whereas gravel bed streams may have a diversity of bars and bedforms but less well-developed levees and backswamps – especially where rivers are laterally mobile, such as to eliminate the incipient development of such form units.

Architectural Ensembles

Qualitatively recognized channel-pattern types initially included braided, meandering, and straight; anabranching varieties of each (in which the river has more than one branch, with islands or swamps between) are also possible (Figure 7A). The term 'anastomosing' is also used for laterally rather stable anabranching styles. These commonly develop in channels with levees and channel-bed aggradation, with avulsion periodically relocating the river course through a backswamp zone. Braided and meandering channels have also proved to be diverse in style; some of the former have more stable islands between

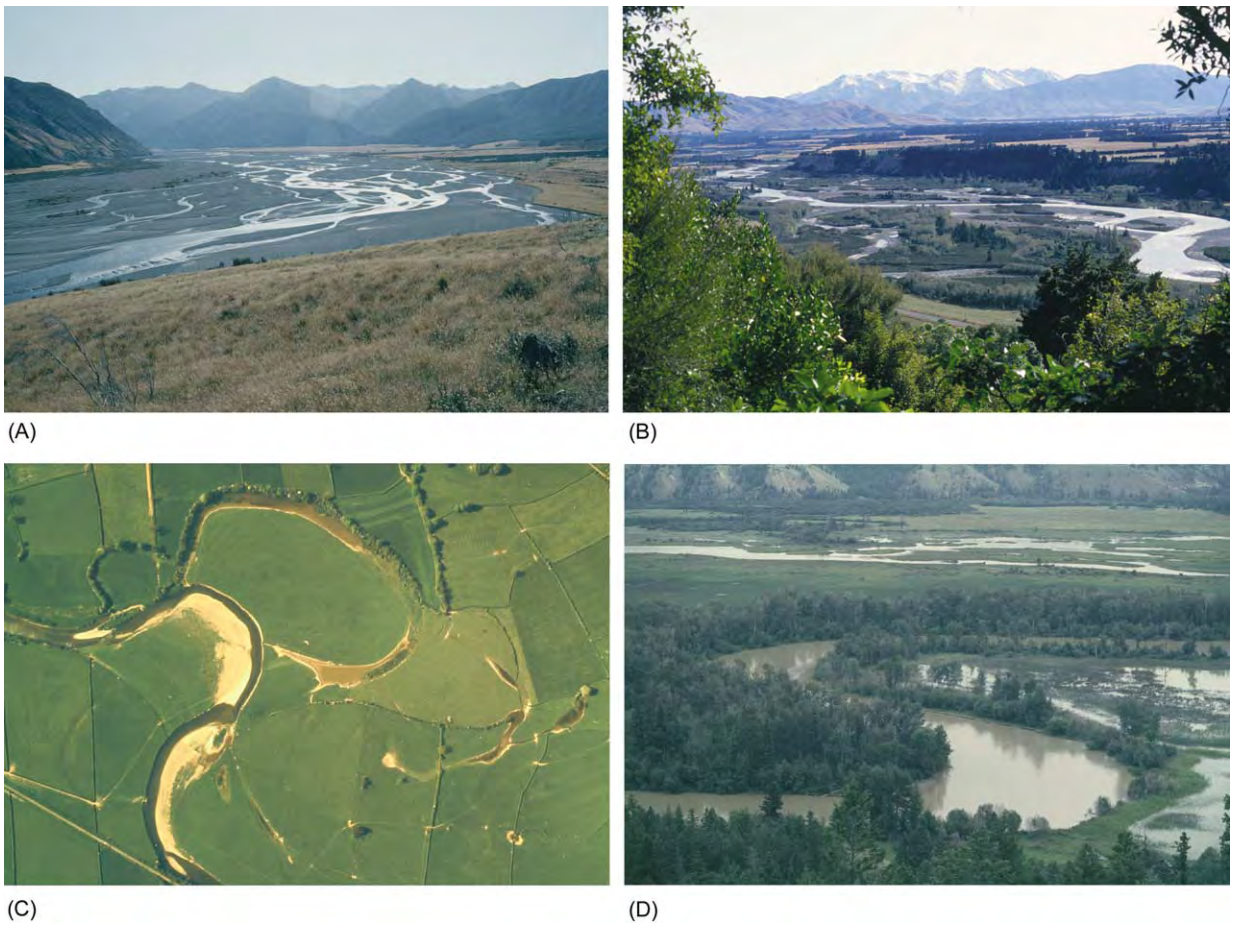

Figure 8 Channel and floodplain styles. (A) The braided course of the Upper Waimakariri River, New Zealand; (B) the Rangitata River at Peel Forest, New Zealand, showing vegetated islands and braid bars; (C) the meandering River Tywi, Wales, UK, showing gravel point bars and water filled cut off channels being filled by fine grained flood sediment; (D) the anastomosing Columbia River, British Columbia, Canada, showing channels, levees with trees, and backswamps (a recent avulsion has created a new disorganized channel in the background).

bar-filled channels (the bars being submerged and migrating at high flows, with scour holes where flow threads join, and deposition at zones of flow divergence) and the latter vary in sinuosity, symmetry, and migration pattern (Figure 7B). Illustrations of four channel-style prototypes are shown in Figure 8.

A similar kind of approach may be taken with architectural ensembles as a whole. Table 2 shows the order and suborder classification of floodplains. The classes are broadly based on energy and sediment size, with subdivision according to factors such as confinement in relatively narrow valleys and the presence of particular sedimentation styles. The observed styles have specified ranges of stream power and grain size, but these may overlap or leave gaps on a stream power/grain size plot (Figure 9). The same also applies to data for rivers designated as braided, meandering, and straight. This is probably because factors other than bankfull power and bed material size are important. Such factors include bank strength (related also to vegetation), the role of overbank flows in bank breaching (as in cut-offs, crevasse formation, and avulsion), and the rate of supply of finer sediment. It is not easy to produce a set of simple process/environment criteria to underpin a qualitative subdivision of ensemble or floodplain types. Such discrimination has been noted, however, on gradient/discharge plots for channel types (Figure 10).

Drainage Basins

Despite local complexities, drainage basins as a whole exhibit general trends in controlling factors from source to mouth (or with increasing drainage area) and therefore in fluvial styles. These are illustrated schematically in Figure 11A, though it should be appreciated that individual catchments may be complex as a result of factors such as lithological

Table 2 A classification of floodplains[a]

Class	*Order*	*Description*
A: High energy non cohesive floodplains	A1	Confined coarse textured
	A2	Confined vertical accretion sandy
	A3	Unconfined vertical accretion sandy
	A4	Cut and fill
B: Medium energy non cohesive floodplains	B1	Braided river
	B2	Wandering gravel bed river
	B3	Meandering, lateral migration
		3a Non scrolled
		3b Scrolled
		3c Backswamp
		3d Counterpoint
C: Low energy cohesive floodplains	C1	Laterally stable single channel
	C2	Anastomosing
		2a Organic rich
		2b Inorganic

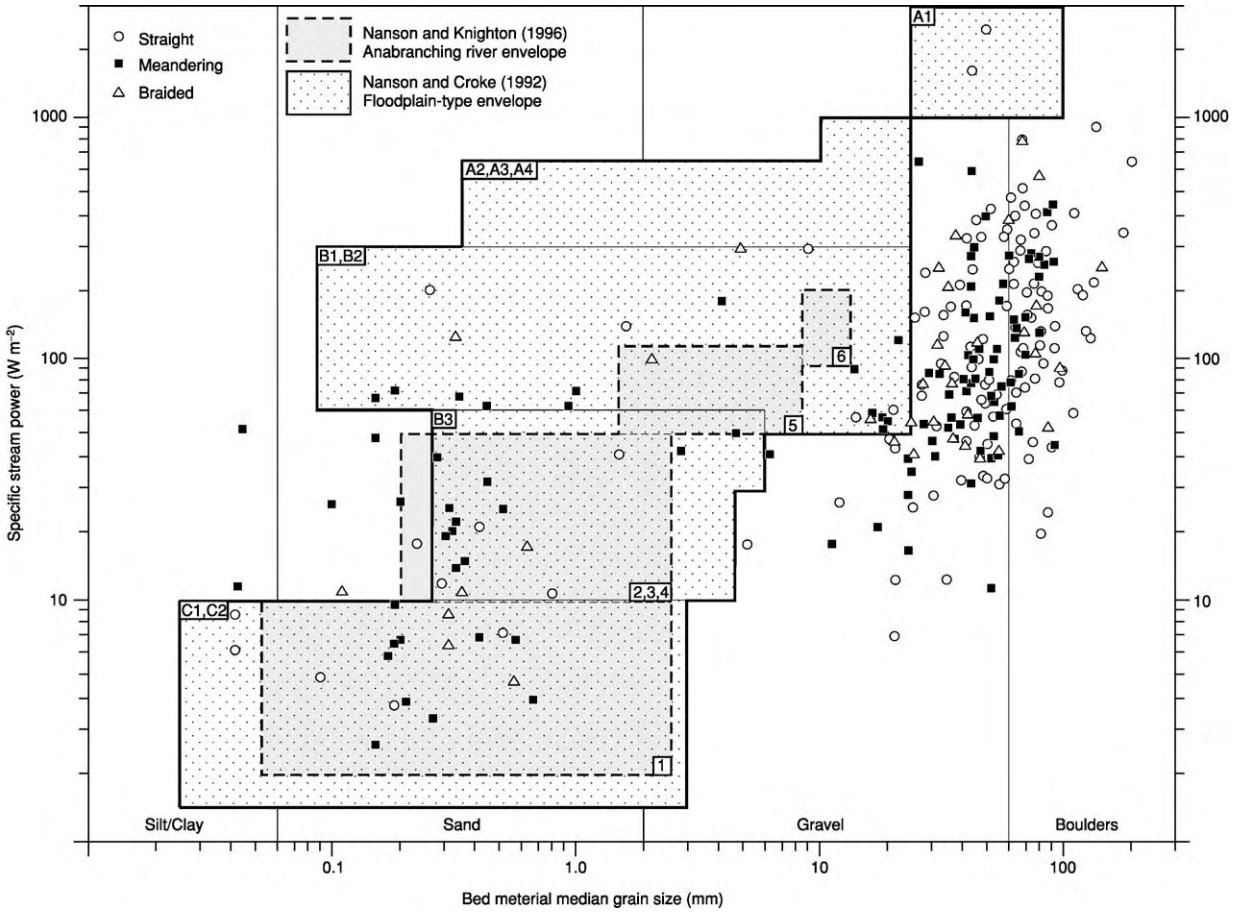

Figure 9 Floodplain types and channel patterns on a bed grain size and unit stream power plot. The envelope boxes overlap and show both the floodplain and the anabranching pattern case study based types. Many of the channel type symbols plot in areas outside the floodplain types, where there may be limited floodplain development, though in part this also reflects a bias in available data towards smaller, steeper streams. The alphanumeric codes and the numbers correlate to the types shown in **Figure 7A** and **Table 2**.

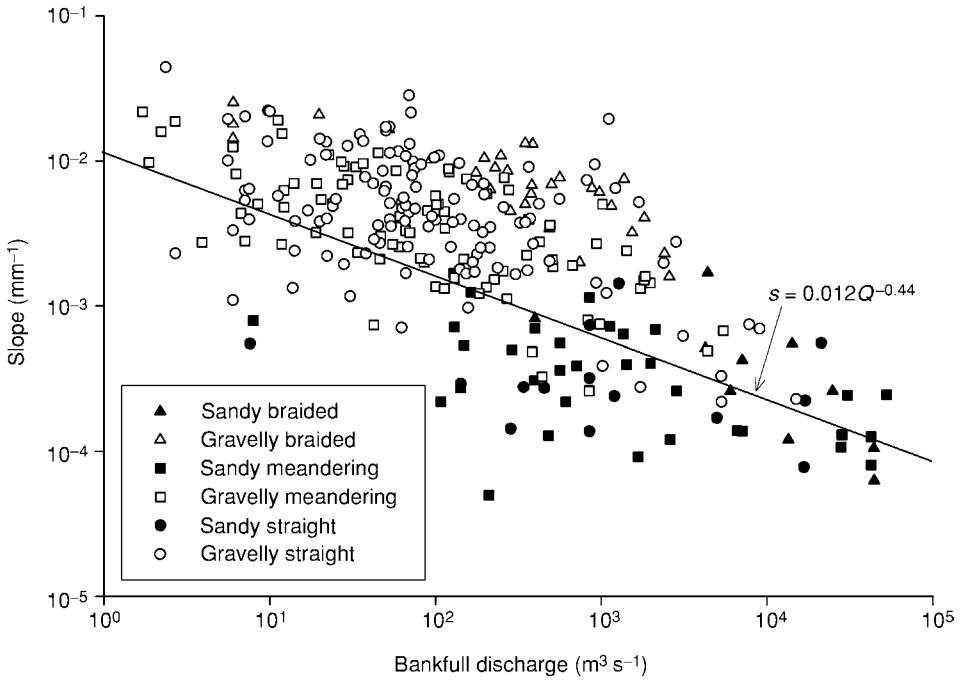

Figure 10 Channel pattern types on a plot of gradient and bankfull discharge in the manner proposed in 1957 by Leopold and Wolman. Their original, but smaller, dataset showed better discrimination, especially between meandering and braided channels. On this plot, sandy channels occur mainly on larger rivers at lower gradients; the threshold between braiding and meandering is higher (and a little more distinct) for gravel bed channels than for sand bed channels. The original Leopold and Wolman threshold is plotted here.

variation or localized tectonic activity leading to gradient modification. But in general, stream gradients decrease and discharge increases with increasing catchment area; stream power (as the product of gradient and discharge) may peak in mid-catchment. Bed grain size decreases downchannel, though this is in practice complicated by factors such as tributary sediment inputs and the existence of step changes in grain size with an abrupt gravel/sand transition. Morphological trends are also apparent (Figure 11B). In headwaters, eroding channels primarily transport hillslope and bedrock erosion materials, which may be coarse (as large or larger than the depth of the channel) and unsorted by river activity. Channels take the form of rapids, pools, and boulder jams. Rare flood events can have dramatic and immediate effects (Figure 12). Lower down-valley, the river sorting and abrasion of transported materials and the increasing dominance of storage and alluvial reworking begin to take effect. Valleys become wider and hillslopes decouple from the river at their foot. In headwaters, channel widths may occupy the whole valley floor, but there is room lower down-valley for rivers to migrate across an increasing body of alluvial storage, with architectural style changing in sympathy with energy, grain size, and other factors. Sediment-transporting events occur more frequently with finer sediment and steadier discharge, though channels may become more fixed in position. In practice, also, the widest valleys may relate to subsiding tectonically defined sedimentation zones in which very thick alluvial (and other) sediments may accumulate, and rivers occupy or migrate across only a fraction of wide valley floors. Here sediment build-up along restricted alluvial ridges allows the periodic relocation of channel belts by avulsion.

Developments in Time

At different scales, it is possible for landforms to achieve quasi-equilibrium with formative factors, exhibit perturbed states in which forms respond and then recover from events/periods of high activity, or evolve unidirectionally towards end-states (in which a highly-organized landscape is reduced to a low-energy and low-relief one following removal of rock mass). These states have been variously approached – initially via qualitative and theoretical proposals (such as WM Davis' influential 'cycle of erosion' proposed more than a century ago, in which uplift initiated drainage development and relief reduction to

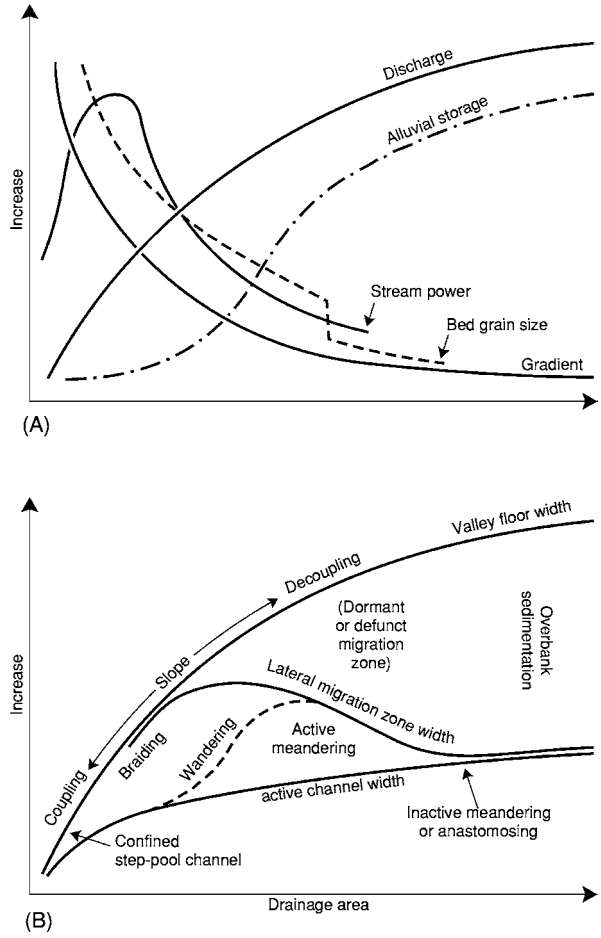

Figure 11 Trends in river catchments (A) in hydraulic factors, based on concepts developed by SA Schumm (in 1977) and M Church (in 2002), and (B) in channel types and activities.

achieve an end-state 'peneplain'). More recently, quantitative modelling has allowed exploration of such developments. Figure 13 illustrates models of drainage evolution; the results can be compared with patterns achieved over very long time-scales in natural landscapes. Such studies may use 'process laws' (based on empirical and/or physically justified relationships) applied iteratively to construct evolving forms. These may be shown to achieve stable pattern states during experimental runs, even though the prediction of individual forms may not be possible (as in the case of individual river bend form and location).

Though unidirectional trajectories in forms have been proposed for higher level landforms, at intermediate scales there has been great concern with perturbations produced by episodic changes in environments (response to a rise or fall in sea-level, tectonic effects, or climate fluctuations that may alter river discharges, sediments, and vegetation cover). Such 'external' changes have also been produced by human agency (including the effects of deforestation and agriculture, mineral extraction, urbanization, and river impounding and channelization). Perturbations over decades to centuries have produced effects that have been closely studied, and these may be ameliorated by good management.

Fluctuations in the rate of catchment erosion and local rates of sediment transfer can result in phases of sediment accumulation and storage, but also of river incision and stored sediment removal. Enhanced delivery may follow climatic change, tectonic uplift, or

human activity over a range of time-scales. Channel incision into alluvial deposits or planar bedrock valley floors may produce terraces and inset channels and floodplains. Incision episodes have been related to periods of decreased sediment supply from upstream, to tectonic river steepening, and to sea-level fall. Characteristically, channel steepening tends to propagate up-valley, with a knickpoint or zone moving headward at the expense of the former low-gradient valley floor or floodplain. Downcutting streams can produce terraces at a variety of levels as they migrate ('unpaired terraces'), whereas episodes associated with the occurrence of forcing events may give 'paired' or regionally developed terraces that can be matched over long distances. Major research efforts have been devoted to relating Quaternary climatic fluctuations (as in glacial–interglacial cycles) to the flights of terraces associated with many mid-latitude rivers, and to the relationships with cyclical sea-level change over rather longer time-scales (see **Figure 14**). Explanatory models have gradually become more complex as the interrelationships between climatic and vegetation change, sea-level fluctuation and tectonics, and river channel activity have been explored.

Studying the effects of environmental change, whether human or natural, has been greatly aided by improving dating techniques for alluvial sediments and by the availability of historical maps and remote-sensing imagery. Episodes of activity can be pinpointed over appropriate time-scales so that, for example, episodes of Holocene and to some extent Pleistocene river activity can be reasonably closely identified. However, alluvial sedimentation is seldom continuous; rivers also rework their own materials to the extent that what is left is only a 'partial archive of remnants' that leaves much activity unrecorded. Nevertheless, evidence is becoming available to allow change/evolutionary models to be compared not simply with static patterns (for example, drainage networks or meander trains) but

Glaciers

M J Hambrey and N F Glasser, University of Wales, Aberystwyth, UK

Introduction

Glaciers are amongst the most powerful geological agents on the Earth's surface. They are not only responsible for carving out some of the world's finest landscapes, but also have left widespread deposits that influence agriculture and groundwater flow and provide abundant reserves of sand and gravel for the construction industry. At present, approximately 10% of the Earth's land surface is covered by glacier ice, whilst during Pleistocene glaciations the figure was at least 30%. Continental-scale glaciations occurred in Permo-Carboniferous, Ordovician–Silurian, Neoproterozoic, and Palaeoproterozoic times. The greatest of these glaciations was during the Neoproterozoic, and this has given rise to the concept of the 'snowball Earth', with some geologists arguing for a near-total freeze-up of the planet, followed by severe greenhouse warming, which might have triggered the explosion of life. When the idea of a great Ice Age was first mooted by the Swiss natural historian Louis Agassiz in 1837 (*see* **Famous Geologists:** Agassiz) it met with fierce opposition. In the following decades, increasing numbers of geologists were won over to the concept, as the evidence for glaciation, in the form of characteristic landscapes and extensive surficial deposits ('drift'), throughout Europe and North America became irrefutable. Towards the latter part of the nineteenth century, glacial deposits were being discovered in rocks as old as the Precambrian, although the validity of a glacial interpretation of rocks of Neoproterozoic age was challenged by many until as recently as the 1970s. It was only after glaciologists began examining the processes of erosion and deposition in modern glaciers, from the late 1960s onwards, that the older records of glaciation could be evaluated systematically.

Global Distribution of Glaciers

The global extent of glacier ice has been documented by the World Glacier Monitoring Service (Table 1). The two largest ice-masses, Greenland (10.9%) and Antarctica (85.7%), account for the bulk of glacier ice on Earth, although it is the remaining 3.4% that impinges directly on human activity (Figure 1). The remaining ice-masses occur throughout the Arctic islands and on high mountains, even in the tropics. It is the major ice-masses that are most likely to

Table 1 Distribution of glaciated areas of the world (data from the World Glacier Monitoring Service, 1989)

Region	*Area (km^2)*
Africa	10
Antarctica	13 593 310
Asia and Eastern Europe	185 211
Australasia (i.e. New Zealand)	860
Europe (Western)	53 967
Greenland	1 726 400
North America excluding Greenland	276 100
South America	25 908
World total	15 861 766

contribute to sea-level rise over the next 100 years as the climate warms. Published figures for the potential contribution of glaciers to sea-level rise have large errors, but Table 2 gives an indication of the relative importance of the different ice-masses. The polar ice-sheets will continue to grow and decay in different places at the same time, until the increase in temperature exceeds the threshold at which they can remain in equilibrium.

Table 2 Potential contribution of the world's ice masses to sea level rise (US Geological Survey website, 2001); note that there are considerable uncertainties in the accuracy of these estimates

Mountain glaciers	0.5

Characteristics of Glaciers and Ice-Sheets

Glacier Morphology

Glaciers range in size from the great ice-sheets of Greenland and Antarctica to tiny ice-masses just a few hundred metres across. The generally accepted definition of an ice-sheet is an ice-mass exceeding 50 000 km^2 in area. The Greenland Ice Sheet forms an elongated dome, with mountains projecting through it near the periphery, whilst the Antarctic Ice Sheet consists of three dynamically separate regions, of which the dome of East Antarctica has by far the greatest volume (Figure 2). Ice-caps are also dome-like masses, but measure less than 50 000 km^2 (Figure 3). Both ice-sheets and ice-caps discharge the bulk of their ice via ice-streams – zones of accelerated flow with slow-moving ice on either side. As ice-streams enter the sea, coalescence leads to the formation of ice-shelves – floating slabs of ice several hundred metres thick. Like ice-caps, highland ice-fields also bury much of the topography, but mountains project through them as 'nunataks'. Valley glaciers are typical of mountain regions, such as the Alps, and are the best studied of all ice-masses (Figure 4). Above them are upland amphitheatre-like basins where cirque (or corrie) glaciers accumulate. Lastly, hanging glaciers are perched on steep mountain rock faces and are so prone to avalanches that below them are regenerated glaciers.

Glacier Mass Balance

Mass balance is the study of the inputs and outputs to the glacial system, i.e. the net gain or loss of snow and ice across a glacier (Figure 5). The inputs to the glacial system are known as accumulation and include all materials that add mass to the glacier, such as snow, refrozen slush, hail, frost, rain, and avalanched snow or ice. The outputs from the system are known as ablation and include anything that removes mass from the glacier, such as direct ice melt, iceberg calving, wind erosion, and sublimation. Mass balance is largely dependent on the prevailing climate since this determines the rates of accumulation and ablation. In general, ablation tends to be dominant in the warm summer months, and accumulation is dominant in the winter months (Figure 5B). The exception to this rule is where iceberg calving occurs throughout the year where an ice-sheet or glacier terminates in water. The rate of growth or recession of a glacier is determined by the difference between the accumulation and ablation rates (called the net mass balance and usually measured over a 1 year period). The point

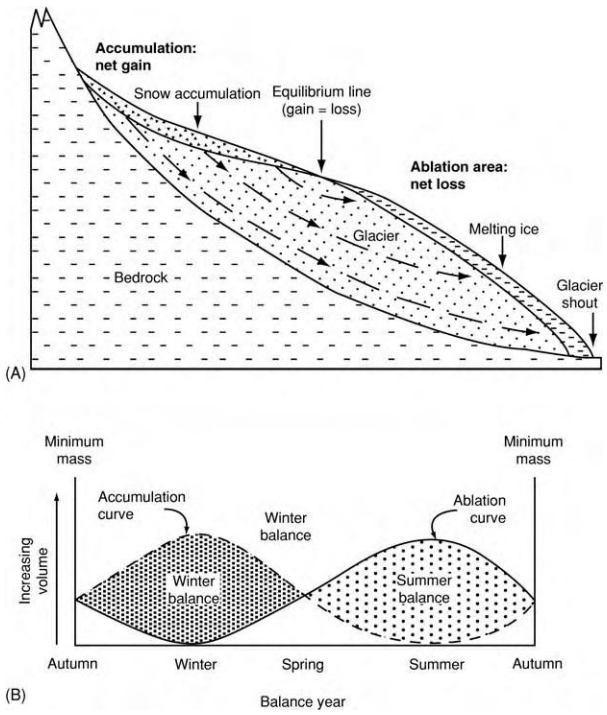

Figure 5 Mass balance regime of a typical glacier in the tem perate regions of the Arctic. (A) Schematic cross section through the glacier, illustrating zones of accumulation and ablation. (B) How the volumes of accumulation and ablation vary over the year, assuming steady state conditions.

on a glacier where accumulation equals ablation is known as the equilibrium line and is normally expressed as an altitude in metres above sea-level. Accumulation exceeds ablation in the upper part of a glacier, whereas the converse is true in the lower part (Figure 5A). Exceptions to this rule occur in parts of Antarctica, where costal snowfall compensates for losses in the middle (drier) reaches of a glacier.

Glacier Thermal Regime

Temperatures within glacier ice vary both vertically and horizontally. Variations in temperature at the base of a glacier are known as the basal thermal regime and are determined by the balance between the heat generated at the base of the glacier and the temperature gradient within the ice, which governs the rate at which heat is drawn towards the ice surface (Figure 6). The most important factors in determining the basal thermal regime are ice thickness, ice surface temperature, geothermal heat, and frictional heat. Heat is generated beneath a glacier by geothermal heat, which enters the base of the glacier from the rocks beneath, and by frictional heat, which is given off as a result of basal sliding and internal deformation. The distribution of ice temperature is vital in understanding the landscapes produced by glaciers because the basal thermal regime is a primary factor controlling the patterns of erosion and deposition.

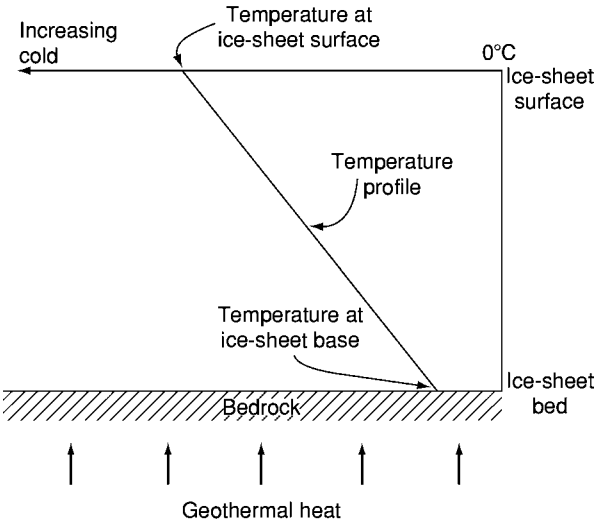

Figure 6 The vertical variation in thermal regime through a polar ice sheet.

This is because the temperature at the base of the glacier controls which of the flow processes (ice creep, basal sliding, and subglacial deformation) can occur and therefore the dynamics of the glacier.

There are three fundamental types of glacier: cold-based, warm-based, and polythermal. Cold-based glaciers are frozen to their beds and produce little basal melt water. Basal sliding cannot occur, and these glaciers flow by internal deformation alone. In contrast, warm-based glaciers produce abundant meltwater that finds its way to the bed; thus basal sliding is an important component of their flow. Warm-based glaciers therefore have the potential for greater flow rates than cold-based glaciers and as a result have a greater ability to modify the underlying landscape. Polythermal glaciers have basal melting in their accumulation zones, basal freezing at their margins, and a transition zone between the two.

Glacier Flow

Glaciers flow primarily because the ice within them deforms under the influence of gravity. Glacier flow is achieved by three mechanisms: internal deformation, basal sliding, and subglacial bed deformation (Figure 7). Internal deformation is achieved by the processes of ice creep, large-scale folding, and faulting. Ice creep is the mutual displacement of ice crystals relative to one another in response to the applied shear stress and results in slow forward motion in the direction of the ice-surface slope. Folding and faulting are common in situations where ice creep alone cannot adjust sufficiently rapidly to the stresses set up within the ice. Basal sliding is the name given to the process whereby a glacier slides over its bed, often on a thin film of lubricating melt water. Sliding is accompanied by a combination of enhanced basal creep and regelation (refreezing) (Figure 8). Subglacial bed deformation is the process by which unfrozen sediment beneath the glacier deforms under the weight of the overlying ice. This occurs when the water pressure in the pore spaces between the sediment grains rises sufficiently to overcome the resistance between individual grains, allowing them to move relative to one another. This is an important process beneath temperate glaciers that overlie poorly consolidated sediments. For example, it has been estimated that 90% of the velocity of Breiðamerkurjökull in Iceland can be accounted for by subglacial bed deformation.

The fastest moving glaciers are typically ice-streams or outlet glaciers terminating in the sea, which may have velocities of several kilometres a year. Mountain-valley glaciers commonly move a few hundred metres a year, whilst small cirque glaciers may move only a few metres a year. Some glaciers alternate between slow-moving ('quiescent') phases and surge phases (when velocities are several orders of magnitude greater than normal). A surge may last for just a few months (as in Alaska) or for several years (as in the high Arctic).

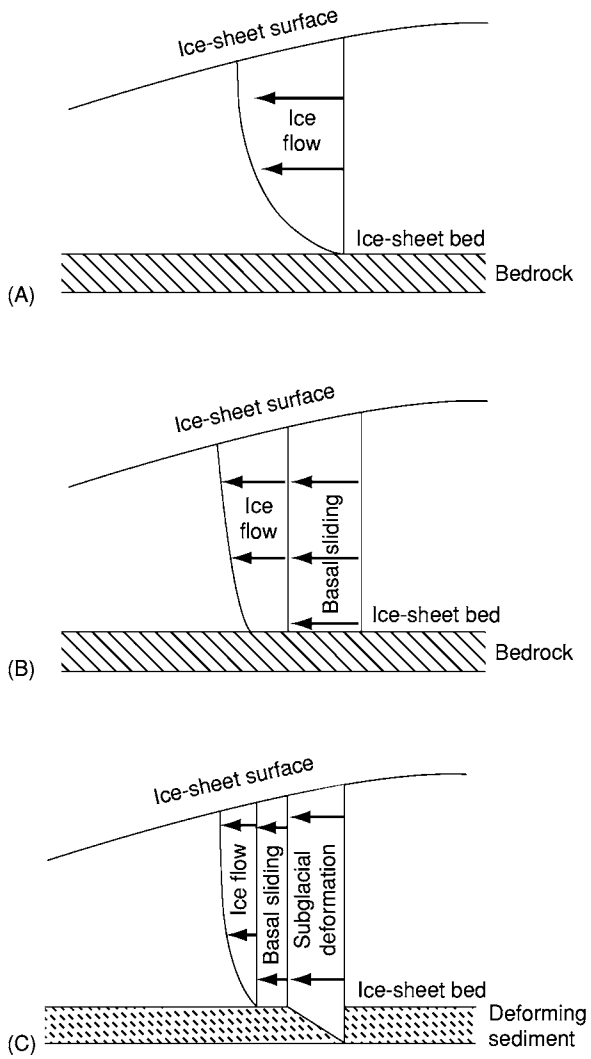

Figure 7 Relative vertical velocity profiles through (A) a cold based ice sheet on bedrock, (B) a warm based ice sheet on bedrock, and (C) a warm based ice sheet on deformable sediment, showing the different components of glacial flow under the different thermal regimes.

Glacier Structure

Glacier ice resembles other geological materials in that it starts as a stratified sequence, in this case mostly of snow, and then undergoes diagenesis (to firn and then to ice) and deformation, producing a wide range of structures. Primary structures include sedimentary stratification, unconformities created in years of

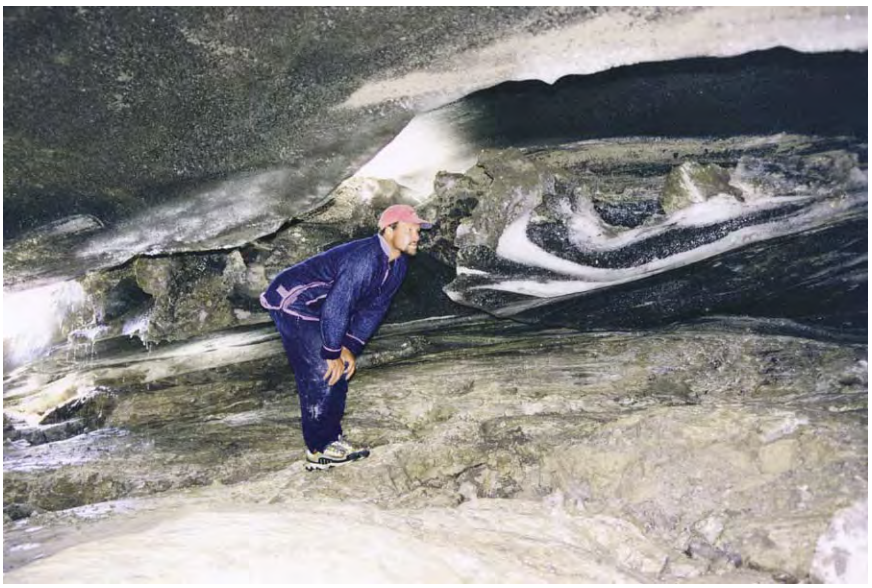

Figure 8 The debris bearing basal ice layer in a cave beneath Glacier de Tsanfleuron, Switzerland, formed by regelation and subsequently modified by folding. © 2005, Photograph, M J Hambrey.

heavy ablation (Figure 9A), and regelation layering resulting from pressure melting and refreezing at the base of the glacier (Figure 8). Secondary structures are the result of internal deformation and include brittle structures, such as crevasses (Figure 9B), crevasse traces, faults, and thrusts, and ductile structures, typified by foliation (Figure 9C), folding (Figure 9D), and boudinage. Structural development in glaciers can be examined in the context of strain rates (usually measured over a 1 year period) and cumulative strain (estimated from velocities and flow-line maps or by finite-element modelling) over several decades.

Glacial Erosion

Processes of Glacial Erosion

Glacial erosion involves the removal and transport of bedrock or sediment by three main processes: quarrying (also known as plucking), abrasion, and melt water erosion. Quarrying involves two separate processes: the fracturing or crushing of bedrock beneath the glacier, and the entrainment of this fractured or crushed rock. Fracturing of bedrock takes place when a glacier flowing over bedrock creates pressure differences in the underlying rock, causing stress fields that may be sufficient to induce rock fracture. Fluctuations in basal water pressure may help to propagate bedrock fractures beneath a glacier. Evacuation of rock fragments or sediment is possible where localized basal freezing occurs, where the tractive force is sufficient to entrain individual clasts, or where debris is elevated along thrusts.

Abrasion is achieved by bodies of subglacial sediment sliding over bedrock or by individual clasts contained within the ice. The progressive breakdown of material in traction provides a mechanism for the continued replenishment of debris that can carry out erosion beneath ice-masses, even where they flow across hard rocks of uniform lithology. Thus, glacial erosion is most efficient beneath temperate ice. Although cold glaciers may achieve limited amounts of erosion, the release of melt water to lubricate basal sliding beneath temperate ice is a prerequisite for widespread and efficient quarrying and abrasion.

Erosion by glacial melt water beneath glaciers is the result of either mechanical or chemical processes. The effectiveness of melt water as an agent of erosion depends on the susceptibility of the bedrock involved (in particular the presence of structural weaknesses or susceptibility to chemical attack), the discharge regime (in particular the water velocity and the level of turbulent flow), and the quantity of the sediment in transport.

Landforms of Glacial Erosion

The landforms produced by glacial erosion are commonly described on three spatial scales: the microscale, the mesoscale, and the macroscale.

Microscale landforms of glacial erosion are those that are below 1 m in size. They are of low-relief amplitude and are often found superimposed on larger landforms. Striae or striations (Figure 10A) are lines or scratches on a rock surface that are produced by glacial abrasion as debris or clasts entrained

Figure 9 Structures in glacier ice: (A) stratification and unconformity in ice cliffs bordering Granite Harbour, Ross Sea, Antarctica; (B) crevasses in Glacier des Bossons, French Alps; (C) foliation in Gornergletscher, Swiss Alps, with the Matterhorn in the background; and (D) 'similar style' folding associated with foliation in Griesgletscher, Swiss Alps. © 2005, Photographs, M J Hambrey.

in the basal ice are dragged over the rock. Microscale crag-and-tails are small elongated bedrock protuberances that form where the rock is preferentially protected from glacial abrasion in the lee of resistant grains or mineral crystals on the surface. Crescentic gouges (Figure 10B) and chattermarks are small cracks, gouges, and indentations created on bedrock surfaces. A variety of different morphologies have been recorded, varying in shape from simple fractures or cracks in the bedrock to larger crescentic gouges in which small chips of bedrock have been physically removed from the bed. Finally, p-forms, s-forms, and microchannel networks include a variety of smooth sinuous depressions and grooves sculpted on glaciated bedrock surfaces (Figure 10C).

Mesoscale landforms of glacial erosion are between 1 m and 1 km in size. Streamlined bedrock features (also known as whalebacks or rock drumlins) are bedrock knolls that have been smoothed and rounded on all sides by glacial action. Stoss-and-lee forms are bedrock features with a pronounced asymmetrical profile: they have an abraded slope on the up-glacier or stoss side and a steeper rougher quarried slope on the down-glacier or lee side. Individual landforms

Figure 10 Microscale erosional landforms: (A) striated and ice moulded limestone at the margin of Glacier de Tsanfleuron, Swiss Alps; (B) crescentic gouges in dolerite beneath Neogene glacigenic sediments, Roberts Massif, Antarctica (ice flow was from left to right); and (C) p forms (melt water eroded and glacially striated channels) cut in limestone, Glacier de Tsanfleuron, Swiss Alps. © 2005, Photographs, M J Hambrey.

are commonly known as *roches moutonnées* (Figure 11A). Rock grooves are similar in morphology to striae, but have greater size and depth (Figure 11B). They range from tens of metres to hundreds of metres in length and may be up to several metres wide and a few metres deep. Rock basins are individual depressions carved in the bedrock, often developed along lines of structural weakness. Melt-water channels span a large spatial scale from centimetre- or metre-scale channels cut in soft sediment or bedrock to large valley-scale melt-water channel systems. Landforms associated with glacial melt water form wherever sufficient quantities of water are released in subglacial, ice-marginal, and proglacial settings.

Macroscale landforms of glacial erosion are those features that are at least 1 km in size. They are significant landscape components, which may contain within them many of the smaller landforms described above. Zones of areal scouring are scoured bedrock consisting of an assemblage of streamlined bedrock features, rock basins, and stoss-and-lee forms. Glacial troughs are deep linear features carved into the bedrock, which represent the effects of glacial erosion where ice flow has been confined by topography and channelled along a valley or fjord (Figures 12A and 12B). Cirques are large bedrock hollows that open down-slope and are bounded up-slope by a cliff or steep slope known as a headwall (Figure 12C). Headwall erosion that continues from two opposing sides until they meet produces a sharp ridge – an arête (Figure 12D). If the process takes place from three or more sides, a sharp isolated peak – a horn – may be the product (Figure 12E). Large stoss-and-lee forms (giant *roches moutonnées*) are between hundreds of metres and several kilometres in size. These valley spurs and hills have a pronounced asymmetric profile, with an abraded slope on the up-glacier (stoss) side and a steeper rougher quarried slope on the down-glacier (lee) side.

Bathymetric Forms Resulting from Glacial Erosion

Various erosional phenomena, mainly associated with grounded ice or subglacial melt water, are found in marine settings. The larger-scale forms are filled by sediment and may be recognizable only in

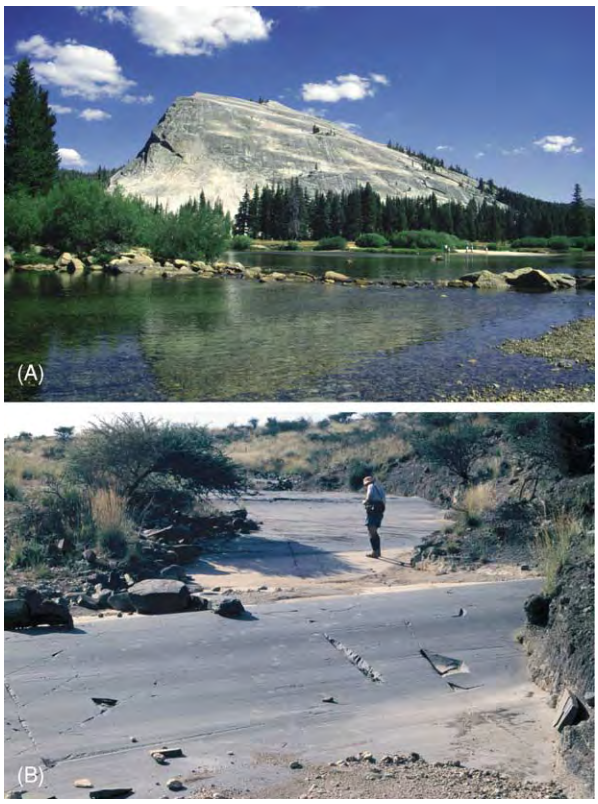

Figure 11 Mesoscale landforms of glacial erosion: (A) *roche moutonnée*, the Lembert Dome, Yosemite, California, USA; (B) shallow striated grooves from the Permo Carboniferous glaci ation, near Douglas, Karoo, South Africa. © 2005, Photographs, M J Hambrey.

seismic profiles. Submarine troughs formed by ice-streams are found on continental shelves and are genetically equivalent to fjords and other glacial troughs but are generally much broader. The largest occur in Antarctica, where they can reach over 400 km in length, 200 km in width, and 1100 m in depth. Steep-sided channels 2–3 km wide, over 100 m deep, and up to 100 km long, carved out by subglacial melt water and subsequently filled by sediment, are known as tunnel valleys. These are well known from the north-west European continental shelf around Britain, the Scotian Shelf off Canada, and Antarctica. Icebergs can also cause considerable erosion if they become grounded on the seafloor. Large tabular icebergs can scour the bed of the sea for several tens of kilometres, leaving impressions up to 100 m wide and several metres deep.

Debris Entrainment and Transport

Glacial erosion and subaerial erosion above a glacier produce a range of sediment types that can be entrained and transported in a variety of ways. The manner in which sediment is transferred through the glacial system is related to the dynamic and thermal characteristics of the glacier. Broadly speaking, polythermal glaciers tend to carry a high basal debris load but little on their surfaces, whereas the reverse is true for temperate glaciers.

As noted above, entrainment of debris at the bed is a product of regelation. Basally derived debris is subject to comminution at the ice–bedrock interface and typically consists of clasts up to boulder size, with subangular and subrounded shapes and faceted and striated surfaces. In addition, there are varying proportions of sand, silt, and clay. Debris on the surface of the glacier (supraglacial debris) is mainly derived from frost-induced rock fall from the crags above and is mainly angular with few fines.

During flow, both supraglacial and basal debris is reorganized. In addition to regelation, the following mechanisms, some of which are illustrated in Figure 13, have been identified

- incorporation of angular rock-fall material within the stratified sequence of snow, firn, and refrozen slush, followed by folding (this debris emerges near the snout at the hinges and upper limbs of the folds, forming medial moraines);
- falling or washing of supraglacial debris into crevasses and moulins;
- incorporation of both supraglacial and basal debris within longitudinal foliation;
- thrusting, allowing debris-rich basal ice and subglacial sediments to be uplifted into an englacial or even supraglacial position; and
- squeezing of subglacial debris into basal crevasses.

Glacial Deposition

Processes of Glacial Deposition

Glacial deposition involves the release of sediment from supraglacial, englacial, and basal-glacial positions. Debris that has been in contact with the bed is heavily modified by intraclast collision, subglacial deformation, and contact with water. Debris that follows a passive transport path (supraglacially or englacially) tends to retain its original characteristics.

Sediment may be deposited directly beneath the glacier or at its margins, or it can be transported long distances away from the glacier by other agents, such as rivers (producing outwash plains) or icebergs. During release from the ice, sediment is reworked by numerous processes, including fluvial processes, debris-flowage, marine or lacustrine currents, and aeolian processes (Figure 14A). The resulting sedimentary facies associations are therefore exceedingly complex, but particular combinations of facies can be

Figure 12 Macroscale glacial erosional landforms: (A) Yosemite glacial valley, California, USA; (B) Kejser Franz Josef Fjord, central east Greenland; (C) a pair of deeply incised cirques on Cuernos del Paine, Chilean Patagonia; (D) arêtes carved in granite peaks, Stauning Alper, East Greenland; and (E) the horn like peak of Ama Dablam, Khumbu Himal, Nepal. © 2005, Photographs, M J Hambrey.

used to determine the glacial thermal regime and tectonic setting. A temperate glacial system in an area of high relief, especially if it is tectonically active, will have a high proportion of supraglacial debris that on release is modified by streams; little sediment of basal character will be preserved. A polythermal glacier tends to produce a mainly basal glacial deposit, only part of which may be reworked by outlet streams.

Glaciers that enter water bodies behave differently according to their thermal regime. Polythermal glaciers tend to have a floating tongue if the water is deep enough, as in the fjords of Greenland, and the dominant facies produced is poorly sorted sediment ('diamicton') derived from the base of the glacier. The ice in temperate glaciers is usually too weak to float, and the glacial terminus is a cliff resting on the seabed. Sediments produced in these situations, typified by the fjords of Alaska, are dominated by subglacial water output (Figure 14B). For the coldest glaciers, terminating as ice-shelves on the continental shelf of Antarctica, direct deposition is restricted to a narrow grounding zone because freeze-on of saline ice at the base of the ice-shelf seals in any remaining sediment. Melt-water production in the grounding zone is generally limited, and the dominant sediment

Dordrecht: Kluwer.)

immediately beyond this area is biogenic and is typically derived from the settling out and current transfer of diatom remains (Figure 14C). This sediment is carried away from the Antarctic coast within icebergs, and some may be released onto the ocean floor hundreds of kilometres from the source.

Glaciotectonic deformation is a widespread phenomenon that affects materials for up to several hundred metres adjacent to and beneath glaciers. Processes such as thrusting and folding within the ice are mirrored by the same processes in subglacial and proglacial settings. All types of material are affected, including wet, dry, and frozen sediments and bedrock. Deformation may detach blocks of rock and frozen sediment that are sometimes hundreds of metres across, leaving depressions in the

ground and producing complex ridge forms in front of the glacier. Much of the material is brecciated, but, if it is wet and fine grained, it may deform in a ductile manner.

Glacigenic Sediments

A number of general terms have been applied to deposits left behind by glaciers and the associated melt water. 'Glacigenic sediment' means 'sediment of glacial origin' in the broad sense, embracing sediments that have been influenced by glacier ice even if only slightly. 'Glacial drift' refers to all material being transported by glacier ice, all deposits released by glaciers, and all deposits of predominantly glacial origin deposited from glacial melt water or in the sea by icebergs.

Traditionally, Quaternary researchers have tended to give genetic terms to glacigenic sediments in the field, but this has led to difficulties where the meanings of the terms have not been agreed and where the origin of the sediment is disputed. The increasingly preferred approach is to describe sediments objectively using textural terms, and classifications are available for the typical range of poorly sorted sediments that exist in glacial settings. The terms 'diamicton' (unlithified), 'diamictite' (lithified), and 'diamict' (both) are used for 'a non-sorted or poorly sorted terrigenous sediment that contains a wide range of particle sizes'. In other words diamicts contain particles resulting from weathering and erosion ranging in size from clay to boulders in various proportions (Figure 15A). We use a range of 1% to 50% for the proportion of clasts within diamicts (from a detailed textural classification presented elsewhere).

The International Quaternary Association (INQUA) has proposed a genetic classification that, although somewhat dated, embraces the terminology used by most glacial geologists. The principal terms are as follows.

- Lodgement till is deposited by 'plastering' of glacial debris from the sliding base of a moving glacier as a result of pressure melting or other mechanical processes. Texturally, the deposit is a diamicton or a muddy or sandy gravel.
- Meltout till is deposited by the slow release of glacial debris from ice that is not moving. Typically, meltout tills inherit the characteristics of the sediment within the basal ice layer and are diamictons.
- Basal till embraces both the above.
- Sublimation till is released by the sublimation of debris-rich ice in subzero temperatures. Texturally this is diamicton, but it is found only in arid parts of Antarctica.
- Deformation till comprises weak rock or unconsolidated sediment that has been deformed or disaggregated, with some foreign material admixed. Texturally this is variable and often breccia-like; rafts of rock or sediment may be many metres in length.
- Flow till is till that has been remobilized by gravity flow, although it is better known as glacigenic sediment flow.

The above INQUA classification refers to modern terrestrial glacigenic sediments. The lithified equivalent of till is 'tillite'. All these deposits are prone to reworking by melt water and wind. Thus extensive well-sorted sand and gravel deposits are a major feature of glacial environments (Figure 15B). There is no agreed genetic classification for glaciomarine sediments. The following terms, however, are commonly used.

- Ice-proximal glaciomarine sediment is sediment that is released either from floating basal glacier

ice or by continuous rainout from icebergs, without subsequent winnowing by currents and waves. Texturally this is normally a diamicton.

- Ice-distal glaciomarine sediment is sediment that is released from icebergs, but is subject to winnowing and admixed with other marine sediment, including biogenic components. Texturally these sediments are usually sandy muds or muddy sands with dispersed stones, and in modern environments they are often rich in diatoms.
- Iceberg turbate is sediment that is deposited on the seafloor and subsequently reworked by grounded icebergs. The end product is commonly a massive diamicton.
- Cyclopels (silt–mud couplets) and cyclopsams (graded sand–mud couplets) are rhythmically laminated sediments derived from the turbid overflow plumes of subglacial discharge, especially in fjords. Iceberg rafting may produce dropstone structures.

Glaciolacustrine facies are similar to those in glaciomarine environments. In addition, lakes commonly have rhythmically laminated sands and muds called varves (or varvites if lithified). Sand laminae represent input to the lake during summer, and silt or clay laminae represent settling out from suspension in winter. Dropstones may disrupt the laminae. Other laminated sediments in lakes or the sea may be deposited from turbidity currents and also include dropstone structures.

Depositional Landforms

Glaciers and ice-sheets produce a large range of depositional landforms that are commonly grouped into ice-marginal and subglacial landforms.

Ice-marginal landforms Ice-marginal landforms are produced by advancing, static, or receding ice-margins, as well as during seasonal fluctuations of an ice-front. They may be deposited directly from glacier ice or be composed of sediments previously deposited by other processes. Ice-marginal landforms are commonly used to reconstruct changes in glacier size, morphology, and extent over time.

Glaciotectonic moraines encompass a broad range of different types of moraine formed by the deformation of ice, sediment, and rock. Of these, the most common are push moraines, which are formed when a glacier flows into sediment and bulldozes material into a ridge.

Dump moraines are formed at stationary or near-stationary ice-fronts, where debris accumulates along the margin or front of the glacier to form a ridge of sediment (Figure 16A).

Ablation moraines (sometimes referred to as ice-cored moraines) form wherever ice-melt is retarded beneath a cover of supraglacial debris. This supraglacial debris may be derived from rock falls and avalanches in the accumulation area, in which case it is often arranged in flow-parallel medial moraines, or it may be composed of subglacial or englacial debris elevated to the ice surface by folding, thrusting, or upward-directed flow lines in the ablation area. Uneven melting gives rise to hummocky moraines (Figure 16B).

Outwash fans and outwash plains (or sandar) are formed where glacial melt water emerges from the glacier and sediment is deposited at or beyond the ice margin, producing extensive braided river tracts composed of sand and gravel. Kettle holes form where sediment is deposited over buried ice.

Kame terraces are formed when sediment is deposited by melt water flowing laterally along an ice-margin. Kames are more fragmentary features, which are formed in a similar manner but often in ice-walled tunnels and against steep valley sides.

Subglacial landforms Subglacial landforms (sometimes referred to as subglacial bedforms) are produced beneath actively flowing ice. The most common of these are a family of ice-moulded landforms, all of which are elongated parallel to the direction of ice flow.

Flutes are low flow-parallel ridges that are rarely continuous for less than 100 m (Figure 16C). Megascale lineations are much larger (tens of kilometres in length and hundreds of metres in width) and are often visible only on satellite imagery. Drumlins are typically smooth oval or elliptical hills that are tens of metres high and long. The origin of drumlins is unclear, but they have been attributed to deposition by actively moving ice and to subglacial sheet floods.

Ribbed moraines (also known as Rogen moraines) are large closely spaced moraine ridges, which are often curved or anastomosing but generally orientated transversely to the direction of ice flow. They may represent the fracturing of a pre-existing subglacial till sheet at the transition from cold-based to warm-based ice.

Geometric ridge networks and crevasse-fill ridges are low subglacial landforms that are composed of material derived from the basal debris layer of the glacier, or material beneath the glacier. They form as a result of the squeezing of subglacial material into basal crevasses or former subglacial tunnels, commonly during surges. Alternatively, geometric ridge networks can also form beneath glaciers as a result of the intersection of foliation-parallel ridges and englacial thrusts.

Figure 16 Glacial depositional landforms: (A) terminal dump moraine (left) of Chuchung Glacier (breached by a stream) and lateral moraine (right) of Ama Dablam Glacier, Khumbu Himal, Nepal (an older moraine with person for scale in the foreground); (B) hummocky moraine formed by the thrusting of subglacial sediment into an englacial position before release, Kronebreen, Svalbard; (C) flutes on proglacial area of Austre Levénbreen, north west Spitsbergen; (D) esker (sinuous ridge of sand and gravel) emerging from beneath Comfortlessbreen, a tidewater glacier in western Spitsbergen. © 2005, Photographs, M J Hambrey.

Eskers are glaciofluvial landforms that are created by the flow of melt water in subglacial, englacial, or supraglacial channels. They are usually sinuous in plan view and composed of sand and gravel (Figure 16D).

Bathymetric Forms Resulting from Glacial Deposition

The morphology and sediment composition of subaquatic features, particularly in fjords and on continental shelves, are less well known than their terrestrial counterparts. As on land, subaqueous depositional assemblages reflect the interaction of a wide range of processes.

Ice-contact features form when a glacier terminus remains quasi-stationary in water, particularly in fjords. Morainal banks form as a result of a combination of lodgement, meltout, dumping, push, and squeeze processes combined with glaciofluvial discharge; poorly sorted deposits are typical of such features. Grounding-line fans extend from subglacial tunnels that discharge melt water and sediment into the sea, and are typically composed of sand and gravel. Developing out of grounding-line fans are ice-contact deltas, which form when the terminus remains stable long enough for sediment to build up to the surface of the fjord. Where a glacier becomes disconnected from the water body, alluvial sediments may prograde to form fluviodeltaic complexes, again dominated by sand and gravel. In addition to these large-scale forms, there are small-scale features that are found particularly on beaches, such as iceberg toolmarks, ridges, depressions from the melting of buried ice, bounce marks, chatter marks, and roll marks. Icebergs can also churn up submarine sediment, particularly on shoals, producing iceberg turbates.

Depositional forms on continental shelves are best known from a combination of deep drilling and seismic profiling. Some, as in Alaska, are simply larger-scale analogues of fjordal features, such as fan-delta complexes, but others show evidence of having formed under floating tongues that are typical of the colder ice of the polar regions. These include subglacial deltas, till tongues, diamicton aprons, and the immense (up to 400 km wide) trough-mouth fans.

Other features are similar to those on land and include shelf moraines, flutes, and transverse ridges.

Conclusions

Glaciers and ice-sheets can be highly effective agents of landscape change, eroding, transporting, and depositing large amounts of material at a variety of spatial scales, from a valley scale to a continental scale. The rates of operation of these processes are strongly controlled by glacier mass balance and thermal regime, which together determine glacier velocity, melt water production, ice deformation styles, and sediment routing through the ice-mass. Glaciers produce a diverse range of landforms and sediments. The classic glacial erosional landforms, such as cirques, glacial troughs, stoss-and-lee forms, and areas of striated bedrock, are generally carved in solid bedrock, although glacial erosional landforms such as melt water channels and tunnel valleys can also form in unconsolidated sediments. Glacial depositional landforms take a variety of forms and include ice-marginal landforms, glaciotectonic moraines, hummocky moraines, outwash fans and plains, kames and kame terraces, and subglacial bedforms. These landforms are typically composed of a range of sediment types, ranging from poorly sorted sediments such as diamicton to well-sorted sand and gravel. Glacial sediments may be deposited in both terrestrial and marine settings, although those deposited on continental shelves and slopes probably have the best preservation potential in the geological record.

Karst and Palaeokarst

M J Simms, Ulster Museum, Belfast, UK

Introduction

Karst is a term applied to terrain with distinctive landforms and underground drainage systems that form through the greater solubility in water of certain rock types, particularly limestone. Karst landscapes are sculpted largely by solution, other rock types largely by mechanical erosion. The word 'karst' has its origins in pre-Indo-European languages, from *kar*, meaning 'rock'. In Slovenia the word 'kras' (or 'krs'), subsequently germanicized as 'Karst', derives from the name of a barren stony limestone area near Trieste, which is still considered the type area for limestone karst. Gypsum and rock salt may form karst,

with extensive gypsum karsts known from Russia and the Ukraine, but their greater solubility renders such landforms more dynamic and, for rock salt, ephemeral in all but the most arid climates. Karst features may also develop, though rarely, on very weakly soluble rocks, such as basalt, granite, or quartzite.

Rock solubility and water are the primary factors in karst development. Arid climates, whether hot or cold, support little karst. Physical rock properties also are important. Highly porous rocks seldom support well-defined karst features, which instead are favoured by low porosity and good secondary permeability, in the form of fractures, focusing the drainage into specific conduits through the karst rock. The removal of rock in solution allows the development of drainage through the rock, rather than just across its surface as happens largely with rocks removed by mechanical erosion. Consequently, karst landscapes generally lack well-developed surface drainage but have underground drainage conduits, or caves. Hence a significant component of karst terrains typically lies beneath the surface, sometimes extending to depths of hundreds, or even thousands, of metres. Intimately associated with the dissolutional aspects of karst are depositional ones. The latter include clastic sediments within the caves and, particularly, minerals deposited by precipitation from karst waters both above and below ground.

Many subdivisions of karst have been proposed. Relict karst is used to denote landforms inherited from earlier climatic or drainage regimes but still subject to modification by the current conditions. Palaeokarst refers to karst features buried by younger rocks and so largely isolated from current karst modification; where uncovered by later denudation, this isolated karst is called exhumed karst. Biokarst encompasses small-scale sculpting of limestone by animals and plants, although the distinction between dissolutional sculpting (true biokarst) and mechanical excavation (bioerosion) is seldom made. Pseudokarst is, as its name implies, 'false karst'. Such features superficially resemble karst but form by quite different processes, such as lava tubes, soil piping, and thermokarst, or cryokarst, formed by localized melting of permafrost.

Often karst geomorphology is regarded as a specialist discipline that is of limited general application to geology or geomorphology. However, ~12% of Earth's terrestrial, ice-free surface is composed of limestone, with 7–10% supporting some form of karst landscape. Furthermore, as much as 25% of the world's population may depend to some extent on karst water supplies. Consequently, the study of karst is crucial to understanding landscape and drainage development over a significant area of Earth's surface.

Karst Processes

The basic process of karst dissolution involves ion dissociation. For rock salt (NaCl), gypsum ($CaSO_4{\cdot}2H_2O$), and quartz (SiO_2), this requires only the presence of water but, on a global scale, the outcrop area of evaporites and the low solubility of quartz render them of only minor and localized significance for karst development. Limestone ($CaCO_3$) and dolomite ($CaMg[CO_3]_2$) are by far the dominant karst rocks but experience very low rates of dissociation in pure water. The addition of free H^+ ions greatly increases the rate of carbonate dissociation and hence even weak acids become effective solvents. In most karst environments, carbonic acid, derived from atmospheric or soil CO_2, is the main source of H^+ ions, although other organic or inorganic acids may be significant locally. The solubility of CO_2 increases with decreasing temperature, in common with other gases. The same is true also for limestone, in marked contrast to most solids for which solubility increases with temperature. Nonetheless, the availability of liquid water and biogenic CO_2 is far more significant for karst development than are low temperatures.

Water with an excess of H^+ ions is commonly referred to as 'aggressive', and continues to take up HCO_3 ions until an H^+/HCO_3 equilibrium is reached at saturation, as in the following equation:

$$CO_3^{2} + 2H^+ \rightleftarrows HCO_3 + H^+ \rightleftarrows H_2CO_3$$

Different karst waters may reach saturation at different concentrations, determined by the initial CO_2 concentration, but this is not a simple straight-line relationship and mixing of different karst waters may increase aggressivity. This phenomenon, called mixing corrosion, may be significant in certain karst environments. Carbonate solubility also is increased by the foreign ion effect, the addition of ions such as Na^+, K^+, and Cl . Seawater is saturated and cannot directly dissolve limestone, but mixing with freshwater can considerably increase carbonate solubility and is of major significance in certain environments. In the same way that an increase in CO_2 concentration increases carbonate uptake, so degassing of CO_2 from a saturated solution causes reprecipitation of calcite.

Dissolution can and does occur in static or laminar flow conditions, though constrained by diffusion rates through the boundary layer. Permeable soil or sediment cover, even when vegetated, may offer only limited resistance to downward percolation of water to the limestone beneath. Although this subsoil water movement may be slow, its dissolutional efficacy is enhanced by higher CO_2 concentrations generated by

respiring plant roots and soil organisms. With faster flow, generally associated with increased water depth and/or conduit width, laminar flow gives way to turbulent flow and there is a rapid (~fivefold) increase in dissolution rate. This laminar–turbulent transition, or turbulent threshold, is very significant for the development of many karst features.

Time is a major factor to consider in the development of karst, reflecting dissolution rates. Features on a millimetre to centimetre scale may form within a few years on limestone, whereas the largest scale landforms may require hundreds of thousands, or even millions, of years to reach their present form. Timescales for karst development on gypsum are much faster, whereas on quartz they are very much slower.

Figure 1 Solution flutes (rillenkarren) on gypsum, Devon coast, England. These may form on gypsum within a few months or years in a humid climate.

Surface Karst (Exokarst)

At the surface of the Earth, karst features are manifest at scales from tens of kilometres down to millimetres. Large-scale karst landscapes and landforms invariably support a diversity of smaller scale features. The type and scale of karst features that develop at a particular location are determined by several factors that can be grouped broadly: (1) intrinsic rock properties such as composition, texture, porosity, and fracturing; (2) extrinsic factors, particularly climate (especially the amount of rainfall), specific environment (terrestrial, lacustrine, or marine), the type and extent of plant cover, sediment cover (if any), and tectonism (uplift or subsidence); and (3) time. In general, karst is best developed when pure limestones with low porosity but good secondary permeability are subject to frequent, rather than heavy, rainfall. Hence karst landforms are better developed in humid temperate or tropical climates than in strongly seasonal ones. Duration of exposure to dissolution is critical; for particular intrinsic and extrinsic conditions there is an optimum time-scale for specific karst features to develop. Beyond this time-scale, dissolution may continue to modify and, ultimately, even destroy the features.

Small-Scale Karst (Karren)

Small-scale solutional sculpting (millimetres to metres), often termed 'karren', develops purely as a function of rock solubility and run off, independently of the underground drainage characteristic of karst terrains. The development time-scale for most karren ranges from a few years to tens of thousands of years under optimum conditions. On exposed limestone solution pans (kamenitzas) form by ponding of water on level surfaces, while solution flutes (rillenkarren; Figure 1), runnels (rinnenkarren), and ripples develop by water flow across inclined surfaces. Fractures, commonly joints, act as initial conduits for flow into the karst aquifer and are widened by dissolution to form grikes (kluftkarren). The limestone between grikes may, depending on factors such as lithology, soil cover, and climate, form flat-topped blocks (clints or flachkarren), rounded blocks, domes or teeth (rundkarren), or sharp pinnacles (spitzkarren), or may break up into fragments (shillow, felsenmeer, or trümmerkarren). Glacially stranded boulders may protect limestone directly beneath them from direct dissolution by rainfall, eventually leaving the boulder perched on a pedestal surrounded by a limestone surface lowered by solution. The height of such pedestals provides a measure of the surface lowering rate (Figure 2). Clints, grikes, solution runnels, and solution pans are common features beneath mineral or organic soils, though typically they are more rounded than those formed subaerially.

Freshwater lake shores support their own unique karren assemblages, strongly influenced by lake water chemistry. Small hemispherical solution pits (Figure 3) are particularly characteristic on flat limestone surfaces around lakes, and notches (swamp notches) may indicate former water levels. Even if the lake water is permanently saturated with carbonate, the limestone can dissolve if seasonal changes in water level trap air pockets in which condensation corrosion occurs; this process forms upward-tapering tubes (röhrenkarren). Similarly shaped, but larger, features called bell holes are found in the entrance zone of some tropical caves and are considered to form by condensation corrosion associated with daily changes in air temperature.

Most karren are essentially abiogenic in origin, but living organisms may contribute directly to limestone

Figure 2 Limestone pedestal beneath a sandstone erratic. The pedestal provides a measure of postglacial (~14 ka) surface lowering of the surrounding limestone. Conspicuous solution runnels (rinnenkarren) have formed on the top of this sandstone erratic despite its low solubility. County Cavan, Ireland.

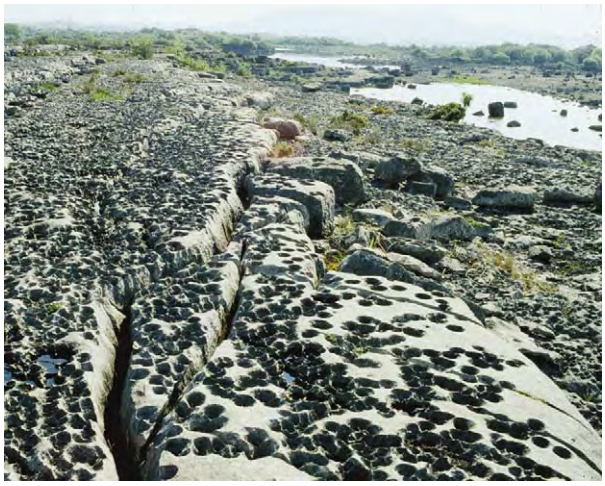

Figure 3 Abundant solution pits, typical of lacustrine karst, on limestone surfaces exposed in the zone of seasonal submergence. Lough Mask, Ireland.

dissolution on a small scale. Certain algae and invertebrates adopt an endolithic habit, living within cavities that they excavate in the rock. Cyanophytes constitute a significant karstic agent in some climates. Where created with acids, these cavities are true biokarst (Figure 4). However, many organisms excavate cavities mechanically, by bioerosion, and these are not strictly biokarst. Algal biokarst has been termed phytokarst and is ubiquitous in intertidal marine environments, where endolithic organisms are the dominant karst agent. In cave entrances or beneath overhangs, light-orientated phytokarst pinnacles, or

Figure 4 Temperate marine biokarst, encrusted with *Mytilus*, in the intertidal zone. The Burren, Ireland.

photokarren, may develop where biokarstic algae are illuminated from just one direction.

Medium-Scale Karst (Karst Landforms)

Medium-scale features (metres to kilometres) can perhaps be grouped together as karst landforms and develop mainly over time-scales of thousands to hundreds of thousands of years. In any karst landscape, dissolution is greatest near the surface where water first comes into contact with the rock, creating a shallow zone of epikarst above less karstified rock. Over time, and dependent on climate, the depth and dissection of this epikarst zone increases. The most characteristic surface karst landform is the doline (sometimes also known as a sinkhole, especially in North America and by engineers everywhere), an enclosed depression from which drainage is underground; on non-karst lithologies such depressions would form lakes. Dolines can form by one or a combination of mechanisms, e.g., by enhanced dissolution through focusing of drainage, by collapse into a cavity beneath, or by downwashing of a weakly consolidated soil or sediment cover into cavities beneath (Figure 5). Collapse dolines may intercept the regional water table to form cenotes; they are particularly characteristic of some lowland karst plains. Irregular, flat-floored depressions may develop by the lateral solution and planation of limestone inundated by seasonal rises in the regional water table. Known as poljes in their type area of the Dinaric Alps, they are fed by springs and drain via sinks, or may fill and empty via the same conduit, known as an estavelle, depending on flood stage or groundwater level.

Drainage in karst terrains is not exclusively subterranean and elements of fluvial geomorphology are common. Valleys and gorges may develop where rivers cross from adjacent non-karst (allogenic) rocks and travel across the limestone surface before sinking.

Figure 5 Suffosion dolines on glacial till, formed by downwashing of sediment into cavities in the underlying limestone. Black Mountain, South Wales.

Many are now largely dry and were formed under different climatic regimes, reflecting either greater rainfall or the blocking of underground drainage by permafrost; Cheddar Gorge in south-west England is a fine example of the latter. So-called blind valleys end abruptly downstream against an often steep slope where a surface stream sinks underground, though the former surface continuation may continue beyond at a higher level. Conversely, headward excavation by a spring may form a valley ending abruptly upstream at a steep slope, called a steephead or pocket valley. Emerging saturated karst waters may precipitate calcite, often under biogenic mediation, to form sometimes extensive deposits of tufa or travertine, such as those of Plitvice, Croatia.

Residual limestone hills at scales from a few metres to hundreds of metres high are an inevitable consequence of focused drainage from surrounding limestone, particularly where this is sufficient for turbulent flow, and the enhanced dissolution rates associated with it, to occur. Although individual hills can be regarded as landforms, they are more logically considered here as elements of the largest scale of karst development, karst landscapes.

Large-Scale Karst (Karst Landscapes)

Karst landscapes can be broadly defined as areas, typically covering many square kilometres, encompassing characteristic assemblages of karst landforms and karren. Generally, though not invariably, they reflect prolonged karstification over several million years and large-scale interactions between geology, tectonics, and climate. The youngest distinct type of karst landscape, characteristic of many cool temperate regions subjected to repeated glaciation during the Pleistocene, is termed glaciokarst (Figure 6). The Burren of western Ireland is a classic example and shows features typical of glaciation, such as ice-plucked

Figure 6 Temperate glaciokarst landscape with typical joint controlled clints and grikes, rinnenkarren, rillenkarren, and kamenitzas. The Burren, Ireland.

crags, scoured rock surfaces, limestone pavements, and erratic boulders. Commonly these are superimposed on pre-existing karst landforms/landscapes, but smaller scale karst landforms and karren, particularly grikes (kluftkarren), small dolines, and caves, have commonly been superimposed on the glacial landforms since the ice retreated.

Fluviokarst landscapes are dominated by valleys cut by surface rivers, either before significant underground drainage had developed or under different climatic conditions, notably periglacial environments, which favoured surface rather than underground drainage. Many fluviokarst valleys are now largely dry because drainage has been captured underground.

Cone karst (Fencong) is dominated by conical or hemispherical hills, typically a few tens of metres high and several hundred metres across, separated by dolines and other irregular depressions. Cone karst develops only in wet tropical climates such as in parts of Java, some Caribbean islands, and particularly in China's Ghizou Province. Tower karst (Fenglin),

Figure 7 Relict karst towers, accentuated by marine undercut ting, in Halong Bay, Vietnam. These testify to active tectonic uplift in a terrestrial environment, prior to drowning by sea level rise or regional subsidence. Photo by Sally Hunt.

perhaps the most spectacular of all karst landscapes, is dominated by often precipitously steep limestone towers, from tens to hundreds of metres high, and is restricted to areas in south-east Asia and the adjacent islands (Figure 7). Cone and tower karsts develop where rates of tectonic uplift exceed, for the former, or are equalled, for the latter, rates of surface lowering at points of focused dissolution, leaving residual hills or towers between. In contrast, prolonged denudation with minimal uplift will, ultimately, produce a low-relief corrosion plain, as typified by the Gort lowlands to the south of Galway, Ireland.

Various classifications describe stages of 'maturity' in karst landscapes; the most useful, and comprehensive, scheme (Figure 8) was developed primarily for engineers and encompasses a range of parameters, including karst class (a qualitative measure based on the scale and diversity of karst landforms), mean doline density, rockhead relief, and typical cave size.

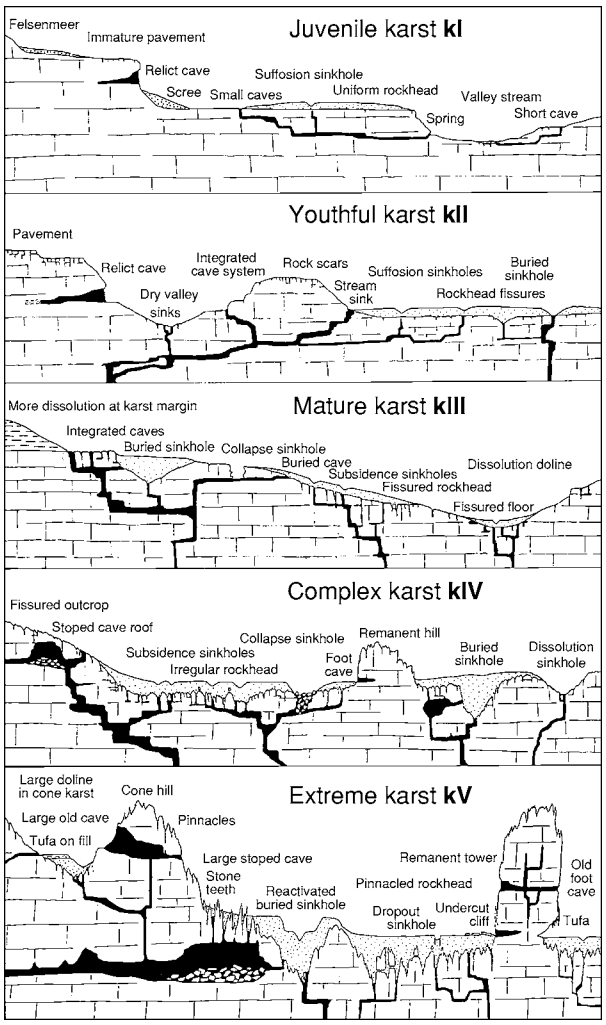

Figure 8 Typical landforms encountered within the five cat egories of ground conditions recognized by Waltham and Fookes in their 2003 engineering classification of karst.

Karst Denudation and Landscape Development

In landscapes encompassing both soluble and insoluble lithologies, differences between erosional and dissolutional processes have a considerable effect on landscape development in tropical and temperate regions. Karst dissolution is a low-energy process that may occur even in static water and, in the case of limestone, is enhanced by a vegetation cover, which increases soil CO_2 levels. Analogous weathering of non-karst rocks may alter their composition and mechanical strength without significant volume change or transport, forming saprolites sometimes many metres thick. These are removed only by erosion, a higher energy process requiring fast water flow but hindered by vegetation, which binds and protects weathered rock and soil. In temperate and tropical environments, limestone may be removed at a steady rate, proportional to mean annual rainfall, whereas erosion of rock and saprolite is more sporadic and depends on the frequency of intense rainfall events and the extent of vegetation cover. In arid regions, limestones commonly prove more resistant to erosion than do other, less well-cemented, rocks. Conversely, in tectonically stable humid climates, the long-term denudation rate of limestones may be significantly greater than is the overall erosion rate on adjacent rocks, reducing limestone outcrops to lowlands flanked by hills of more slowly denuded lithologies.

Karst Drainage

A significant element of drainage in karst landscapes is underground. Drainage into a karst aquifer is either

autogenic, where derived from a karst catchment, or allogenic, originating on non-karst rocks. Commonly, input to a karst aquifer is mixed. Autogenic recharge is diffuse, as rainfall across the entire karst outcrop, whereas allogenic recharge is concentrated at discrete stream sinks or swallets. Most negotiable caves are associated with such swallets. Water re-emerges from a karst aquifer at a rising (also known as a resurgence or spring). Typically, this occurs at the lowest point that the karst rock is exposed at the surface, although impermeable layers within a karst aquifer may cause a rising to be perched at a higher level. Resurgences may be free-draining streams or may rise from depth under hydrostatic pressure. The more than 300 m-deep Fontaine de Vaucluse in France is an example of the latter; the term 'vauclusian spring' has been coined to refer to the point of emergence of water under pressure.

Caves (Endokarst)

Underground drainage conduits are a fundamental element of karst. Those large enough for a person to enter are called caves, an artificial definition constrained by the size of the caver! In fact, water can move slowly along submillimetre fractures, but at widths of ~5 mm laminar flow gives way to turbulent flow (the turbulent threshold, or hydraulic jump) and dissolution rates increase significantly. Such 'protocaves', often anastomosing networks of small tubes, commonly are found on fracture planes adjacent to larger caves that have developed from them. The development of a cave, from inception to destruction, is called speleogenesis.

Fractures commonly represent the initial routes for water flow, and the configuration of many passages is strongly influenced by the spatial distribution and orientation of joints, faults, and bedding planes. Rectilinear passage networks arise where inception is dominated by vertical fractures, whereas meandering passages imply inception on subhorizontal ones. Passage shape may be influenced by these fractures but also is strongly controlled by passage location with respect to the 'water table'. Above, in the vadose zone (see Figure 9), water occupies only the lower part of the passage and flows downwards, as in surface streams and waterfalls; dissolution here forms canyonlike passages and vertical shafts. Sequences of deep vadose shafts and canyons, sometimes descending a kilometre or more, are characteristic of high mountain karst regions such as in the Alps. Below, in the phreatic, or 'saturated', zone, fractures and

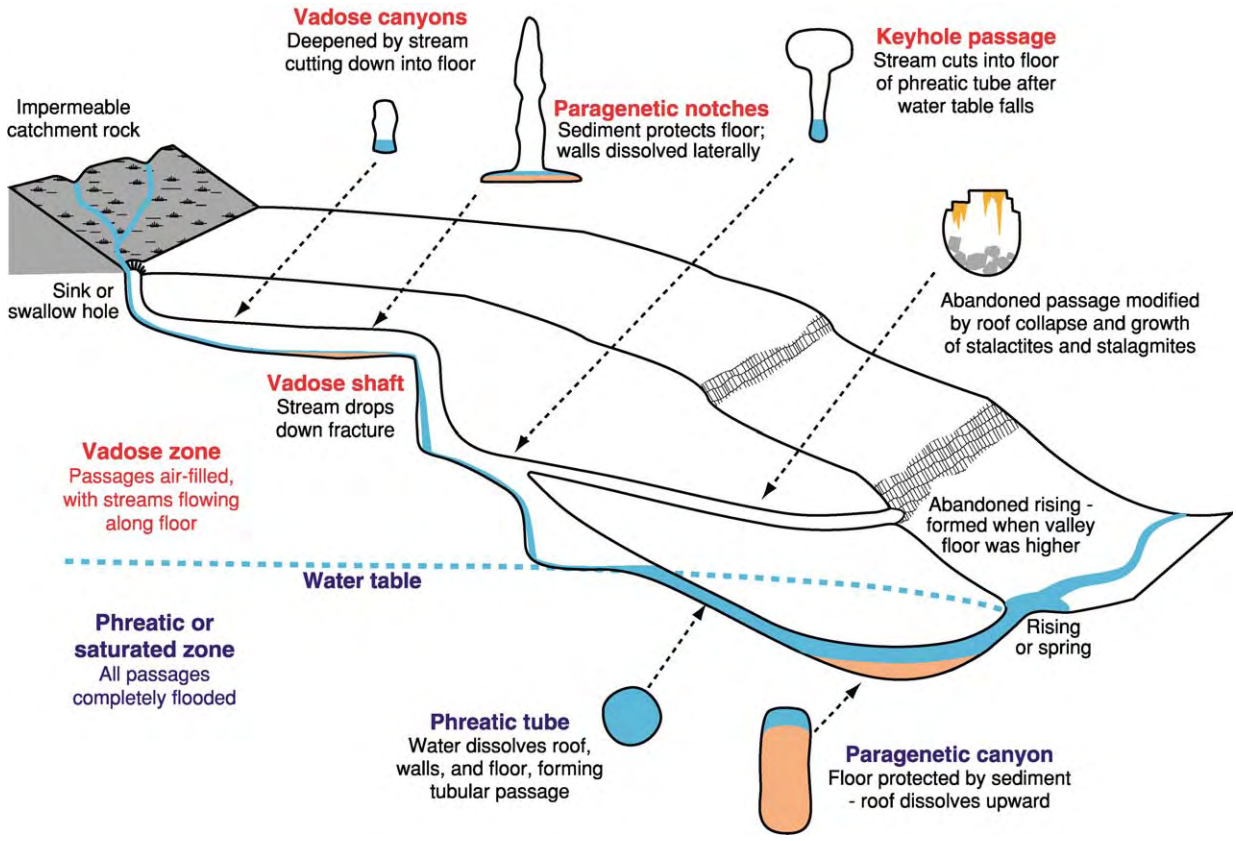

Figure 9 Diagrammatic section through a cave system to show the various features discussed in the text.

Figure 10 Relict paragenetic canyon, with sediment removed, extending upwards from the bedding plane on which the anastomosing 'proto caves' first developed. The Burren, Ireland.

cavities are water filled, and water flow follows the path of least resistance, often flowing upwards if necessary. Dissolution here occurs in all directions, forming passages with circular or elliptical cross-sections, as seen in the drained tubes of Kentucky's Mammoth Cave and still forming in the active phreas of Mexico's Yucatan, often with blind pockets formed by eddies or by mixing corrosion where percolation water emerges from a minor fracture into a flooded passage. Mixing of karst waters from separate sources may enhance dissolution locally, influencing both conduit configuration and shape. Sediment aggradation is common both in vadose and in phreatic passages and may armour the floor against downward dissolution, causing lateral or upward dissolution by paragenesis (this is a process quite distinct from mineral paragenesis). In vadose passages, lateral dissolution may form paragenetic notches at stream level, spectacularly seen in some of the huge river caves of Mulu, Sarawak. In phreatic environments, dissolution may raise the roof, forming a largely sediment-filled paragenetic canyon. Paragenetic canyons (Figure 10) extend upwards from their initiation level, such as a bedding plane, whereas vadose canyons (Figure 11) cut downwards from it. A drop in aquifer base level may flush out sediment fill from paragenetic canyons and/or form 'keyhole' passages by vadose incision in the floor of former phreatic tubes. The two types of canyon passages can be distinguished by the presence of either undulating wall notches, indicating phreatic paragenesis associated with undulating sediment banks, or horizontal notches, indicating vadose conditions. Keyhole passages, with a vadose trench incised in the floor of a phreatic tube, are particularly significant for interpreting the history of karst aquifers, indicating rejuvenation when base level drops below the cave passage.

Water in a karst aquifer may be confined by an impermeable rock (aquifuge), whereas impermeable or weakly permeable layers (aquicludes or aquitards) may influence water movement through the rock, allowing the development of perched aquifers above regional base level. Hence the altitude of a particular phreatic passage may reflect only local conditions. Eddies caused by turbulent water flowing across limestone in caves and surface streams commonly form asymmetric concavities, called scallops, which are invaluable flow indicators in relict cave passages (Figure 12). Their steeper slopes face downstream, and their size is a function of flow velocity. Smaller scallops indicate faster flow than larger ones; vadose scallops are sometimes only 1–2 cm across, whereas phreatic scallops may be 1 m across! An approximate rule of thumb for calculating flow velocities (in metres per second) is to divide 3.5 by the mean length of the scallops in centimetres.

Figure 12 Heavily scalloped relict phreatic pressure tube entering a larger cave passage. The strongly asymmetric scal lops provide clear evidence of upward flow, under pressure, into a larger water filled passage. Deflection of these scallops above the pressure tube indicates flow from left to right in the main passage. Ogof Llyn Du, North Wales.

Figure 13 Typical cave fills in an active vadose cave. Spe leothems (stalactites) are deposited by carbonate saturated per colation water emerging along joints on roof. Coarse clastic sediments are carried into the cave by fast flowing water. Marble Arch Cave, Northern Ireland. Photo by Tony Waltham.

Most caves form by an overall downward movement of water through the karst aquifer from sink to rising, but a few form by very different processes. Some are created instead by hydrothermal springs or by the action of sulphuric acid formed from hydrogen sulphide rising from hydrocarbon deposits beneath. Encompassing some of the largest and longest caves in the world, such as the Carlsbad and Lechaguilla caves in New Mexico, they contain some of the most extraordinary arrays of speleothems (cave mineral deposits) known, with gypsum a major component.

Over time, cave passages may collapse or be infilled by clastic sediment, transported in from the surface, or by speleothems (Figure 13). Clastic sediments provide important information on environmental histories and potentially can be dated using techniques such as optically stimulated luminescence. Calcite and aragonite speleothems (stalactites, stalagmites, and flowstone) are the most common mineral deposits, precipitated in response to CO_2 degassing of carbonate-saturated percolation water emerging into air-filled cavities and hence providing evidence of vadose conditions. They are immensely important in karst research because the calcite can be dated radiometrically, particularly by uranium-series disequilibrium, and can provide information on palaeoclimate and hydrology.

Figure 14 Spectacular palaeokarst shaft developed in, and capped by, marine Carboniferous limestones. The size of this pothole, filled with non marine clastics, provides evidence of the scale and duration of this intra Carboniferous emergent episode. Cookstown, Northern Ireland.

Palaeokarst and Interstratal Karst

Palaeokarst is defined as karst that has been buried by younger rocks. It is a common, though often unrecognized, component of successions in which limestones are present (Figure 14), and serves as a clear indicator of terrestrial environments and, to some extent, duration of emergence. Interpretation

of palaeokarst may be complicated by two factors; it is usually visible only in two, rather than three, dimensions; and burial by younger rocks does not prevent palaeokarst being modified or even destroyed by subsurface dissolution. Small-scale karst microsculpting with relief of a few centimetres, such as rillenkarren or solution pits, is readily destroyed by pressure solution associated with rock overburden. Lithological contrasts commonly act as a focus for water movement and the development of interstratal karst, which may resemble palaeokarst but is younger than the overlying rock. Interstratal karst is especially prevalent in highly soluble rocks such as gypsum and rock salt. Cave passages may remain open as potential conduits for water flow long after burial of the karst surface, and sometimes are invaded and infilled by mineralising fluids. Such occurrences may be difficult to distinguish from syngenetic mineral deposits, in which conduit formation and mineralisation were penecontemporaneous, but mineralized palaeocaves commonly include some clastic sediment infill beneath the mineral deposits. Remains of organisms within caves are protected from destruction by weathering and scavengers; hence palaeokarst caves encompass many important fossil lagerstätten. Although some animals are adapted for life in caves, most remains found are of animals and plants washed in or fallen in from the surface.

Landslides

S F Burns, Portland State University, Portland, OR, USA

Introduction

Landslides are a major form of geohazard that cause millions of dollars of damage and many deaths each year. They result from the movement of masses of rock, earth, and debris down a slope under the influence of gravity. They can occur at all scales, from a few metres across to several kilometres, and at all rates, from metres per year to metres per second. The term landslide is really a misnomer because the material can move not only by sliding, but also by flowing and/or falling. Landslides are important superficial processes for geomorphology, moving sediment down the slope where water in streams can eventually carry it away. They are generally triggered by water, but sometimes earthquakes and even volcanic eruptions can lead to landsliding. On land the water comes mainly from heavy and persistent rainfall but also can come from rapid snowmelt. Submarine landslides may be triggered by cyclic wave loading as well as by earthquakes, and frequently follow marine trangressions.

Possibly the largest landslide on land occurred some 10 000 years ago in south-western Iran. Called the Saidmarreh Landslide, a mass of limestone 15 km long, 5 km wide, and 300 m thick slid off the underlying marl bedrock and travelled a distance of 18 km while dropping only 1000 m. One of the largest underwater slides has been described to have

occurred on the continental margin of the Atlantic Ocean off the coast of Spanish Sahara in water depths over 2000 m and covering an area of 18 000 km^2. It probably originated after the last glacial advance when sea-level was 100 m lower than it is today. Landslides have also been identified on other planets like Mars, where one with a volume of 100 km^3, 60 km long, and 50 km wide that has travelled 2 km, leaving a scarp 6 km high, has been identified.

Loss of Life and Property due to Landsliding

Human and economic losses from landslides are considerable worldwide and continue to grow as pressures of expanding population cause development to extend into less stable hillslope regions. It is estimated that each year landslides kill nearly 600 people around the world, and cause over $12 billion (US) damage (direct and indirect losses). Direct losses include the cost of rebuilding the structures, whereas indirect losses are concerned with commercial loss, reduced real estate value, and loss of productivity. Japan is one of the most affected countries, suffering over $4 billion (US) loss per year. The United States, Italy, and India each have total annual losses of between $1 and $2 billion (US) each.

The worst landslide disaster in historical times occurred on December 16, 1020 in Kansou, China when over 180 000 people were killed. Many of these people were living in homes excavated in or built on the slopes of loess (silt). This soil has a metastable fabric and collapsed during an earthquake-triggered event. One of the worst disasters in recent years happened in 1998 when an ancient landslide reactivated in Kelso, Washington (USA), and 60 houses on it were destroyed, causing over $25 million (US) of damage to homes and utilities (Figure 1).

Figure 1 Home destroyed in 1998 in Kelso, Washington, by a thrust of soil under it as an ancient landslide reactivated, destroying 60 similar homes over a four month period. Note the main street in the foreground has also been destroyed.

Factors Determining Slope Stability

The stability of a slope can be considered as two forces working against each other: Driving forces (or shear stress) work to cause slope materials to move down-slope, whereas resisting forces (shear strength) act to keep the materials on the slope. When the ratio of resisting forces over driving forces (called the factor of safety) is greater than 1, the slope is stable. When it is less than 1, the slope usually fails.

'Water' can both increase the driving forces and reduce the resisting forces, thereby reducing stability. Saturation from rainfall can increase the slope mass, thereby increasing the driving forces. Filling soil pores with water also reduces soil strength by increasing pore pressure and reducing the effective stress, and possibly allowing particles to pass by one another so further reducing the internal resistance of the soil to sliding. To reduce the risk of landsliding on a slope, the first consideration should therefore be the removal of excess water.

As the angle of slope increases, the driving forces also increase. Cutting a road into a slope could easily oversteepen it, making that slope more prone to landsliding unless a retaining wall is built. Each geological material has a characteristic 'angle of repose', which is its maximum stable angle, related to its frictional strength. For instance, the angle of repose for an uncemented sand is about 35°, and slopes steeper than this are likely to fail. Clay, shale, serpentinite, and uncompacted fill are all slope materials prone to failure, having significantly lower angles of repose.

'Vegetation' is also important to slope stability for it increases resisting forces through its roots that bind the soil. Trees also act as natural suction pumps that remove water from the soils through evapotranspiration, thereby further increasing slope stability.

If the bedrock is inclined somewhat parallel to the slope, it is called a 'dip slope', and the stability will be determined by the bedding plane strength, which may well be lower than the mass strength. Shales are particularly weak, as are buried 'fossil' soils on these dip slopes. The Gros Vente Landslide that dammed the Gros Vente River in 1925 in Wyoming (USA) and the Vaiont disaster in Italy in 1963 are examples of dip slope failures. Adding a stockpile or a structure to a slope can also increase the driving forces on a slope, reducing its stability.

Types of Landslide

Various classification schemes and names have been given to describe landslides, depending upon the

process that brings the soil and/or rock down the slope. Landslides are generally classified into process groups based on their rates of movement and corresponding amounts of water contained within the landslide mass (Figure 2).

'Falls' refers to the free fall of detached materials, usually rocks, that descend down a steep slope. Frost heave or heavy rains generally dislodge rocks from cliffs, causing a free fall to the bottom of the slope. A collection of this rockfall material at the bottom of the slope is called 'talus'. Rockfalls can be spectacular, such as the 9000-m^3 rockfall that plunged 500 m into the valley at Yosemite National Park in California on 10 July 1996, travelling at 300 km h^{-1}. It generated an air blast that leveled 2000 trees! Another example of a large rockfall happened near the village of Randa in the Pennine Alps of Switzerland in the early 1990s (Figure 3).

A 'topple' is a type of rock displacement where there is forward movement of a block rotating around a fixed hinge. This can occur where jointing in a slope is steeply inclined and parallel to the cliff-face. In some places in the world, this is an important factor in cliff retreat (e.g., Tasmania) and also in recently glaciated upland regions (e.g., Scotland). Toppling is also very common in basalt cliffs where columnar jointing is present.

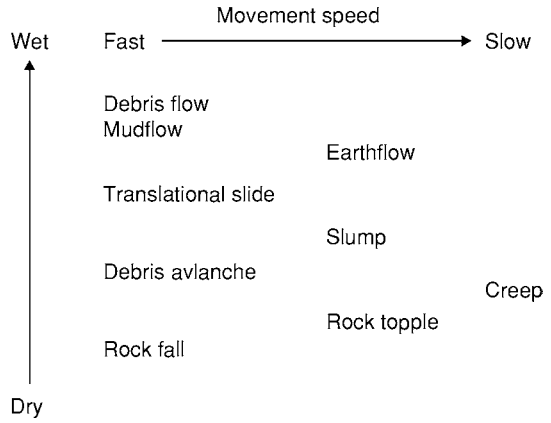

Figure 2 Landslides classification that relates water content to movement speed.

Figure 3 Large rockfall that occurred in the early 1990s in the village of Randa in the Pennine Alps of Switzerland.

'Translational slides' occur along a failure surface in the bedrock and move parallel to the surface. Most of the time the slide fractures at the base and breaks into many pieces. When the landslide moves as a uniform piece, it is called a slab failure or block slide. The failure surfaces upon which such landslides move are generally clay layers, shale layers, or palaeosols (old, buried soils) that parallel the slope. A classic translational slide occurred on 23 June 1925 in Gros Vente, Wyoming, USA. Over many years this slope of sandstone overlying shale (that dips at 20°) had been undercut by the stream at the bottom of the slope. Heavy snowmelt and heavy rains saturated the sandstone that consequently slid on the shale bed into the stream, damming it up and forming Gros Vente Lake.

If the sliding mass occurs along a curved-upward plane and shows rotation, it is called a 'rotational slide', which may develop into a 'slump' if the integrity of the failed mass is destroyed. Such movements are common in mudstones and clay soils or where there is a resistant geologic layer overlying a weaker layer. Such landslides tend to be small, producing gently inclined surfaces on the sides of steep slopes as the mass rotates (backtilts). Many large slumps occurred in Panama between 1914 and 1920 during the construction of the Panama Canal; one was so large that the whole of one side of the canal rotated into the canal itself. The slide was so large that the toe of the slide stuck up as an island in the center of the canal. Note the rotational slide movement affecting a house built on the toe of an ancient landslide that reactivated in 1996 in Tigard, Oregon, USA (Figure 4).

'Flows' occur when material moves down-slope as a slurry, generally due to continuous, permanent deformation of the sediment. 'Debris flows' consist of material ranging in size from clay to boulders mixed with water, displaying plastic flow behaviour. They form steep, lobate fronts with marginal levees. Mudflows are very similar to debris flows but contain finer-grained particles and tend to exhibit more viscous flow characteristics.

Debris flows and mudflows originate in upland source areas from many small soil slips that deliver sediment rapidly to create a stream, often the result of persistent rainfall. Deposition forms a fan-shaped deposit when the gradient becomes flat. Figure 5 shows a house in Dodson, Oregon, along the Columbia River Gorge, USA, that was buried by eight debris flows over a four-day period in February 1996.

Figure 4 Slump destroys a house in Tigard, Oregon, USA; note deformation of supporting pillars. This home was built on the toe of an ancient landslide that reactivated in February 1996.

Figure 5 Debris flow burying a house in Dodson, Oregon, USA, alongside the Columbia River Gorge; eight debris flows occurred here in February 1996.

Velocities can reach 55 km h^{-1}. Debris flows pose a significant hazard to life and property within the debris fans and along the stream valleys that connect the source areas to the debris fans. Debris flows are most common in arid regions, in alpine areas, and on the side of volcanoes. Deposits from debris flows can be differentiated from stream deposits by their high density, due to an abundance of clay and silt in the matrix. 'Debris torrents' are special types of debris flow that commonly consist of large volumes of logs and woody debris in addition to sediment in the slurry, occurring mainly in main drainage channels.

Debris flows that originate during volcanic eruptions are called 'lahars'. One of the world's most devastating debris flow disasters involving a lahar occurred on 13 November 1985 in Armero, Colombia, when a lahar originating 50 km away on the volcano of Nevado del Ruiz roared down the Lagunilla River Valley. It consisted of a 40-m-high wall of mud by the time it hit the town of Armero, burying 23 000 people. Debris flows are so dangerous because they travel at high velocities over long distances, and occur with little warning. America's volcano, Mt. Rainier, is the most dangerous because of its lahar risk: 55 lahars have originated from Mt. Rainier over the past 10 000 years, travelling up to 40 km from the mountain. Thousands of people live within a 40-km radius of Mt. Rainier and face this potential danger. The 1980 eruption of Mt. St. Helens also produced lahars that traveled more than 120 km from the mountain, destroyed 27 bridges over rivers, buried about half of Highway 504 to the west of the volcano, and delivered 34 million m^3 of mud to the Columbia River, 45 km from the volcano, which blocked shipping in the main channel.

'Earthflows' travel more slowly and generally originate on hillslopes as large tongues that break away from scarps; they slow down as they lose water. Heavy and persistent precipitation on steep slopes underlain by weak soils produce such flows. Rates range from 0.17 to 17 km h^{-1}. Once the main movement has occurred, they continue to show creep movement for years afterwards.

'Quick clay landslides' are a special type of flow, characterized by thixotropic clay, especially glaciomarine deposits formed in coastal areas of Norway, Sweden, and eastern Canada. Isostatic rebound of these clays following glacial melting has exposed the sediment to weathering and flushing out of the salts by rainwater-fed groundwater. Sudden vibrations can subsequently cause the deposit to liquefy and flow. A classic example occurred in Rissa, Norway, in April 1978 as 5 million m^3 of quick clays failed, destroying seven farmhouses and moving at a rate of 30 km h^{-1}. One person was killed in this flow, which was triggered by a simple excavation in a local farmyard.

The fastest and most destructive landslides are called 'debris avalanches', or 'sturtzstroms'. They travel at speeds up to 300 km h^{-1}, travel long distances (sometimes in excess of 50 km), and may be very large (some have been in excess of 80 million m^3). Why do these landslides travel such large distances at such high velocities and large volumes? An early idea was that the debris moved on a trapped layer of air. More recent hypotheses stress semielastic collisions between landslide particles: the body moves until all of the original (potential) energy is consumed by friction between the particles. Another hypothesis stresses internal melting and basal melting of the debris, thereby decreasing friction. This last idea comes from a study of the 2.1-km^3 Kofels Landslide in the Otz Valley in Austria where fused rock, resembling obsidian (and called frictionite), is found in layers throughout the base of the debris avalanche,

Figure 6 The May 18, 1980, eruption of Mt. St. Helens in Wash ington, USA, seen here in 2004, was initiated by a 5.2 magnitude earthquake that also triggered a large debris avalanche seen in the foreground. It has been dissected by the Toutle River. Note Castle Lake, which was formed as the landslide dammed Castle Creek, to the centre right.

Figure 7 Soil creep expressed in trees with bent trunks called 'pistol butt' trees or 'trees with knees'. The trees are Radiata pines in New Zealand's Southern Alps.

and pumice-like rocks abound at the edges, presumably being shed by this prehistoric landslide as it moved at high velocities.

The world's largest historical landslide, which occurred when Mt. St. Helens erupted in 1980, was a debris avalanche. It traveled over 25 km down the Toutle River Valley at a velocity over 150 km h ^{1} (Figure 6). In Yungay, Peru 22 000 people were killed in 1970 when a debris avalanche of over 80 million m^3 descended from the volcano, Nevado Huascaran, traveling a distance of 14.5 km in 7 minutes at a velocity of about 300 km h ^{1}. It jumped 300 m out of the valley to bury the village that was perched supposedly out of harm's way on a shelf. Another debris avalanche occurred in Elm, Switzerland, in 1881 after heavy rains and caused 10 million m^3 to move 5.5 km in less than a minute at 310 km h ^{1}, killing 115 people. Another 70 people were killed in 1903 in Frank, Alberta, when 30 million m^3 of limestone debris cascaded down the slope above the town at a velocity of 100 km h ^{1}. One the earth's largest debris avalanches dammed the river at Gohna, India, in 1893 during the monsoon rains with 3.6 billion m^3 of debris.

Significant movement on slopes can also occur but at rates almost imperceptible. This is called 'creep', with rates in the range from 0.1 to 100 mm yr ^{1}. Causes can be freeze–thaw or shrink–swell processes operating on the soil sediments, assisting movement down-slope by gravity. Evidence of movement is found in cracked walls, leaning telephone poles and walls, and trees with knees (pistol-butt trees) (Figure 7). Movement occurs mainly in the soil on the slope. Creep may also be a precursor to the failure of a slope during a landslide. It is also a common feature of a landslide mass after it has come to rest, and slopes within the failed mass regain equilibrium. Ancient earthflows have been known to exhibit creep thousands of years after the initial movement of the landslide. Hoofed animals grazing on the sides of slopes when they are wet cause small-scale terraces to form from creep, and these are called 'terracettes'.

Reactivation of Ancient Landslides

If land has moved once, there is a high chance of it moving again given the right conditions. As population pressures increase, people move onto marginal land, which may be more prone to landslides. It is therefore imperative to recognize ancient landslides and assist the planning process, for instance, with maps to raise awareness of their presence prior to building.

Geomorphologists are particularly interested in reading the landscape for signs that tell of past landslides, in order to identify active processes and understand the evolution of the landscape. First indications are scarps (arcuate steep slopes cut into the hill where the landslide has torn away). Second is hummocky topography ('bumpy' ground produced by the landslide mass weathering over time). A hummocky slope with a steep, half-moon slope at the top usually indicates that an old landslide has occurred there. Younger landslides will generally have different vegetation on the slide mass than the surrounding slopes. In coniferous forests, landslides generally are covered with deciduous trees for the first hundred years after the failure. If one can see the actual sediments making up the landslide, the colluvium there is likely to be unsorted and angular in shape as all particles have been mixed together randomly.

Prevention of Landslides and Mitigating Their Impact

Prevention of landsliding or repairing the damage occurring as the result of a landslide necessitates understanding the basic relationship of driving forces and resisting forces. The need is to reduce the driving forces and/or increase the resisting forces on the slope. Decreasing the slope angle to less than the angle of repose for the slope will significantly increase stability. Removing water from the slope through drains or temporary water diversion by the use of tarps in full will decrease the driving forces and increase the resisting forces. Building a buttress at the bottom of the slope by erecting a wall of boulders, building a concrete wall with weep holes (to prevent build-up of water pressure behind it), or building a gabion basket wall will increase the resisting forces of the slope.

Recognizing and mapping old landslides is important. Planning regulations recommend not building on ancient landslides, so preventing disasters like Kelso, Washington. Replacing slope vegetation aids the slope stability and increases the resisting forces through the removal of water. In rockfall-prone areas, the use of screens or sprayed-on shotcrete will keep the rock fragments on the slope, as will rock bolts for the larger boulders. Avalanche shelters will provide additional protection, aided by electronic fences to give warning of rockfall events.

A landslide killed 2600 people in Longarone, Italy, on 9 October 1963. The second highest concrete dam in the world had just been built to a height of 265 m—the Vaiont Dam at the base of Mt. Toc. The reservoir area was prone to landslides, and it was known that Mt. Toc had sedimentary beds that dipped steeply into the valley below and that the slopes had been oversteepened by the river at the base. Filling of the reservoir aggravated the situation, raising the groundwater level (and water pressure) at the base, aggravated by persistent heavy rains that raised the reservoir level 20 m higher than expected within a short period. The slope began to creep at a rate reaching 400 mm day^{-1} the day before failure. On the day of failure, 240 million m^3 of rock broke away on the south side of the valley and slid down into the reservoir, rapidly displacing the water and creating a huge wave 100 m high, which topped over the dam and flooded the Piave River Valley. A total of 2600 people were drowned. Today, the dam still stands, intact. Its foundations were adequate, but the location with respect to the reservoir impounded behind was quite inappropriate. The landslide could have been prevented if the planners had paid attention to the broader context of the location and, in particular, the effect of impounding on slope instability of the reservoir margins, and the movements that had been noted from the past.

Particle-Driven Subaqueous Gravity Processes

M Felix and W McCaffrey, University of Leeds, Leeds, UK

Introduction

Particulate subaqueous gravity flows are sediment-water mixtures that move as a result of gravity acting on the sediment-induced density excess compared with the ambient water. The mixtures can range from densely-packed sediment flows, that are essentially submarine landslides, to very dilute flows carrying only a few $kg\,m^3$ of sediment. Gravity flow can take place in lakes and oceans, but some dense flows also occur in rivers. Sediment volumes transported by individual events can range up to thousands of cubic kilometres, although most events are of much smaller magnitude. Due to their infrequent occurrence and destructive nature, much information about subaqueous gravity processes comes from the study of their deposits and from laboratory experiments. Flow initiation mechanisms, sediment transport mechanisms, and flow types are described here separately, to emphasise the sense of process continuum needed to appreciate the development of most natural subaqueous gravity flows. This is followed by a description of internal and external influences on flow behaviour. Finally, the influence of flow regime on individual deposits is outlined.

Flow Initiation Mechanisms

A variety of processes can generate subaqueous gravity currents, with varying initial concentrations.

Direct Formation From Rivers

Currents can be formed when turbid river water flows into bodies of standing water such as lakes or oceans. If the bulk density of the turbid river water (sediment plus interstitial fluid) is higher than that of the receiving body of water, the river outflow will plunge, travelling along the bed as a hyperpycnal flow (or plume) beneath the ambient water. Such sediment-laden underflows may mix with the ambient water and transport sediment oceanward as particulate gravity currents. Although sometimes these river-derived flows are of high concentration (e.g., the Yellow River hyperpycnal plume), mostly they are dilute. Direct formation of subaqueous gravity currents in this way is, however, the exception rather than the rule. More commonly, the bulk density of the turbid river outflow is less than that of the ocean, and turbid surface plumes are generated. Nevertheless, particulate gravity flows can also form from surface plumes if material settling out collects near the bed at high enough concentrations to begin moving. A similar effect results from flow generated by glacial plumes where the sediment is slowly released into the water body.

Where the interstitial fluid in a hyperpycnal plume is of lower density than that of the ambient fluid, as is the case when freshwater rivers flow into brackish or fully saline bodies of water, ongoing sedimentation may induce buoyancy reversal. Thus, the gravity current will loft, in a manner similar to some subaerial pyroclastic density flows, and the flow will essentially cease to travel forwards, resulting in the development of abrupt deposit margins.

Sediment Resuspension

Loose sediment on the seafloor can be resuspended if bed shear stress is high enough. This can occur during storms or during passage of flows caused by density differences as a result of temperature or salinity. The resulting suspended sediment concentrations can be high enough to allow the mixtures to flow under the influence of gravity. As in the case of river-derived flows, resuspension usually generates initially dilute currents.

Slope Failure

Flows of much higher concentration may form as a result of slope failure. Sediment on submarine slopes can become unstable as a result of slope oversteepening during ongoing sedimentation, and during sea-level falls, as a result of high inherited pore fluid pressures and gas hydrate exsolution. Slope failure can alternatively be triggered by externally applied stresses, due to earthquakes, or as a result of loading induced by internal waves in the water column above (which chiefly occur in oceans). Initially, the failing mass becomes unstable along a plane of instability and a whole segment of the slope starts moving. Retrogressive failure and/or breaching can continue, adding material following the initial loss of stability. The concentration of this mass is at packing density but can become more dilute as flow continues.

Terrestrial Input

Not all subaqueous gravity flows need originate under water. Landslides, pyroclastic flows, and aeolian sediment transport originating on land can enter

lakes or oceans and continue flowing underwater if the rates of mass flux are sufficiently high.

Grain Transport Mechanisms

Matrix Strength and Particle-Particle Interactions

Within dense flows, grains can be prevented from settling as a result of matrix strength (Figure 1). This strength may arise if some or all of the particles are cohesive. The resulting cohesive matrix prevents both cohesive and non-cohesive particles from settling out. In addition, particles can be supported by matrix strength within flows of non-cohesive grains if the particles are in semi-permanent contact, as is the case for flows whose densities are close to that of static, loose-packed sediment. For slightly lower concentrations, inter-particle collisions will help keep particles in suspension.

Hindered Settling and Buoyancy

Settling of particles can be slowed down by water displaced upwards by other settling particles (Figure 1). Such hindered settling is especially effective in dense mixtures with a range of grain sizes so that the smaller particles are slowed down by settling of the larger particles. The presence of smaller particles also increases the effective density of the fluid that the particles are settling in and thus enhances the buoyancy of the suspended particles and reduces settling rates.

Turbulence

The motion of sediment-laden flows can generate turbulence through shear at the bed, internally in the flow or at the top of a dense layer. The turbulent bursts generated at the bed tend to have an asymmetrical vertical velocity structure, with slower downward sweeps and more rapid upward bursts. This turbulence pattern counteracts the downwards settling of particles, moving them higher up in the flow (Figure 1). Turbulence generation is hindered and dissipation increased, however, if the particle concentration is high, or if the flow is very cohesive or highly stratified.

Flow Types

Broadly speaking, flows can be divided into three main types, depending on density:

Dense, Relatively Undeformed Flows, Creeps, Slides and Slumps

Flows of this type essentially have the same density as the pre-failure material. In each case the sediment moves as one large coherent mass, but with varying amounts of internal deformation. Grains remain in contact during flow and thus matrix strength is the main sediment transport mechanism. Such flows will stop moving or shear stress becomes too low to overcome friction, at which point the entire mass comes to rest. Flow thickness and deposit thickness are essentially the same, although flows may thicken via internal thrusting or ductile deformation as they decelerate prior to arrest. Slope creep caused by gravity moves beds slowly downslope with gentle internal deformation of the original depositional structure. Slides undergo little or no pervasive internal deformation, while slumps undergo partial deformation but the original internal structure is still recognisable in separate blocks. Thicknesses of slides and slumps range from several tens of metres to 1–2 km and travel distances can be up to about 100 km, with displaced volumes of up to 10^{12} m^3, although most flows are considerably smaller.

Dense, Deformed Flows: Rockfalls, Grain flows, Debris Flows and Mudflows

In flows of this type, sediment still moves as one coherent mass, but concentrations can be lower and the mass is generally well mixed, with little or no preservation of remnant structure from the original failed material. Sediment support mechanisms are matrix strength, buoyancy, hindered settling, and grain-grain collisions. Rheologically such flows are plastic (i.e., they have a yield strength). Clast types generally range from purely cohesive in mudflows, to cohesive and/or non-cohesive in debris flows (Figure 2) and purely non-cohesive for grain flows and rockfalls (where movement is by freefall on very steep slopes). These types of flow are formed as a

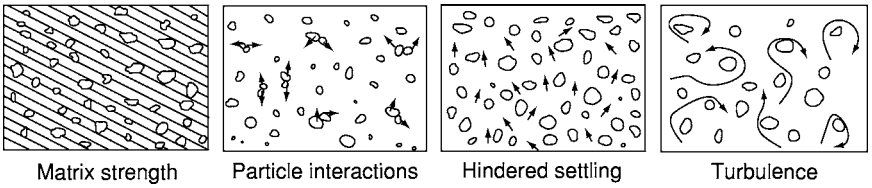

Figure 1 Schematic illustration of the principal grain transport mechanisms, shown in decreasing order of concentration from left to right.

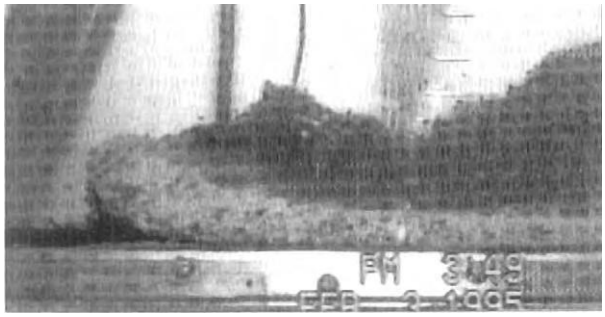

Figure 2 A laboratory debris flow from right to left. Note: a dilute turbidity current has been generated on the upper surface of the debris flow due to erosion of material by fluid shear. (After Mohrig *et al.* (1998) *GSA Bulletin* 110: 387 394.)

result of rapid internal deformation following slope failure, from high concentration river input or from reconcentration of dilute flows (described below). Flow and deposit thicknesses can be up to several tens of metres with travel distances of several hundreds of kilometres. Erosion can add material to the flow and thus extend both travel distances and size of deposit – neither of which, therefore, necessarily relate to the initial flow mass. Motion will stop once friction is too high and flows will generally deposit *en masse*. Debris flows may develop a rigid plug of material at the top of the flow, where the applied stress falls below the yield strength. Such flows move along a basal zone of deformation, and may progressively 'freeze' from the top downwards, ultimately coming to rest when the freezing interface reaches the substrate.

(Partly) Dilute Flows: Turbidity Currents

In flows of this type, the sediment does not move as one coherent mass (Figure 3). These flows are generally dilute although parts of these flows can be of high concentration, especially near the bed. In the dilute parts of these flows, sediment is transported in either laminar or turbulent suspension. In higher concentration areas additional sediment transport mechanisms, such as grain-grain interactions, hindered settling, and buoyancy effects may also play a role. Rheologically, the dense parts of such flows can behave plastically, but the dilute parts are Newtonian. Concentrations in turbidity currents range from only a few kg m^3 to concentrations approaching those of static, loose-packed sediment. The dilute parts of these flows are commonly strongly vertically density-stratified. Turbidity currents can be formed via dilution of debris flows (see below), directly from river input or from resuspension of sediment.

Turbidity current thicknesses can be up to several hundreds of metres and can increase during flow due to turbulent entrainment of ambient water. Velocities can be up to tens of m s, but more commonly are around 1 m s or less. Larger flows, such as the well-documented Grand Banks event of 1929, may travel distances of a few thousand kilometres, even on nearly flat slopes, although distances of tens to hundreds of kilometres are more common. Sediment eroded during flow can add to the driving force and will increase flow duration and travel distance. Flows will gradually slow down as sediment settles out, with coarse material being deposited proximally and fine material distally. Deposit thicknesses generally are significantly smaller than flow thickness and are on the order of cm to dm, but can be up to multi-metre scale for large flows. However, ongoing sedimentation from flows of long duration can result in deposits whose thickness relates principally to flow longevity rather than flow thickness. Consequently, it is generally more difficult to interpret flow properties from analysis of turbidity current deposits (turbidites) than it is for the denser flow types.

Flow Transformations

Transformations of one flow type into another are common. Initially-dense slide masses may be disrupted due to internal shear, liquefaction, and disaggregation on various scales. If this deformation is sufficiently vigorous all the original structure of the failed material will be lost and the slides transformed into debris flows. In turn, these can transform into turbidity currents by erosion of sediment from the front and top of the dense mass due to ambient fluid shear (Figure 2), by disaggregation and dilution, and by deposition of sediment, diluting the flow. Turbidity currents can be transformed into debris flows if they reconcentrate, for example when mud-rich flows slow down. Further transformation into slides is not possible once the original internal structure is broken up.

The extent of transformation depends on flow size, velocity, and sediment content. Variable degrees of

transformation can lead to the development of different flow types within one current, both vertically and from front to back. This co-occurrence of different flow types is especially common in flows with a dense basal layer and more dilute upper part. Thus, classification schemes which subdivide flows on the basis of discrete flow types do not recognise the diversity of natural flows, in which different types of flow may occur simultaneously and vary in relative importance in time and space as the flows evolve.

Internal and External Influences on Flow Behaviour

Flow behaviour is influenced both by internal factors such as concentration and grain size distribution and external factors such as input conditions and topography.

Flow Velocity

The driving force, and hence velocity of subaqueous gravity currents increases with both concentration and flow size. However, resistance to internal shear will increase with increasing viscosity due to increasing particle concentrations, and with increasing yield strength caused by cohesive particles. This will inhibit the increase of flow velocities. However, because concentration-induced resistance to shear does not scale with flow size, it can more readily be overcome by the higher gravitational driving forces of larger flows, which are, therefore, faster than smaller flows.

Flow Duration and Run-Out Length

Slope failure-induced slumps and slides that do not transform into debris flows and/or turbidity currents will generally be of short duration and have run-out lengths on the order of the initial failure size. If the failed sediment mass does transform into a debris flow, the duration and run-out length depend on the mobility as described above, with larger flows travelling further. However, because debris flows stretch out as they are flowing and because they may incorporate material by erosion, their run-out length may not be directly related to the initial failure size.

The duration and run-out length of turbidity currents depend on their size and sediment content, and hence also on their formation mechanism. Sustained input from rivers or glacial plumes can result in long duration flows, even if the input concentration is low. Turbidity currents that are generated from slope failures can have a short duration input, but tend to stretch considerably due to turbulent mixing and will thus increase in flow duration provided the transported sediment is kept in suspension. The ability of a flow to keep sediment in suspension, known as the flow 'efficiency', directly affects flow run-out lengths. Flow efficiency depends on flow magnitude, with larger flows being more efficient, and on grain size, as finer grains settle out more slowly than coarser grains. The presence of fine sediment in the flow also increases the ability to carry coarse sediment so both types of sediment will be carried further and both flow duration and run-out length will be increased.

Spatial and Temporal Changes to Flow

Flows are influenced both by the input conditions and by the terrain over which flow takes place. Flow behaviour therefore varies both temporally and spatially, causing local areas of erosion and deposition that lead to a deviation from a simple decelerating depositing flow and complicate the depositional pattern. Both spatial and temporal changes in flow behaviour can be caused by changes in sediment content of the flow: erosion adds driving force to the flow and increases velocity, while deposition slows flows down. Temporal changes to flow can also be caused by changing input conditions. River input from floods leads to flows that initially have a progressive increase in velocity followed by a long period of decreasing velocity. In retrogressive failure ongoing detachment of discrete sediment masses will result in pulsed sediment input; the rate of input generally tends to peak rapidly, and then diminish as successive slope failures reduce in size.

Local spatial changes in flow are caused by changes in the topography (**Figure 4**). The angle of the slope on which flow takes place is obviously important for gravity driven flows; when slope angle increases, the flow will go faster although the velocity increase will be diminished by the increase of friction with the ambient water. Nevertheless, small changes in slope angle can change flow behaviour. If the slope angle decreases, very dense flows can be stopped as the basal friction becomes too high. More dilute flows may undergo hydraulic jumps, in which they abruptly thicken and decelerate. This deceleration can cause coarser sediment to be deposited. Local changes to flow can also be caused by changes in the constriction of the flow path. When a flow goes into a constriction, velocity will increase. Where a flow can expand, as at the end of submarine canyons, velocity will decrease.

Momentum Loss

The evolution of flow behaviour can be different along flow-parallel and flow-transverse directions. Momentum will be greater in the direction of flow

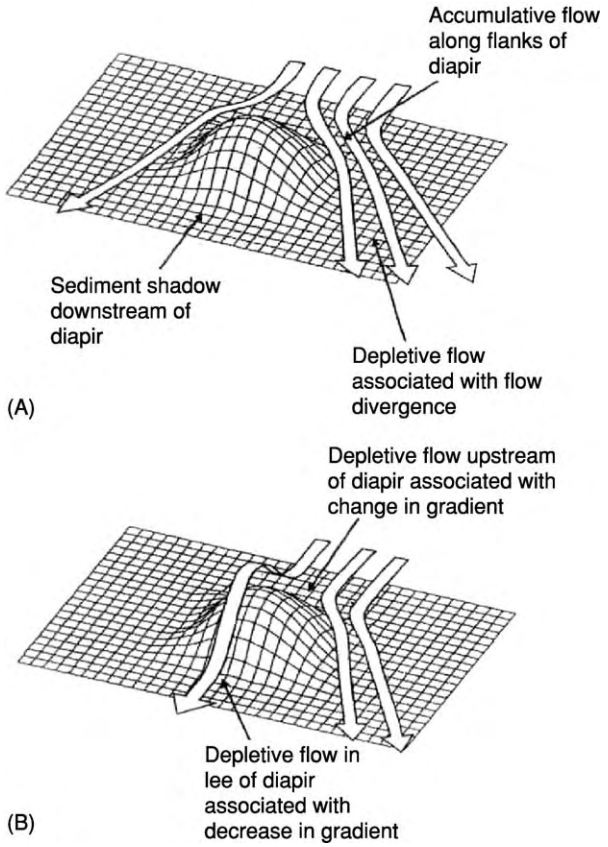

Figure 4 Schematic illustration of the interaction of turbidity currents with (A) high amplitude and (B) low amplitude bathymetry. Flows are uniform if the velocity does not change with distance and are non uniform if the velocity does change. Accumulative flows have spatially increasing velocity while depletive flows have decreasing velocity. (After Kneller and McCaffrey (1995) SEPM, Gulf Coast Section, 137 145.) Published with the permission of the GCSSEPM Foundation; Further copying requires permission of the GCSSEPM Foundation.

than in the transverse direction. For coarse sediment in dilute flows, this means transport is principally in the main flow direction as rapid transverse momentum loss results in rapid deposition. This is less the case for fine-grained sediment, which will stay in suspension more easily and will thus generate momentum for flow in the transverse direction. These differences are not so important in restricted parts of the flow path, such as in canyons, but are important in less confined settings.

Channelised flow

If flows are erosive they can create conduits (incisional channels) both for themselves and for later flows. In aggradational systems, dense flows such as debris flows will start to form levees at their edges where flow becomes too thin to overcome the matrix strength. Sideway expansion of coarser-grained turbidity currents may lead to loss of momentum in the transverse direction, and thus greater rates of off-axis than on-axis deposition. This incipient levee formation may lead to the development of aggradational channels (Figure 5). These channels, which are generally sinuous, and often meandering, partly confine flow and can carry sediment downstream for long distances. Dilute parts of the flow can overtop the levee crests resulting in overspill and deposition of thin sheets of relatively fine-grained sediment that decrease in thickness away from the channel. This winnowing process causes the flows progressively to become relatively depleted in fine grained material, resulting in the development of sandy lobe deposits at the end of relatively muddy channel-levee systems. Levee height decreases downstream and flows become less confined. Like subaerial channels,

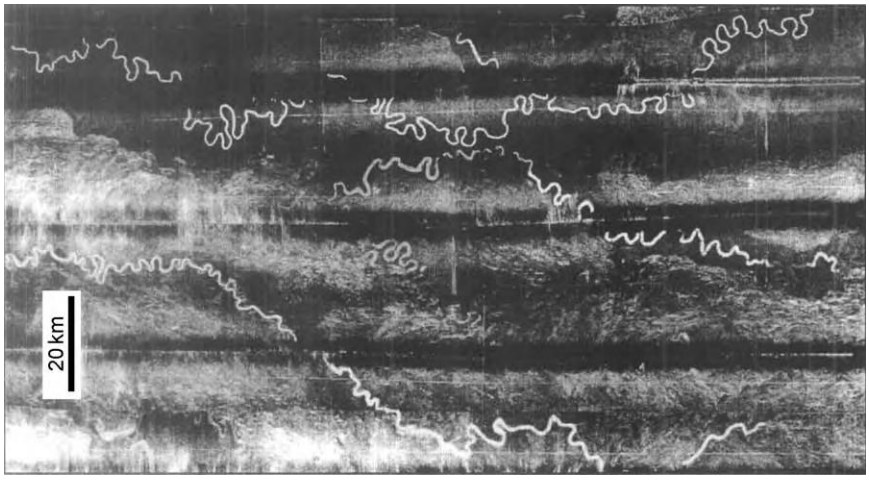

Figure 5 GLORIA image of sinuous submarine channels on the Indus fan. (From Kenyon *et al.* (1995). In: Pickering *et al.* Atlas of Deepwater Environments: architectural style in turbidite systems: London: Chapman and Hall, 89 93.)

aggradational submarine channels may undergo avulsion, resulting in the formation of internally-complex sedimentary fan deposits. Although channels are largely formed by the flows themselves, they can be influenced by pre-existing topography.

Flow in Unconfined Basins

When the basin size is very large compared to the flow, the flows are effectively unconfined. Flows that are not strong enough to erode and that are not captured by antecedent channels can start to spread out. Fine-grained, efficient turbidity currents spread out more evenly in all directions than their coarser-grained counterparts as a result of differing rates of momentum loss. Such unconfined flows can be influenced by Coriolis forces, being deflected to the right in the northern hemisphere, and to the left in the southern hemisphere. Unconfined flows deposit sediment in lobes, with deposit thicknesses decreasing in all directions away from the depocentre. Development of depositional topography may cause subsequent flows to be steered away from depocentres of previous flows and to deposit relatively more of their sediment load in offset positions in a process of autocyclic compensation. Deep-sea fan systems can form in unconfined basins settings through this process.

Flow in Confined Basins

When the basin size is smaller than or of the same size as the flow, the basin margins will prevent flow from expanding and the basin is said to be confined. Processes of topographic interaction induce spatial changes to flow, as detailed above. Flows can overcome small topographic obstacles, but as obstacle height increases relative to the flow height, part or all of the flow will be diverted. Flows in confined basins can be reflected back and forth between different basin margins if enough energy is available, which can result in reworking of the part of the deposit laid down during a previous pass of the flow. If the basin walls are sufficiently high to prevent any of the flow escaping, the basin is said to be ponded. In this case all the sediment is retained in the basin, and any mud present in the flow will be distributed in suspension evenly across the basin and will slowly settle out. The spatial restriction created by confined or ponded basins will hinder flow expansion. Thus, although autocyclic processes can play a role in dictating sedimentary architecture, in general basin fill patterns will be dominated by the confinement. Successive deposits can gradually fill up a basin completely. This can result in flows being able to partially bypass the basin, and enter the next basin downstream, in a process known as fill-and-spill.

Flow Regime Recorded in Depositional Sequences

Erosion and Bypass

If flow power is large enough, erosion can take place, which can remove significant volumes of sediment. This material adds to the driving force of the flow and can lead to acceleration (a process called ignition), and increased flow duration and travel distance. Smaller-scale erosion can form structures that indicate palaeoflow direction, including grooves, where an object is dragged along the bed, and flutes, where turbulent motions erode a characteristic shape that is deeper upstream, and both flares and shallows downstream. Erosion can take place beneath both debris flows and turbidity currents, although flutes require turbulence for their formation, a condition more likely to be met in turbidity currents. Not all flows are capable of erosion, but this does not necessarily mean they deposit their transported load. Bypass of sediment is common in upstream areas and may leave no record in the deposit. This behaviour is closely related to the process of autosuspension, in which sediment is transported by turbulence generated by flow caused by the density difference due to the sediment itself. Strictly speaking, such flows neither erode nor deposit.

Deposition

Eventually all flows, whether they start out as dense or as dilute flows, will lose their momentum and deposit their sediment. Dense flows such as slumps and debris flows will leave deposits whose structure more or less corresponds to that of the flows themselves. This is not the case for turbidity currents, which generally deposit their sediment progressively. Whether deposition takes place at all in turbidity currents depends on local flow competence and capacity. Flow competence indicates which grain sizes can be transported by a flow of a given velocity and flow capacity indicates how much sediment can be carried by a flow of a given velocity. The depositional structures of turbidity current deposits (turbidites) are influenced by the grain sizes carried in the flow, the velocity of the flow, and the sediment fall-out rate. High sediment fall-out rates cause suppression of primary sedimentary structures and lead to the formation of massive (structureless) deposits. The grains in these deposits tend not to be packed at maximum density and commonly re-organise themselves post-depositionally, expelling pore water in the process. This process commonly produces structures that overprint any primary depositional fabric. If fall-out rate is low enough, structures such as ripples and

laminations can be formed, depending on grain size and flow regime. Deposit thickness is influenced both by flow size, with larger flows resulting in thicker deposits, and also by flow duration, with sustained flows being able to deposit thick beds, even if the flows themselves are not particularly large.

Various models have been proposed to describe the vertical succession of features in an idealised turbidite. The most widely applied is the model of Bouma, which describes a sequence deposited by a gradually decelerating turbidity current. Because all flows must eventually wane, full or (more commonly) partial Bouma sequences are developed quite frequently, particularly in relatively distal locations. However, the assumption that flows gradually decelerate over the entire flowpath is unlikely to be met, and many deposits will not look like this or other standard sequences. The influence of temporal changes and spatial changes on deposits will be reflected in terms of bed thickness and grain size distribution (grading). These are schematically presented in the diagram of Kneller for turbidity current deposits (Figure 6). This scheme is strictly valid only for flow where concentration does not change, which limits the applicability of the approach, but it illustrates the idea well. Finally, it should be borne in mind that depositional sequences may be reworked by surface currents, dewatering, and/or bioturbation. These processes may obscure any evidence of flow character that was originally recorded in the deposit.

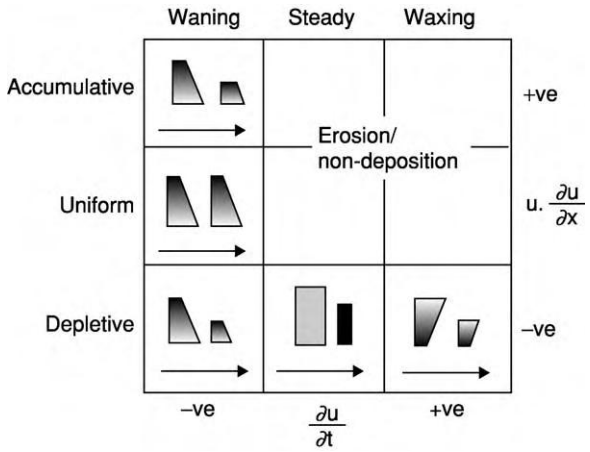

Figure 6 Schematic representation of vertical and lateral grain size variation within single beds as a function of the combined effects of flow steadiness and uniformity. The two logs in each field represent relatively proximal and distal configurations, respectively (arrow indicates flow direction). Flows are steady if velocity does not change with time and are unsteady if the velocity does change with time. Waxing flows have temporally increasing velocity while waning flows have decreasing velocity. Non uniformity definitions are given in Figure 4. (After Kneller and McCaffrey (1995) SEPM, Gulf Coast Section, 137 145.) Published with the permission of the GCSSEPM Foundation; Further copying requires permission of the GCSSEPM Foundation.

Summary

Subaqueous particulate gravity currents may exhibit a wide range of concentrations, magnitudes, grain size, and type and flow velocities, all of which may change as flow develops. Flow behaviour is dictated both by input conditions (affecting flow magnitude, grain size distribution, and duration), and by the flow pathway (including its bathymetry, and the erodibility of the substrate). Thus, subaqueous particulate gravity currents form a complex and variable range of flow types, which together constitute the principal means by which coarser-grained clastic material is transported into the deep ocean.

Deposition from Suspension

I N McCave, University of Cambridge, Cambridge, UK

Introduction

Geological treatments of sediment dynamics generally lose sight of the fact that the last event of dynamic importance that happened to the sediment was that it was deposited. Instead, most accounts concentrate on the process of transport. Of course, a fair amount of work deals with the creation of bedforms, many of which are depositional, but occur in the transport regime of 'steady' flow, as well as in the 'unsteady' regime of flow deceleration which leads to deposition. It is not possible to deal sensibly with the topic of deposition from suspension without some mention of how material is transported, and so this article deals briefly with this aspect after giving an outline of the controlling factors and before describing the processes of deposition.

Almost any material, even boulders, can be transported in an aqueous turbulent suspension if the flow is large and sufficiently rapid. Even gravels were in suspension in the flood following the bursting of the glacial Lake Missoula in western Washington State (USA). However, most material deposited from suspension is mud and fine sand. Indeed, most (>50%) of the sedimentary geological record is of silt and finer sizes (<63 μm). Fine silt and clay, material of $\leq$10 μm, has the peculiar property that it can stick together, thereby transforming its settling velocity distribution. This, in turn, affects its response to changes in factors controlling its transport and deposition, such as the boundary shear stress and turbulence intensity.

The term 'suspension' is normally applied to material supported by turbulence in a boundary layer. However, in the oceans, much past work has referred to 'suspended particulate matter' (SPM) or 'total suspended matter' (TSM) obtained by filtration. This material, unless in the ocean bottom mixed layer, is not suspended but sinking, and thus, in a sense, is being deposited, although it may have several kilometres to go to reach the bottom. This material, comprising 'pelagic flux', is also affected by settling velocity transformations and is included in this article.

This article deals with controlling factors, entry into and maintenance in suspension, and aspects of deposition: pelagic flux and deposition from boundary layers on to flat beds and bedforms. It mainly concerns deposition from water, but some of the diagrams in non-dimensional form are applicable to air, and some comparisons are made with dust deposition from wind.

Controlling Factors

Particle Settling Velocity w_s

The still-water settling velocity of spheres collapses nicely on to a single curve when plotted as a dimensionless Reynolds number Re_p ($= w_s d/\nu$) vs. another dimensionless number used by (amongst others) M.S. Yalin in 1972, and here called Yalin's number: $\Xi = (\Delta\rho_s g d^3/\rho\nu^2)$ (Figure 1) (w_s is the settling velocity, d is the diameter, $\Delta\rho_s = \rho_s - \rho$ is the solid minus fluid density, and ν is the kinematic viscosity). It should be noted that the abscissa Ξ contains material variables only, i.e., particle size and density and fluid viscosity and density. It should also be noted that the curve has two straight line segments and a curved transition joining them. The upper segment is $Re_p = 1.75\Xi^{0.5}$, with a lower limit around $d = 2$ mm, and is thus applicable to gravel in water. The lower segment is Stokes' law, $w_s = \Delta\rho_s g d^2/18\mu$, where μ is the molecular viscosity ($\mu = \rho\nu$), applicable below $Re_p \approx 0.5$ or $d < 100$ μm in water and air. A further order of complexity is introduced by the fact that particles are not often spheres. Dietrich has developed empirical relations that deal with the varying shapes of solid particles which always sink more slowly than spheres. We can note in passing that Figure 1 divides into a coarse end (gravel), in which $w_s \propto d^{1/2}$, and a fine end (silt and clay), in which $w_s \propto d^2$, whilst the transition is occupied by sand for which, roughly, $w_s \propto d$. Density exerts a strong control, but only for a minority of particles – most solids are quartz-carbonate density (2500–2900 kg m^{-3}). The molecular viscosity of water ranges mainly from 0.9×10^{-3} to 1.5×10^{-3} Pa s (25 to 2°C), and thus gives nearly a factor of two variation. For air, the viscosity is $\sim 1.8 \times 10^{-5}$ Pa s, but as its density is only 1.2 kg m^{-3}, the kinematic viscosity is $\sim 1.33 \times 10^{-5}$ m^2 s^{-1}.

Much greater variation is due to the bulk density variations of particles that are not solid: aggregates, hollow particles, and grains containing gas bubbles. There has been little systematic study of the latter, although they are clearly important in hot volcanic dust suspensions (e.g., ignimbrites). The most important classes of hollow particles are foraminifera, diatoms, and radiolaria. Forams are often partially sediment filled, resulting in saturated bulk densities

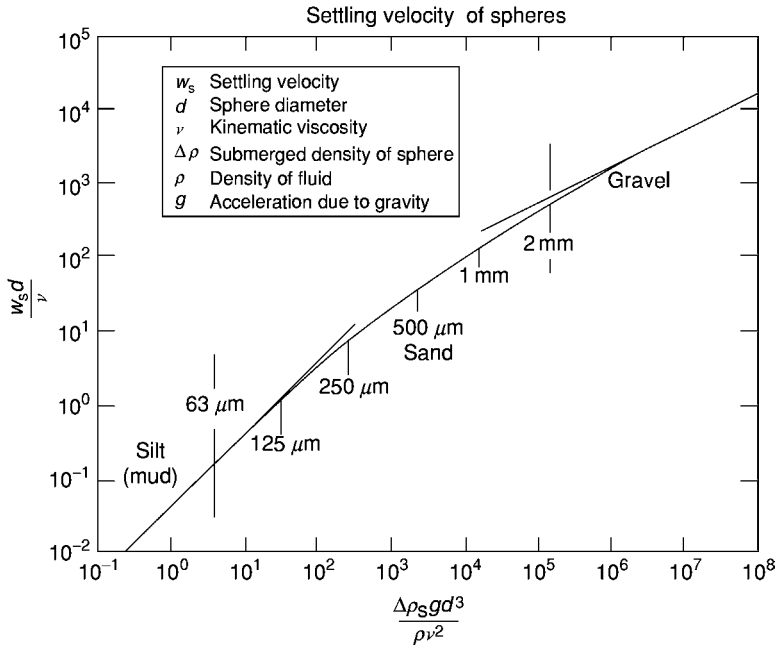

Figure 1 Universal settling velocity curve for spheres. Axes are the particle settling Reynolds number, $Re_p \quad w_s d/\nu$, and Yalin's number, $\Xi \quad \Delta\rho_s g d^3/\rho\nu^2$. This allows variable density particle and size fluid viscosity to be accommodated.

(that is the mean density of the foram shell plus sediment and water in the cavities) of 1150–1550 kg m ^{3}. (For simplicity, a deep seawater density of 1050 kg m ^{3} is used.) This gives a large range of $\Delta\rho_s$ from 100 to 500, which translates straight into a settling velocity straddling the Stokes' boundary, but giving a settling velocity of 125–500 m per day for 200 μm forams. With variable size, density, and viscosity, sinking rates can be from 50 to 1000 m per day. In air, the settling velocities are much faster but, because the viscosity is less, the viscous-dominated Stokes' settling region also persists up to 100 μm. However, the fast falling speed means that sand is almost never suspended by wind.

Aggregation

Most fine silt and clay is deposited as aggregates. These aggregates may be formed by physical (often referred to as flocculation, sometimes coagulation) or biological processes, generally involving the feeding and production of real or pseudo-faeces. The finest particles (d below 1 μm) are brought into contact by molecular buffeting known as Brownian motion. Here, for similar sized (diameters d_i, d_j) spherical particles, the probability of an encounter (i.e., number of collisions per cubic metre of suspension per second) is proportional to $TN_0{d_{ij}}^2$ and inversely proportional to $\mu d_i d_j$ (where d_{ij} is the sum of the diameters of the two colliding particles). This is clearly favoured by high concentration (N_0) and temperature (T) and opposed by viscosity (μ). Larger particles are brought together either by turbulent shear, where the collision probability is proportional to $N{d_{ij}}^3 \, du/dz$, or by larger, fast-sinking particles sweeping up finer ones, like rain falling through mist. In both cases, larger particles grow more rapidly because, when d_i is large and d_j is small, the sum cubed is large, whereas, when the size difference is not great, ${d_{ij}}^3$ is not large either. (This also takes into account the fact that the number concentration distribution of particles is such that there are far fewer large than small particles. The simplest standard is a flat log volume vs. log diameter distribution, which is equivalent to the cumulative number (log) vs. size (log) with a slope of -3. This means a ratio of 1000 1 μm particles to just one of 10 μm diameter.) The rainfall analogy above is particularly apposite for airborne dust, because one method of deposition is washout in which falling rain droplets form aggregates with dust particles by collision and carry them to earth. The other mechanisms of aggregation, Brownian motion, and shear also act on fine particles in air.

A key feature of much aggregation is the presence of organic mucus which acts as 'glue', allowing particles which get close to stick. Many organisms produce mucopolysaccharides, notably bacteria which sit on particles. Although there has been progress in implementing schemes to calculate particle aggregation, they are not yet simple or robust and represent the

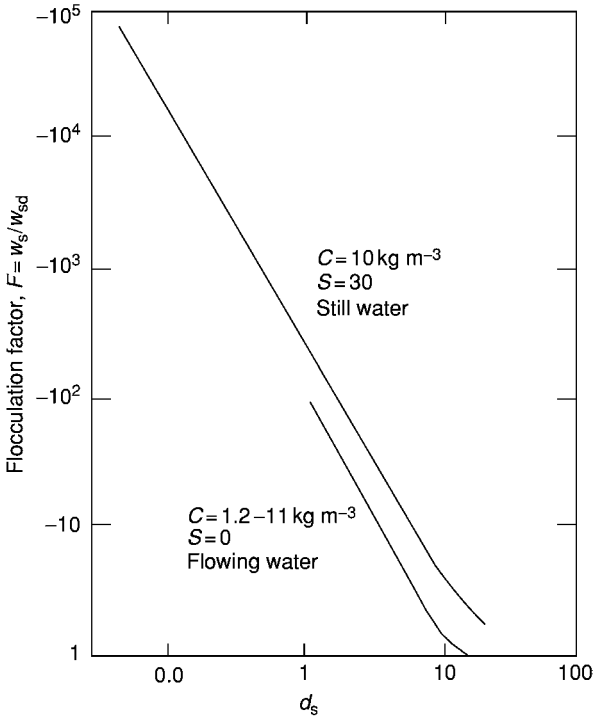

Figure 2 Flocculation factor F (ratio of floc settling velocity to settling velocity of the primary particles from which it is made) vs. diameter of the primary particles. It should be noted that F is negligible in flowing water for $d_{50} > 10\,\mu$m. Data from Migniot C (1968) Etude des proprietes physiques de differents sediments tres fins et de leur comportement sous des actions hydrodynamiques. *La Houille Blanche* 7: 591 620 and Dixit JG (1982) *Resuspension Potential of Deposited Kaolinite Beds*, MS thesis, U. of Florida, Gainesville.

frontier of research in cohesive sediment dynamics. The importance of aggregation is shown in Figure 2, where the 'flocculation factor', the ratio of the settling velocity of an aggregate to the settling velocity of the primary particles from which it is made, can be up to 10^5.

Aggregates are not stable entities. The organic membrane covering faecal pellets decays and the mucus that holds aggregates together also degrades, and so particles fall apart whilst sinking. Aggregates assembled by moderate levels of turbulence in the outer part of the boundary layer may be broken up by more energetic turbulent eddies close to the boundary. The relationship between aggregate size and boundary shear stress is very poorly known and, if the floc diameter $d_f \propto \tau^{\ n}$, then n ranges from 0.25 to 1 (τ is the shear stress in the fluid). The larger aggregates, which can be up to 5 mm in diameter, are thus found in the moderately turbulent, high-concentration environment of the estuarine turbidity maximum above the region within a metre of the bed. Closer to the bed, high shear breaks these large sloppy aggregates into smaller pieces. The density of flocculated sediment decreases as the flocs increase in size. A simple expression based on field data is $\Delta\rho_f = 4.9 d_f^{\ 0.61}$, where the floc excess density $\Delta\rho_f$ is in kg m^{-3} and the floc diameter d_f is in millimetres. This yields floc excess densities of less than 10 kg m^{-3} for 300 μm aggregates (compared with solid particles, where it is $\sim$1600 kg m^3). Nevertheless, because the settling velocity increases as the square of the diameter, large flocs settle at the same speed as fine quartz sand grains, or at >200 m per day, which means that they reach the bottom quickly, resulting in significant clearing of the water in a 10 m deep estuary in a slack-tide period of 2 h.

Boundary Layer Turbulence

A fluid flowing over a surface exerts a drag force on it. The drag at the boundary slows the fluid down, but some distance out, known as the boundary layer thickness, the average flow speed no longer changes much with distance. Most rivers are completely boundary layer as are shallow marine tidal flows. In the atmosphere and deep sea, the boundary layer extends several tens of metres above the surface. Boundary layers are intensely turbulent, and the drag force τ_0 exerted on the bed is related to that intensity because the stress is transmitted by eddies. In the vertical plane, $\tau_0 = -\rho\overline{uw}$, where u is the turbulent component in the flow direction and w is the up and down component (actually perpendicular to stream lines which may not be quite vertical). This expression is very important because u and w are related, so that $\tau_0 \propto \overline{w}^2$. This vertical turbulent velocity is responsible for keeping particles in suspension, and the turbulent stress $\overline{uw}$ either causes aggregation or, at higher values, disaggregates fine particles. The term (τ_0/ρ) has the dimensions of a velocity squared and that velocity is called the shear or friction velocity: $U_* = (\tau_0/\rho)^{1/2}$. From the above, it can be seen that $U_* \propto \overline{w}$.

Regions of the Boundary Layer

Flows may be distinguished as laminar or turbulent on the basis of their Reynolds number, Ul/ν, where l is some relevant length scale (e.g., depth of a river, diameter of a particle) (*see* **Unidirectional Aqueous Flow**). Low Reynolds number flows are laminar, high Reynolds number flows are turbulent. In a turbulent flow, the speed decreases towards the bed because of the drag, so that very close to the bed the flow becomes laminar, or at least dominated by viscosity, in a layer known as the 'viscous sublayer' of the turbulent boundary layer. This is very thin. In water, for a flow that just moves very fine sand ($U_* = 0.01$ m s^{-1}, $\nu = 10^{-6}$ m^2 s^{-1}), $\delta_v = 10\nu/U_*$ is just 1 mm thick. (In

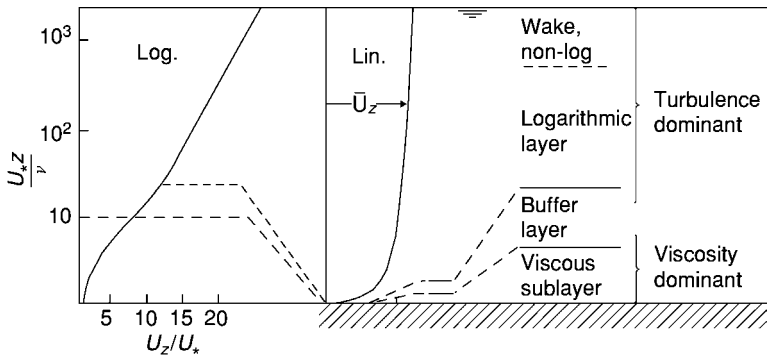

Figure 3 Regions of the turbulent boundary layer for a flow 1 10 m deep. In the centre, the linear representation of flow speed vs. height cannot resolve the viscous sublayer, but the speed vs. log height (z, expressed as a Reynolds number) shows it very well.

air, for the same stress, its thickness is similar, about 0.5 mm.) However, this is ten times the diameter of very fine sand. The shear across this layer is very large; for $U_* = 0.01\,\mathrm{m\,s^{-1}}$, the speed goes from 0 to $0.1\,\mathrm{m\,s^{-1}}$ in just 1 mm. Weak aggregates cannot survive this shear and break up. Above this sublayer, there is a transition ('buffer layer') to a region in which the flow speed varies as the logarithm of height above the bed (Figure 3). As the flow speed decreases, U_* decreases and δ_v increases, so that, in deposition, most particles that are going to become part of the geological record have to get through the viscous-dominated layer. Although viscous dominated, this layer is actually not laminar. Spatially, it has a structure of high- and low-speed streaks, and temporally very high-speed 'bursts' of fluid out of the layer and 'sweeps' of fluid into it from outside. These are associated with stresses typically up to 10 times the average (and extremes of 30 times), and so the mean shear example given above is a minimum, and even strongly bound particles may find themselves ripped apart just as they were getting within sight of the bed and posterity. Above the viscous sublayer, the 'buffer layer' is overlain by a zone in which the flow speed varies as the logarithm of distance from the bed (the 'log layer'). This zone is fully turbulent with eddies becoming longer with height above the bed and turbulence intensity becoming smaller.

The roughness of the bed positively influences the drag and turbulence, but also provides quiet regions in between large grains where fine particles can settle. Fine sediment can thus be deposited in the interstices of gravel, affecting several processes, e.g., the spawning of salmon.

Critical Conditions for Suspension

Two views of the critical suspension condition are as follows: (1) at critical movement conditions, the turbulent intensity can hold particles up, and so suspension depends on whether the particles are ejected from the viscous sublayer; and (2) sublayer ejections are fast, and so suspension depends on whether the vertical turbulent velocity can hold the particles up after injection into the flow. The second view was held by many, but recent work suggests that the first view may be correct. This view is based on high-speed video observations of particles close to the bed, which show that there is a threshold level of shear stress for the particles to respond to turbulent ejections of fluid from the viscous sublayer. The second view would mean that fine to very fine sand would immediately go into suspension as soon as it moved. For example, for 100 μm sand, the critical erosion shear velocity U_* is $0.012\,\mathrm{m\,s^{-1}}$, and the settling velocity of this very fine sand is $0.008\,\mathrm{m\,s^{-1}}$, and so it is capable of being held up by the flow, but video data show that it is not suspended. This means that there is a region of bedload transport for all particles of settling velocity, at least down to $\sim 30\,\mu$m silt. This is shown on a conventional non-dimensional erosion diagram in Figure 4.

The significance of this is that, in a decelerating flow, below the suspension threshold, material may continue to move, but not in suspension. Experimentally it has usually been found easier to determine the critical suspension condition with increasing flow, rather than failure of suspension on decreasing flow. It is generally assumed that the two views are equivalent.

Transport in Suspension

Once material is moved out of the near-bed region, it is held in suspension by the action of fluid turbulence. For this, because the vertical turbulent component of velocity is about the same as the shear velocity U_*, the normal suspension criterion is that $w_s/U_* \leq 1$.

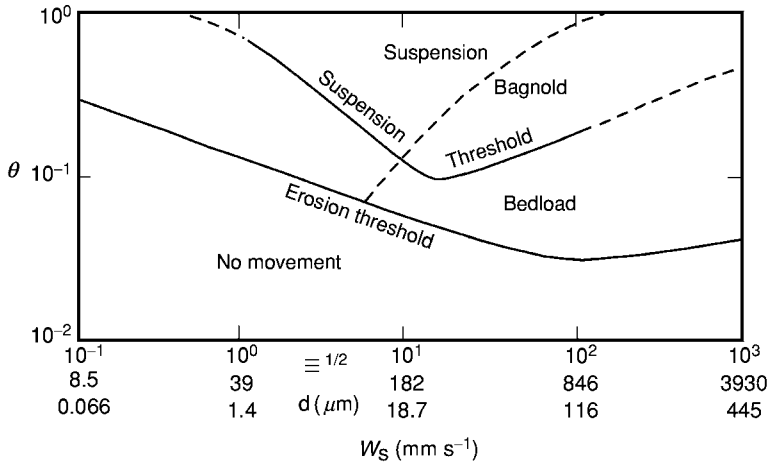

Figure 4 A critical erosion diagram on non dimensional axes with a critical suspension line added. This divides the diagram into regions of suspension, bedload, and no movement. Below the suspension threshold, material falls out and, as the capacity of a flow to carry bedload is limited, deposition will ensue. Two suspension lines are shown, ''suspension threshold'' results from view (1), while ''Bagnold'' expresses view (2); see text $\theta \quad \tau_0/\Delta\rho_s g d$, $\Xi \quad \Delta\rho_s g d^3/\rho\nu^2$.

Particles in 'steady' transport diffuse up from the source at the bed and sink back down under gravity with a balance in steady state. This is expressed as

$$Cw_s + \varepsilon_s dC/dz = 0$$

where the first term is gravity settling and the second is upward diffusion (ε_s is the sediment diffusivity). The result of this is that, for a given value of U_*, the faster settling grains are found closer to the bed and the finer slower settling particles are more uniformly distributed over the flow depth (Figure 5). In the bottom of a deep flow, the concentration at height z in the flow is $C_z = C_a(a/z)^{\zeta}$, where C_a is the concentration at height a (the point near the bed at which a measurement is made) and $\zeta = w_s/\kappa U_*$, where κ is von Karman's constant (0.4). This means that, with our suspension criterion, $w_s \leq U_*$, we would not expect much material in suspension for $\zeta > 2.5$. Figure 5 shows this. Here, it can be seen that relatively fine material (with $\zeta < 0.125$) is distributed throughout the whole flow. This is the fine silt and clay of river 'washload'. Closer to the bed, the relatively coarser sediment is concentrated. Clearly, if the flow slows down, the coarser material will be rapidly deposited because it is only just above the suspension threshold and has very little distance to reach the bed.

In air, there is very little suspension of sand. Above camel height in a 'sandstorm', the suspended material is virtually all silt and clay-sized dust. Saltation (which is bedload) is confined to the lower ~1.5 m, and very little material of >70 μm is carried in suspension.

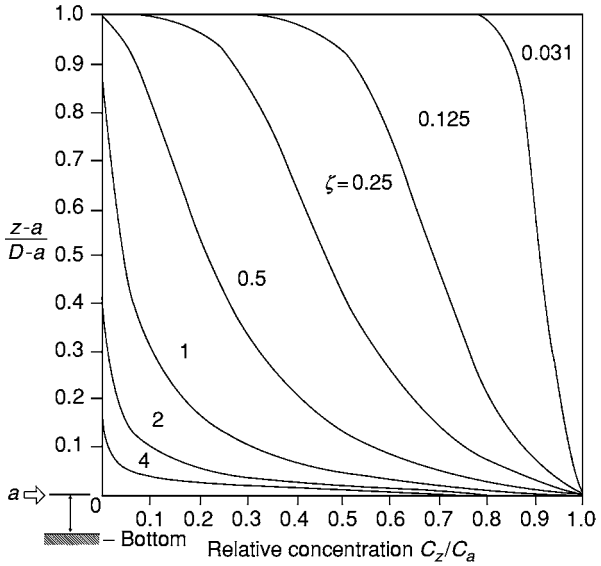

Figure 5 Variation of concentration with height of particles with increasing ratio $\zeta \quad 2.5w_s/U_*$. This shows material with high values of ζ close to the bed. This could be quite fine grained material if the flow has become very slow (low U_*).

Sinking Deposition: Pelagic Flux

The oceans are full of particles that are sinking, some slowly, some fast. The origin of most of this material is from biological production in the upper ocean. Thus, it comprises organic matter, calcium carbonate, and opal. It has been shown theoretically and by the use of sediment traps that most of this material would not reach the seabed were it not for the process of

aggregation which transforms its settling velocity spectrum. The aggregates are faecal pellets and 'marine snow', loose aggregates based on mucus and gelatinous structures made by zooplankton. This material sinks at ~100 m per day, a huge increase over the 2 m per day of a 5 μm coccolith. Aeolian dust rained out on to the sea surface also becomes incorporated into these aggregates, providing a rapid route to the bed.

Only if there is very slow flow at the bed in the bottom boundary layer will these aggregates plummet down directly on to the bed. This is true for most of the ocean most of the time, but some areas have fast currents which can break up the aggregates and control deposition.

Close to continental margins, the action of waves on the outer shelf and internal waves on the shelf-break and slope leads to the resuspension of material. This resuspended sediment spreads out on surfaces of density contrast as intermediate nepheloid ('cloudy') layers and flows down-slope in bottom nepheloid layers. These turbid layers are found all over the sea bottom, some more concentrated than others. Most fine sediment deposition involves some transport and removal from nepheloid layers, except for coarser (sand-sized) components which simply sink to the bed. Continental margins thus contain much material that is rained out of suspension and moved in bottom nepheloid layers during deposition.

Deposition from Turbulent Boundary Layers

The 'deposition' of bedload is rather straightforward: it stops moving. This occurs in water at a shear stress only slightly lower than the critical erosion stress. In fact, we cannot measure the erosion stress precisely enough to distinguish between erosion and deposition stresses, and so they are effectively the same. In air, high-speed grain bombardment of the bed keeps the bedload moving until the stress has been reduced to ~80% of the critical value. For suspended sediment, once the stress has decreased below the suspension threshold (see Figure 4), material will sink into the near-bed region, thereby increasing the concentration and causing some material to be deposited.

One well-documented consequence of the concentration increase is that the flow becomes density-stratified. This reduces turbulence intensity by absorbing turbulent energy in order to keep grains up. A reduction in turbulence means a reduction in shear stress, and deposition ensues. An extreme case is the suppression of the ability of a highly concentrated flow to sort sediment, resulting in the deposition of the massive graded A division at the base of Bouma-type turbidites. As the concentration decreases, turbulence is sufficient to sort the succeeding B division into laminae.

Deposition from different modes of transport is reflected in sediment size distributions. In a typical S-shaped cumulative size frequency curve for sands, the coarse tail reflects material that was always carried as bedload, the central part of the distribution reflects material carried intermittently in suspension, and the fine tail is made up of the 'washload' – long-distance suspensions. However, for air, the coarse tail is the 'creep' part of the bedload, the central part is the saltation component, and the fine tail is sand and dust from suspension.

Processes of Deposition

Fine sediment may reach the bottom in one of three ways. It may settle to the bed under gravity, it may impinge on the bottom as a result of molecular agitation in Brownian diffusion, or it may be transported downwards by eddy diffusion. The critical region of particle transport for all three of these processes lies within the viscous sublayer of a turbulent boundary layer, because, in most cases in which deposition occurs, a large part of the bed is covered by the sublayer. Simple calculations show that settling, even of 1 μm particles, is several orders of magnitude greater than the diffusive deposition rate. As diffusion is only likely to be important for the smallest particles, we can safely neglect it, and consider deposition to be controlled by particle settling through the sublayer to the bed. In the case of rain washout of dust and falling of 'marine snow' in areas of slow deep-sea currents, particles reach the bed at relatively high speed with no intervention of turbulence or the viscous sublayer.

Rate of Deposition

Experiments in flowing water show that, below a certain shear stress τ_d, for $C_0 < 0.30\,\mathrm{kg\,m^{-3}}$, the concentration in suspension C_t decreases exponentially with time t

$$C_t = C_0 \exp(-w_s p t/D)$$

where D is the depth of flow (or thickness of the boundary layer), C_0 is the initial concentration, and p is the probability of deposition; the probability is given by $p = (1 - \tau_0/\tau_d)$ (this includes nearly all normal marine conditions; only intense storms, estuaries, and mass flows have higher values). In this expression, τ_d is the limiting shear stress for deposition, the stress below which all the sediment will eventually deposit. This yields $R_d = C_b w_s (1 - \tau_0/\tau_d)$ for the rate of deposition R_d ($\mathrm{kg\,m^{-2}\,s^{-1}}$). Here, C_b

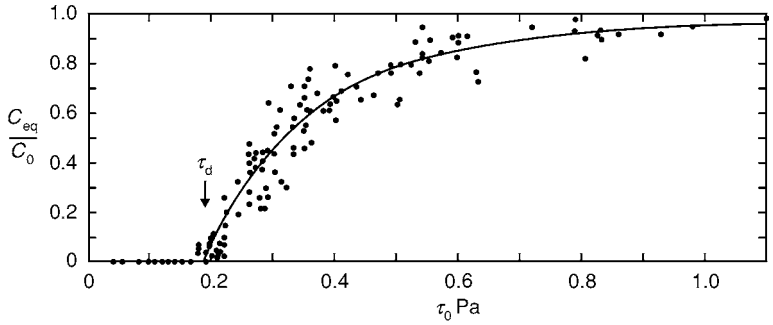

Figure 6 Diagram showing the equilibrium concentration (C_{eq}) of material in suspension as a ratio with the amount initially in suspension (C_0, 1.25 kg m ^{3} in this case) as a function of the bottom shear stress (τ_0). This shows that some material is deposited at shear stresses as high as 0.6 Pa, but that, below τ_0 0.2 Pa, all is deposited, thus defining the limiting stress for deposition (τ_d) of this material. Reproduced from McCave IN (1984) Erosion, transport and deposition of fine grained marine sediments. In: Stow DAV and Piper DJW (eds.) *Fine Grained Sediments: Deep Sea Processes and Facies, Special Publication, Geological Society of London 15*, pp. 35 69.

is the value near the bed. If there is no flow, this reduces simply to the settling flux $C_b w_s$.

At higher concentrations, $C = 0.3$–$10\,\mathrm{kg\,m^{-3}}$, C declines logarithmically with the logarithm of time, $\log C = -K \log t + \text{constant}$, in which $K = 10^3(1-\tau_0/\tau_d)/D$. It has also been noted that, at high concentration, some material is deposited at $\tau_0 > \tau_d$ (Figure 6); an equilibrium concentration is attained, which reduces as τ_0 is reduced to τ_d. This means that some mud can be deposited from relatively fast flows, as long as the concentration is fairly high ($>1\,\mathrm{kg\,m^{-3}}$). The significance of this is that, after storms or under turbidity currents, fine sediment may be deposited under flow speeds of several tens of centimetres per second. The deposition of mud at $\tau_0 = 0.4$–0.5 Pa in Figure 6 is occurring under conditions capable of moving coarse sand of 0.5–1 mm. It is emphatically not the case that mud is only deposited under 'quiet water' conditions when sand cannot be moved.

Limiting Shear Stress for Deposition τ_d

The value of this is not well known, but is probably related to the diameter or, more properly, the settling velocity of the particles, whether aggregates or single grains. The safest assumption is that it is given by the critical erosion stress for non-cohesive grains because, below this value, movement ceases and any grain reaching the bed would be removed from the transport system. This is shown in the critical erosion diagram (Figure 4). An alternative, based on measurements in a laminar flow cell, is $\tau_d = 0.048\Delta\rho_s g d$.

Deposits Formed from Currents

Often, fine sediment deposition may occur from flows of, for example, 0.1–0.2 m s ^{1}. What influence might this have on the character of deposits? A current of 0.1 m s ^{1} in a deep boundary layer having a shear velocity of 4×10^{-3} m s ^{1} allows the deposition of particles larger than 20 μm, but the deposition of finer particles is suppressed. Work on suspended material in nepheloid layers has shown that it comprises aggregates made of silt and clay-sized particles and organic matter. The suppression of the deposition of the finer particles must result in a more silty deposit, but does not eliminate clay completely, because some is caught up in larger fast-settling aggregates, the strongest of which survive stresses in the buffer layer and are deposited. Thus, there is fractionation of a suspension during deposition to yield a more (or less) silty deposit. Some people tend to think that this results from 'winnowing', but this is a process of selective erosion not deposition. Two sorting processes occur: (1) fractionation during deposition, yielding more silty accumulations by deposition under higher shear stress; and (2) fractionation during intermittent erosion, yielding a more compact deposit with (micro) erosion surfaces marked by thin lag layers of terrigenous coarse silt and sand grains and foraminifera.

Above about 10 μm, the flocculation factor in flowing water becomes quite small, as many aggregates are broken up by flow in the buffer layer, particularly by strong flow (but may re-aggregate when away from the bed) (Figure 2). This means that, under stronger flows, this material can be size sorted according to its primary grain size. This part of the size spectrum (10–63 μm) comprises what has been called 'sortable silt' (as opposed to the cohesive material finer than 10 μm), and its mean size has been used as an index of the flow speed of the depositing current. The method gives results showing a striking correspondence to climate change-driven deep circulation changes.

Bedforms from Suspension

Bedforms from sandy suspensions are covered in (*see* **Sedimentary Processes:** Depositional Sedimentary Structures). Some structures seen in the deep sea, but rarely preserved in mudstones, are worth noting.

Mud Waves

Mud waves are regular undulations of the sediment surface with wavelengths of about 0.5–3 km and heights of 10–100 m. Most mud waves are very nearly symmetrical, but they contain subsurface layering that indicates migration. Observed migration usually is up-slope and up-current, but instances of down-current migration have been observed. Under a simple flow, maximum shear stress is expected on the up-stream face of a wavy bedform, and lower shear stress, with a greater deposition rate, on the downstream side. This would give downstream migration of the wave. Commonly observed upstream migration has suggested to some that mud waves are analogous to fluvial antidunes developed under a supercritical flow.

An alternative is that the mud waves form under internal lee waves initially triggered by an upstream topographical disturbance, without the necessity for a supercritical flow speed. Temperature data over mud waves show that such an upstream phase shift does occur, that the implicit internal-wave phase velocity is $0.05\,m\,s^{-1}$, and that this is very similar to the measured flow velocity required for the internal wave to be stationary. The flow pattern over the waves has widely spaced stream lines, giving a small velocity gradient and shear stress (= high deposition rate) on the upstream slope and the opposite on the downstream slope. This would give the observed upstream migration.

Longitudinal Ripples

Longitudinal ripples are elongated features parallel to the depositing flow, probably with helical secondary circulation involved in their formation. In the deep sea, they are 5–15 cm high, 0.25–1 m wide, spaced at 1–5 m apart, and up to 10 m long, and have a generally symmetrical cross-section with sides slightly concave upwards (Figure 7A). In many cases, the ripples have a mound of biological origin at the upstream end. Surface markings on some ripples demonstrate the action of oblique flows, with flow separation and a zone of helical reversed flow on the lee side.

Dating by ^{234}Th (half-life, 22 days) suggests that longitudinal ripples form by deposition from suspension, occurring in a few episodes of very rapid deposition following deep-sea storms. Subsequently, the ripple is scoured by flows that may be oblique to its trend, giving the surface markings seen in deep-sea photographs. These structures have not been recorded from shallow marine or estuarine muds, although closely spaced features up to a few tens of centimetres apart have been seen on tidal flats.

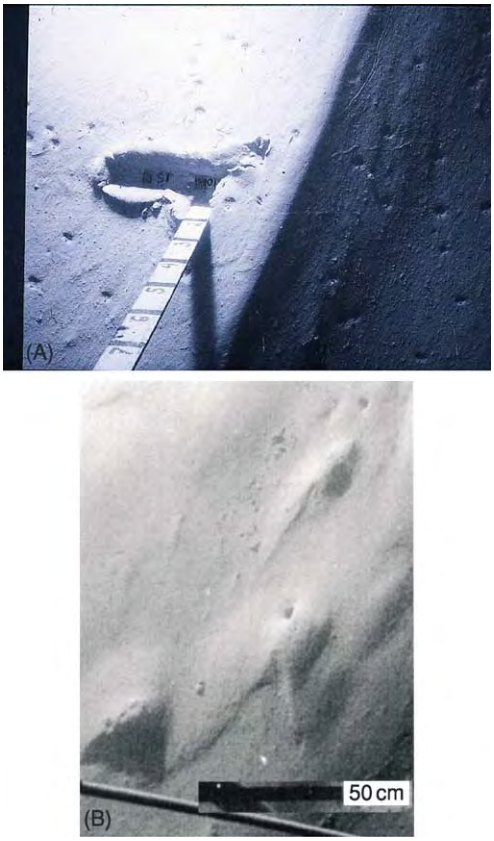

Figure 7 Photographs of bedforms in mud from the deep sea. (A) Longitudinal ripple. Scale bar has penetrated the mud; width of view, ~40 cm; relief of ripple, ~12 cm. (B) Barchan ripples. Both from the Nova Scotian Rise at 4800 m depth.

Smaller, Current-Controlled Bedforms

Smaller, current-controlled bedforms are also revealed by deep-sea photography. The photographed features of the seabed can be arranged in a sequence indicative of increasing flow speed. The progression is from tranquil seafloor (biological mounds, tracks, trails, and faecal pellets), through increasing overprinting by current effects, to features showing clear evidence of erosion. Biological activity is almost ubiquitous, so that a smoothed surface is indicative of an appreciable current, sufficient to remove the surface effects of biota. The most common features are actually biologically produced faecal mounds, tracks and trails, and pelleted surfaces. Mounds are often modified by current activity, the most frequent structure being mound-and-tail formed by lee-side deposition. As suggested above, it may be that longitudinal ripples are very large tails on mounds. Both structures are

excellent current direction indicators. Transverse ripples are sometimes seen in muds, but barchan-shaped (crescentic) ripples are more common (Figure 7B). Some are formed rapidly on deposition from high-concentration suspensions in deep-sea storms, and others are winnowed crescentic silt ripples. Both tend to nucleate around biogenic mounds. Unfortunately, the preservation potential of these structures as distinctive stratification patterns is negligible. Mud is so nutritious that it is populated by a rich burrowing infauna (producing the mounds) and the main structure is pervasive bioturbation.

Nomenclature

Parameter

$\Delta\rho_s$	density difference($=\rho_s-\rho$); unit, kg m^{-3}; dimension, M L^{-3}; value, 1650 (water), 2650 (air)
δ	boundary layer thickness; unit, m (mm); dimension, L
ε	eddy diffusivity; unit, m^2 s^{-1}; dimension, L^2 T^{-1}
μ	dynamic viscosity; unit, Pa s; dimension, M L^{-1} T^{-1}; value, 1×10^{-3} (water), 1.8×10^{-5}(air)
ν	kinematic viscosity ($=\mu/\rho$); unit, m^2 s^{-1}; dimension, L^2 T^{-1}; value, 1×10^{-6} (water),1.5×10^{-5} (air)
ρ	fluid density; unit, kg m^{-3}; dimension, M L^{-3}; value, 1000 (water), 1.2 (air)
ρ_s	sediment density; unit, kg m^{-3}; dimension, M L^{-3}; value, 2650 (water and air)
τ	shear stress; unit, Pa ($=$ N m^{-2}); dimension, M L^{-1} T^{-2}
C	concentration (by mass/volume); unit, kg m^{-3}; dimension, M L^{-3}
D	flow depth; unit, m; dimension, L
d	grain size; unit, m, mm, μm; dimension, L
g	acceleration due to gravity; unit, m s^{-2}; dimension, L T^{-2}; value, 9.8 (air)
J	collision probability; unit, m^3 s^{-1}; dimension, L^3 T^{-1}
N	concentration (by number/volume); unit, m^{-3}; dimension, L^{-3}
U_*	shear velocity ($=\sqrt{(\tau/\rho)}$); unit, m s^{-1}; dimension, L T^{-1}
u,v,w	velocity components (w, vertical); unit, m s^{-1}; dimension, L T^{-1}
x,y,z	space coordinates; unit, m; dimension, L

Subscripts

0	at the bed, or at $t=0$, e.g., τ_0, U_0, N_0
50	50 percentile value, median (e.g., d_{50})
B	Brownian
b	near bed (e.g., C_b)
c	critical value (e.g., τ_c for critical erosion stress)
d	deposition (e.g., τ_d)
f	floc
i,j	i and j particles
p	particle
S	shear
s	sediment (e.g., ρ_s)
v	viscous sublayer (e.g., δ_v)
z	at height z above the bed (e.g., U_z)

Superscripts

— above	time-averaged value parameter

Constants and Dimensionless Numbers

ζ	Rouse number; $w_s/\kappa U_*$
κ	von Karman's constant; 0.4
Ξ	Yalin's number; $[(\rho_s-\rho)gd^3]/(\rho\nu^2)$
k	Boltzman's constant; 1.38×10^{-23} J°K^{-1}
Re	Reynolds number; U_*d/ν, w_sd/ν, etc.

Equations

$\delta_v = 10\nu/U_*$	Viscous sublayer thickness
$w_s = \Delta\rho g d^2/18\mu$	Stokes' settling speed

Fluxes and Budgets

L Frostick, University of Hull, Hull, UK

Introduction

The word 'flux' when applied to sediments has come to mean the movement of particles of rock from upland areas down to a receiving basin, the fundamental processes of landscape evolution, and the geological cycle (Figure 1). The basin which receives the sediment can be terrestrial, either a lake, inland sea, or valley, but the most important basins are the seas and oceans which eventually claim more than 99% of the sediment produced on land. Understanding how, where, and why sediment moves into these basins is fundamental to interpreting and predicting the way in which a basin was formed or might evolve in the future and is, therefore, central to the economically important discipline of basin analysis.

Controls on Sediment Fluxes

The rate of sediment flux to basins is governed by a complex series of interactions amongst the physical and chemical processes which bring about rock uplift, weathering, erosion, and transportation (*see* **Sedimentary Rocks:** Mineralogy and Classification). The quantities of sediment that arrive at a receiving basin are the product of these processes integrated across the total area of supply. As the contributing processes can and do alter in both space and time, sediment fluxes also vary at a range of scales in response to geological and climatic changes. Understanding the controlling processes is, therefore, central to predicting fluxes which are, themselves, key to developing accurate models of basin development.

Weathering

The reason why rock fragments are worn away is inextricably linked with the tectonic processes which produce uplift. As rocks rise up to form hills or mountains and successive surface layers are stripped off, the minerals contained in them move from a dry, hot, high pressure environment to one with an abundant water supply from rainfall and where the temperature and pressure are relatively low (*see* **Sedimentary Environments:** Depositional Systems and Facies). Under these new conditions many minerals become unstable and begin to break down. This process is called weathering and it causes what were originally solid rocks to fragment into smaller fragments which are more easily moved. It is these particles, along with the dissolved products of weathering which, once transported and deposited, make up all sediments and sedimentary rocks (*see* **Weathering**). The way in which a rock breaks down is directly related to its composition. Rock forming minerals are stable at different temperatures and pressures and those that form under conditions most unlike those at the Earth's surface are the most unstable. Quartz is the rock forming mineral that is most stable during weathering and this is the reason why quartz is the predominant mineral in present day beach and river sands and is also common in most ancient sandstones. The rate at which weathering occurs depends on climate, with rapid breakdown favoured by the high rainfall and temperatures of tropical areas and slow weathering occurring where water is absent or solid, i.e., in deserts and arctic zones (*see* **Sedimentary Environments:** Deserts).

Transport

The breakdown products of weathering are transported away from their site of formation and downslope in several ways. On steeper slopes, and for the

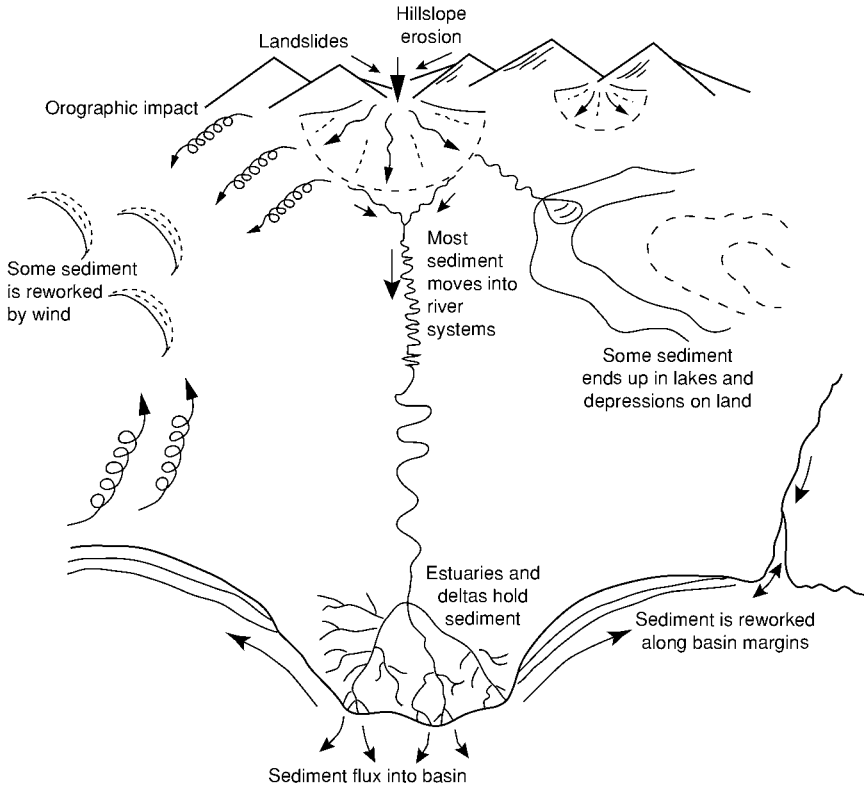

Figure 1 Diagrammatic representation of the way in which sediment moves through the landscape from the mountains to the ocean basins. (Adapted from Frostick LE and Jones SJ (2002) Impact of periodicity on sediment flux in alluvial systems: grain to basin scale. *Geological Society of London Special Publication* 191: 81 95.)

larger particles this may occur as a result of gravity alone acting on the particles, which cause rolling, sliding, and avalanching. Such processes are episodic and often linked with the development of instability as rainfall wets the slope (Figure 2). Some material may be removed by wind but this is important only in desert areas and steep rocky slopes which are devoid of the protection offered by vegetation. In all areas with flowing water it is the movement of that medium that induces sediment to move down the slopes and into adjacent valleys. The water sometimes flows as a shallow sheet over wide areas (called overland flow) but more often collects into small channels, generally known as rills. From here the sediment moves into streams and rivers to complete its journey to the receiving basin. Over the majority of the continental landmasses, where temperatures are high enough for water to remain liquid for most of the time, rivers are the main transporting medium for sediment and flux rates, therefore, vary with the character of the river network. Large, long-lived and integrated networks, such as those of the Mississippi, Congo, and Amazon rivers, deliver large volumes of water and quantities of sediment over long periods. The Mississippi, for example, brings to the Gulf of Mexico one tonne of sediment for every 400 tonnes of water during periods of flooding. When the river is flowing less fast, this may diminish to 0.35 tonne. At the present time, nearly 70% of the total sediment supplied by rivers to marine basins comes from five large rivers, the Ganges/Brahmaputra, Amazon, Huang Ho, Irrawaddy, and Mississippi (Table 1).

In arctic and subarctic areas and where mountains are sufficiently high to generate significant quantities of snowfall, glaciers become a major agent for sediment transport. In the past, shifts in the climatic balance have led to major glacial events when ice-sheets spread out from the polar caps and engulfed large areas of previously temperate landmasses. During these periods, soil and other surface deposits are scoured from the landscape and accumulate in basins.

Climate and Tectonism

Both the character and quantity of sediment carried by a river will reflect the climate and geology of the drainage basin. Even in adjacent river basins, differences in these factors can lead to huge contrasts in sediment fluxes. One example of this can be seen

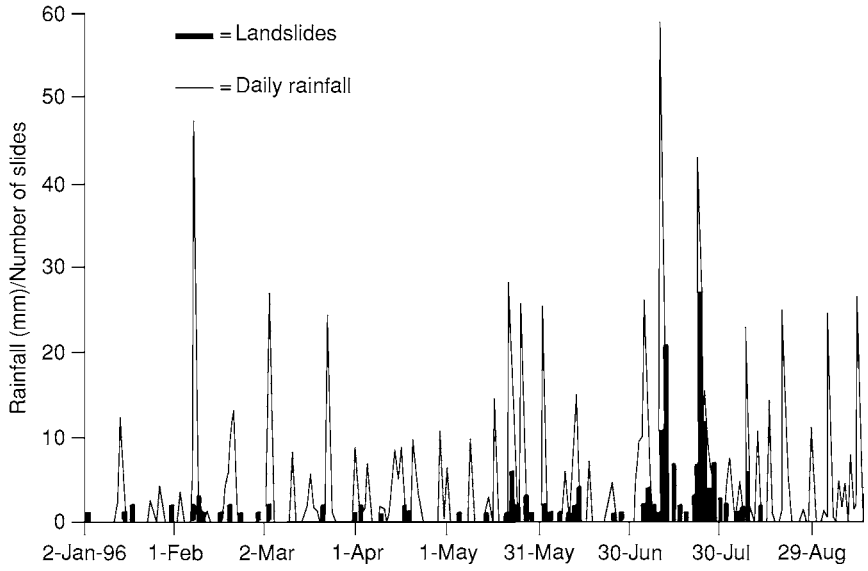

Figure 2 Diagram of the relationship between avalanche frequency and the occurrence of rainfall in the mountains near Wellington, New Zealand. The process is very episodic and each event will produce a 'slug' of sediment which will move down adjacent streams. (Adapted from Crozier MJ (1999) Prediction of rainfall triggered landslides: a test of the antecedent water status model. *Earth Surface Processes and Landforms* 24: 825 833.)

Table 1 The 24 rivers of the world with the largest annual sediment fluxes. Major Rivers Ranked by Sediment Load

Ranking	*River*	*Mean water discharge, 10^3 m^3 s^{-1}*	*Mean sediment load, 10^6 ta^{-1}*
1	Ganges/Brahmaputra	31	1821
2	Amazon	200	1190
3	Huang Ho	1	922
4	Irrawaddy	13.5	356
5	Mississippi	18	352

24	Columbia	6	36

in Brazil, where the sediment laden Rio Solimoes meets the sediment poor Rio Negro to form the Amazon River in a spectacular river confluence where the contrast is so marked that it can be seen from space (Figure 3). Sediment fluxes are at a maximum where tropical weathering results in rapid release of particles, large rivers are generated by high rainfall, and tectonic activity promotes uplift and steep slopes. One such area is the Himalayas where the monsoon rains sweep sediment into the vast Indus, Ganges, and Bramaputra rivers. The courses of these rivers and the locations of their outlets into the Indian Ocean are also controlled by tectonic activity, areas of uplift shedding water into adjacent lowland areas. At the mouths of these rivers much of the sediment load is deposited and deltas may build out into the adjacent basin. Large accumulations of sediment on the continental shelf can also lead to the development of turbidity currents which sweep material offshore into large submarine fans (e.g., the Bengal fan) (*see* **Sedimentary Environments:** Shoreline and Shoreface Deposits). Such localised deposits are characteristic of all areas where rivers debouch into larger water bodies and their morphology and sedimentology are largely controlled by the nature of basin processes actively redistributing the sediment.

Basin Processes

The character of the basin receiving the material removed from the land surface will control its dispersion. The balance between subsidence rates and sediment supply is particularly important, since if a deposit is buried rapidly it is less likely to be removed and reworked by waves and currents. In some areas sediments form large river deltas, e.g., the Mississippi (Figure 4), in others the deposit is submerged and

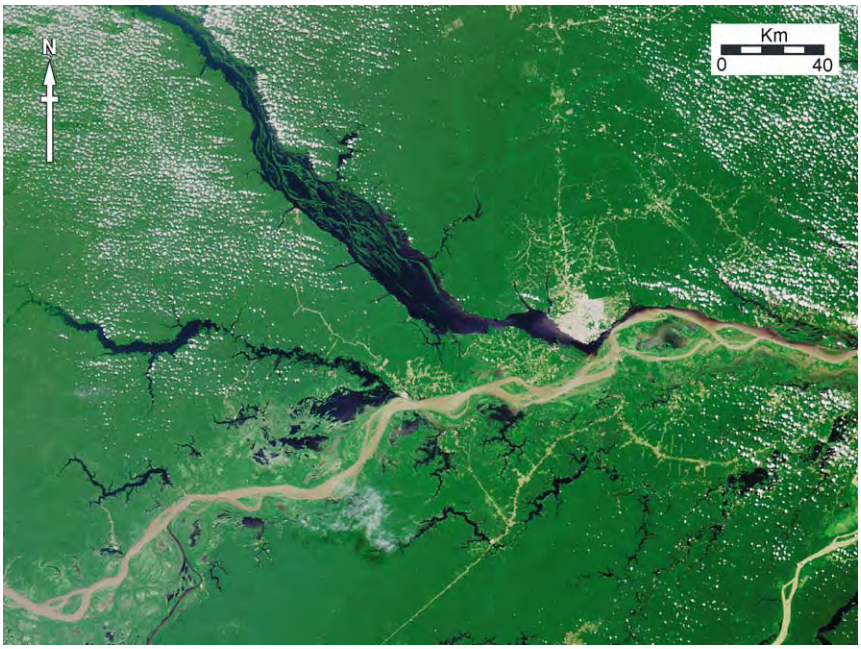

Figure 3 Satellite remote sensing image of the confluence between the sediment laden Rio Solimoes (showing brown) and the clear waters of the Rio Negro (showing black) to form the Amazon River. The Solimoes crosses soft glacial silt and sand, whereas the Negro passes through old hard rocks resistant to weathering. The two water bodies remain essentially separate for tens of kilometres downstream of the confluence. (Picture taken from the TERRA satellite using the multi angle imaging spectroradiometer on 23/7/2000.)

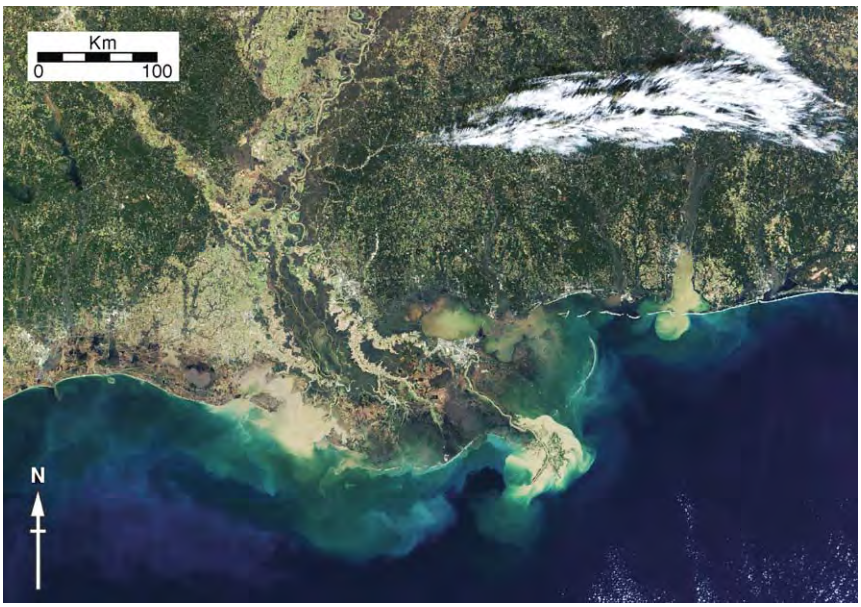

Figure 4 Satellite remote sensing image of the Mississippi Delta on the south east coast of the USA, showing a sediment plume issuing from the mouth of the main channel. This sediment will settle out in the adjacent ocean basin. (Picture taken from the TERRA satellite using the moderate resolution imaging spectroradiometer.)

Figure 5 Satellite remote sensing image of tidal sand banks off the coast of Guinea in West Africa. Note the plumes of sediment moving along the channels between the banks. The high tidal velocities are reworking sediment supplied by local rivers. (Picture taken from LANDSAT 4TM using bands 3, 2, and 1 for red green and blue colour channels, respectively.)

forms either a single fan or breaks up into a series of sand-banks (see, e.g., the coast of Guinea, West Africa, shown in Figure 5). As with the supply of sediment, the intensity of basin processes, such as tides, waves, and currents will also vary over distances, giving a complex spectrum of interactions that can lead to a plethora of deposit types.

Wind Blown Sediment

The flux of sediment in wind may be a minor factor in most areas today, except from in our major deserts, e.g., the Sahara, but in the past it has been significant and has led to the accumulation of extensive loess deposits, e.g., in China. Dust loadings in the atmosphere have changed in response to climate change, both on the scale of millennia, e.g., during the last Ice Age (Late Glacial Maximum) and at a decadal scale, e.g., in response to natural oscillations in climate associated with changes in ocean currents (e.g., the North Atlantic Oscillation). At present, most dust is derived from the worlds desert areas where reduced vegetation allows high-speed winds to pick up predominantly silt-sized particles and transport them for thousands of kilometres before finally depositing them downwind. The Sahara is the world's major source of wind-blown dust, producing between 400 and 700×10^6 tons.a ^{1}, approximately half the total amount of wind blown or aeolian dust estimated as being supplied to all the worlds oceans (*see* **Sedimentary Processes:** Aeolian Processes). At times of major dust storms, the dust being blown out of the Sahara can travel long distances and penetrate far out into the Atlantic Ocean. The composition of this dust is important as it adds nutrients to the deep oceans and influences their productivity (*see* **Sedimentary Processes:** Deep Water Processes and Deposits). Although quartz is the dominant mineralogy, dusts may contain compounds with appreciable proportions of aluminium, iron, magnesium, and calcium.

Flux Variations Over Time

Sediment fluxes at a point will vary over both short and long time scales as a result of temporal changes in any of the controlling variables. At the longer time-scales of geology, both climate change and tectonic uplift can bring about large-scale changes in flux rates. One example of the impact of climate change is the large-scale fluctuations in sediment movement during glacial and interglacial periods of the Quaternary, approximately 1.8 million years before present. Evidence of the fluctuations is found in the preserved deposits of this time, particularly the oceanic deposits, which received rock fragments ranging in size from flour to the size of a house carried by ice as it ground its way in glaciers across the barren landscape.

Periodicity in tectonic uplift has also been linked to major shifts in sediment fluxes. In the Himalayas, for example, there have been four major periods of uplift over the past 12 million years, each linked with a higher rate of sediment accumulation in adjacent basin areas (Figure 6). Local changes in surface elevation, as a result of tectonic activity, will impact on both where a river flows and how fast it flows. Higher flow speeds associated with steeper slopes will allow a river to pick up more sediment from its bed, thereby causing it to cut down and increasing fluxes. When slopes get less steep, less sediment can be carried by lower energy flows and material accumulates in the river valleys.

At shorter time-scales, sediment fluxes change in response to fluctuations in water discharge (Figure 7), the majority of the material being carried during flood periods when the rivers are more energetic. Any changes which impact on the delivery of water to the river system, for example, changes in rainfall patterns surface vegetation and land use, can result in shifts in flood frequency and impact on sediment fluxes. One example is in the American midwest during the late nineteenth and early twentieth centuries where the removal of vegetation, as a result of intensifying agriculture, led to floods becoming more intense (*see* **Sedimentary Processes:** Catastrophic Floods). This, combined with the removal of the protection from erosion offered by plants, led to rapid erosion and the development of 'badlands'.

The Importance of Geology

The rock types within the river system will control the rate at which sediment can be produced and supplied to the river system. This can lead to the development of very different environments in otherwise identical basins. For example, in the African rift, lakes in areas where the rocks are mainly old, hard, and resistant to weathering are deep and sediment starved (e.g., Lake Tanganyika), whereas those in areas containing volcanic rocks and old sediments are sand- and mud-rich and generally more shallow (e.g., Lake Baringo). The same factors are important in controlling the way in which sediments filled up ancient basins. For

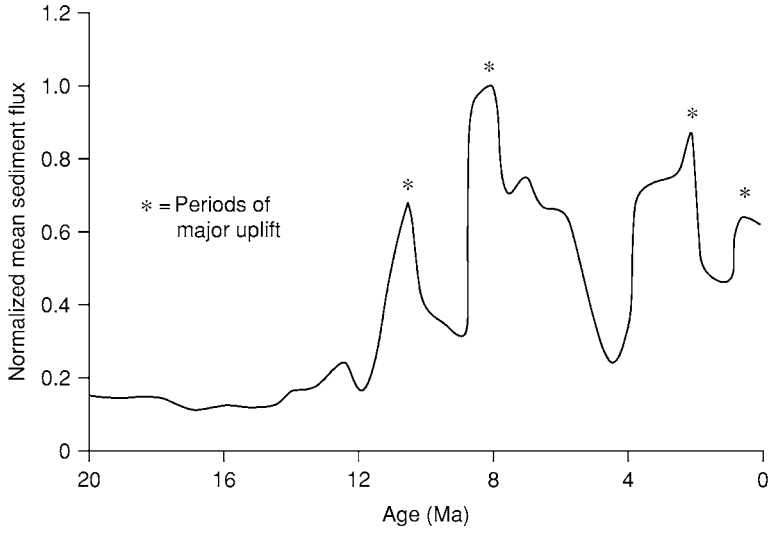

Figure 6 Variations in sediment fluxes from the Himalayas. High fluxes relate to periods of active uplift. Figure 7 Variations in suspended sediment transport for the Meuse and the Rhine Rivers (left) showing how sediment flux varies over flood events. (Adapted from Asselman NEM and Middlekoop H (1998) Temporal variability of contemporary floodplain sedimen tation in the Rhine Meuse delta, The Netherlands. *Earth Surface Processes and Landforms* 23: 595 609.) and bed material transport for Nahal Yatir, Israel and Oak Creek, USA (right) showing the difference between sediment fluxes in ephemeral (Nahal Yatir) and perennial (Oak Creek) rivers. (Adapted from Laronne JB and Reid I (1993) Very high rates of bedload sediment transport by ephemeral desert rivers. *Nature* 366: 148 150.) plotted against water discharge over flood periods. Fluxes generally increase with increasing water discharge, reaching maxima at flood peaks.

example, the Cretaceous to Tertiary Tucano and Reconcavo basins of Brazil are similar in size and structure but whereas the Reconcavo has a low sediment flux and is oil retaining the Tucano Basin contains interconnected sands that allow any oil generated to escape (*see* **Petroleum Geology:** The Petroleum System). When a geological map of the area is consulted, it is evident that the Reconcavo Basin was formed on ancient and hard gneisses which could only be broken down very slowly, whereas the Tucano Basin was cut into soft sedimentary rocks. This example highlights the economic importance of understanding the controls on sediment flux.

Sediment Budgets: Modelling the Past and Predicting the Future

The complexity of controls on sediment fluxes conspires with changes in rates that occur at all timescales to make the interpretation of the past and predictions of the future equally problematic. Added to this, the role of river drainage basin in storing and releasing sediment, thereby modulating the impact of environmental change on sediment flux, is still poorly understood. Even the direct measurement of present-day fluxes is fraught with difficulties since the costly nature of making such measurements usually means that data are collected only from a small number of points and for very short periods of time. As rivers are the main means of sediment delivery to basins, many of the flux calculations that exist are based on short periods of measuring water and sediment discharges which are then used to extrapolate to larger areas and longer periods, ignoring the limitations of the data. This makes the calculation of sediment budgets for any area very difficult; even under ideal circumstances with good data they generally only give a crude approximation of what is really happening.

Estimations of sediment fluxes and the understanding of sediment budgets are central to the science of

basin analysis. Basin analysts endeavour to determine the controls on where and how sediments are deposited in a basin and they provide essential information to those wishing to exploit natural mineral resources, for example, oil, gas, and diamonds. In the case of oil and gas, it is important to locate sands and other permeable and porous rocks that might act as oil and gas reservoirs (*see* **Petroleum Geology:** The Petroleum System). In addition, identifying parts of the basin and periods of time when sediment fluxes are low and the organic debris from which oil is formed can accumulate undiluted by other sediments, is a vital part of exploration. For placer deposits such as diamonds, rivers are the main transport system and they deliver these important heavy minerals to the basin for reworking into economic beach deposits, e.g., in South Africa diamonds are delivered by the Orange River to the coast of Namibia.

SEDIMENTARY ROCKS

Contents

Mineralogy and Classification

R C Selley, Imperial College London, London, UK

Introduction

Rocks and Their Classification defined the three main classes of rock: igneous, metamorphic, and sedimentary. It described the main features by which the three types of rock may be distinguished, and presented anomalous examples of each. The classification of igneous and metamorphic rocks is described in **Igneous Processes** and **Metamorphic Rocks:** Classification, Nomenclature and Formation, respectively. This article describes the mineralogy and classification of sedimentary rocks.

Sedimentary rocks are formed from the detritus of pre-existing rocks: igneous, metamorphic, or sedimentary. The way in which rock is weathered, eroded, transported, and deposited is discussed in detail elsewhere (*see* **Weathering, Sedimentary Processes:** Fluxes and Budgets, **Unidirectional Aqueous Flow**, and **Sedimentary Environments:** Depositional Systems and Facies). Sediments possess a wide range of particle size, ranging from boulders to clay, and of chemical composition, including silica, lime, or ferromagnesian volcanic detritus. These parameters of particle size and composition are used to classify sedimentary rocks. Sedimentary rocks commonly exhibit two properties that may be used to differentiate them from igneous and metamorphic rocks.

1. Where they crop out at the surface of the Earth, sedimentary rocks generally show stratification (layering). The strata indicate successive episodes of deposition. Layering is usually absent from igneous rocks, but is found in some metamorphic rocks.
2. When examined under the microscope, sedimentary rocks are generally seen to consist of particles. Void space (porosity) is commonly present between the constituent grains. Interconnected pores give the rock permeability. Permeability allows fluids to migrate through rock, and enables rock and soil to drain. Additionally, fossils are only found in sedimentary rocks, some of which are, indeed, made up of nothing else.

Mineralogical Basis for Sedimentary Rock Classification

In the earliest classifications of rock, such as that proposed by Charles Lyell (*see* **Famous Geologists:** Lyell), four classes were recognized: volcanic, plutonic (these two are now grouped as igneous), metamorphic, and aqueous. The aqueous rocks were subdivided into three groups: arenaceous, argillaceous, and calcareous. The term 'aqueous' has long

been abandoned, as it is now known that sediments are deposited by aeolian, gravitational, and glacial processes, as well as by purely aqueous ones.

The processes of weathering, erosion, transportation, and deposition are nature's way of chemically fractionating the Earth's surface, and lead to a logical classification of sedimentary rocks based largely on their chemistry and mineralogy. Serendipitously, this fractionation correlates broadly with their mode of formation. Although geologists broadly agree about the definition of the main classes of sedimentary rocks, there is no unanimity about all of them.

In 1937, Goldschmidt proposed a classification based on five chemical groups, namely: (1) resistates, (2) hydrolysates, (3) oxidates, (4) carbonate precipitates, and (5) evaporites. In 1950, Rankama and Sahama added a sixth: reduzates. The resulting classification highlights the chemical fractionation that results from sedimentary processes, but produces some very strange and uncouth names.

Meanwhile, a practical field-based classification had been widely adopted, although with some variation in the fine detail. It had long been noted that fractionation on the surface of the earth naturally divided rocks into those that had never gone into solution, and might therefore be termed 'allochthonous' or 'detrital', and those formed from minerals that had been dissolved in surface water, and had precipitated out. These are termed 'autochthonous' or 'chemical' rocks. The allochthonous or detrital sediments are subdivided by grain size. The autochthonous or chemical sediments are subdivided by mineralogical (chemical) composition (Table 1).

Geopedants will already notice the inconsistency of this classification. The detrital sediments are composed of a wide range of minerals, and thus exhibit a diversity of chemistry, which is ignored for the purposes of their classification. Similarly, the chemical rocks may occur in a wide range of particle size, from boulders of limestone to sapropelic muds. Nonetheless, the classification displayed in Table 1 is not for the benefit of geopedants, but for practical use by geologists. There is no consensus on the classification of sedimentary rocks proposed in Table 1. Note that the caption reads 'A classification of sedimentary rocks' not 'The classification of sedimentary rocks'.

The main groups of sedimentary rocks are now described briefly, pointing the way to articles in this encyclopedia that describe them in more detail.

Table 1 A classification of sedimentary rocks

Allochthonous or detrital sediments
Classified by grain size
Gravel/conglomerate
Sand/sandstone
Silt/siltstone
Clay/claystone (sometimes also termed 'mudrocks' or 'shales')
Autochthonous or chemical sediments
Classified by mineralogy
Carbonates (limestone and dolomite)
Evaporites (gypsum/anhydrite, halite, etc.)
Residual (bauxite, laterite, kaolinite)
Kerogenous (peat, lignite, coal)
Ironstones (haematitic, chamositic, and sideritic)
Phosphates (guano)
Siliceous (chert, opal)

Allochthonous or Detrital Sediments

As defined earlier, the allochthonous or detrital sediments are the insoluble residue of weathering of pre-existing rocks: igneous, metamorphic, or sedimentary. The mineralogy is very varied, depending on the source material and the type and duration of the weathering process (*see* **Weathering**). The mineralogy also correlates crudely with the grain size. Conglomerates tend to be polymineralic, sandstones are dominated by quartz, and mudrocks are dominated by clay minerals. Table 1 shows the subdivision of the allochthonous or detrital rocks by grain size, gravel, sand, silt, and clay being the basis for conglomerate, sandstone, siltstone, and mudstone, respectively. The terms 'rudaceous', 'arenaceous', and 'argillaceous' have also been applied to conglomerates, sandstones, and shales, but are little used now. The main groups of detrital sediments are now described briefly.

Conglomerate

Conglomerate is composed of particles of gravel, that is to say of particles of greater than 2 mm in diameter, consisting, with increasing size, of granules, pebbles, cobbles, and boulders. Collectively, conglomerates have also been known as rudaceous rocks. Conglomerates are distinguished from breccias by the fact that the clasts are rounded, whilst those of breccias are angular. Because of their large size, conglomerate clasts are composed of many grains or crystals (depending on whether they were derived from earlier sediments or from crystalline igneous or metamorphic rocks). They may thus be composed of a wide range of minerals. When derived from igneous or metamorphic rocks, conglomerates may be composed of the wide range of minerals found in the parent rock. By contrast, conglomerates derived from sediments will reflect their source mineralogy, but will tend to be composed of a higher percentage of minerals that are stable at the Earth's surface, rather than in the parent rock. The concept of sediments as the insoluble residue of pre-existing rocks is again a useful one to recall. This is illustrated

by the vast volumes of flint (chert) gravels to be found on the beaches of north-west Europe. These flints originate in rare horizons in the Cretaceous Chalk. As Charles Lyell wrote: "The entire mass of stratified deposits in the Earth's crust is at once the monument and measure of the denudation which has taken place." Gravels and conglomerates are described in greater detail in **Sedimentary Rocks:** Rudaceous Rocks.

Sandstones

Sandstones are composed of particles with an average size of between 2.00 and 0.0625 mm in diameter. They have four constituents: grains, matrix, cement, and, sometimes, porosity (Figure 1). Sand-sized particles form the framework of the rock. Matrix, the finer grained material that may infill space between the framework grains, was deposited at the same time as the framework grains. Cement is the term that describes minerals precipitated in pores after the deposition of the sediment. Thus, matrix is syndepositional and cement is postdepositional. Cement and porosity are described in **Sedimentary Rocks:** Sandstones, Diagenesis and Porosity Evolution, which deals with the diagenesis of petroleum reservoirs. Framework grains and matrix are described below.

The framework grains of sandstones are normally composed of varying amounts of the mineral quartz (silica, SiO_2). In order of decreasing abundance, sandstones also contain feldspar (a suite of calcium, potassium, and sodium silicates), micas (sheet silicates, with varying amounts of iron, magnesium, and aluminium), a complex of ferromagnesian minerals, informally termed 'mafics', and heavy minerals (those with densities significantly greater than that of quartz (2.65 g/cc), examples of which include iron ores, mica, siderite, zircon, and apatite). Sandstone may also contain sand-sized grains composed of more than one mineral or crystal. These are termed 'rock fragments' or 'lithic grains'. Sand-sized rounded green grains of the complex mineral glauconite are a common constituent of shallow marine sands (glauconite is described in **Minerals:** Glauconites). Sandstones often contain fossil fragments. Teeth, fish scales, and bone are largely phosphatic. The most common fossils, however, are shells, mainly composed of lime, calcium carbonate ($CaCO_3$). With increasing lime content, sandstones grade into calcareous sandstones, then to sandy limestones, and finally to pure limestone, composed entirely of calcium carbonate, and with negligible quartz. Thus, although typically composed of quartz, sandstones also contain a range of other minerals. These are used as a basis for naming and classifying sands and are important because of their impact on geophysical well-log interpretation.

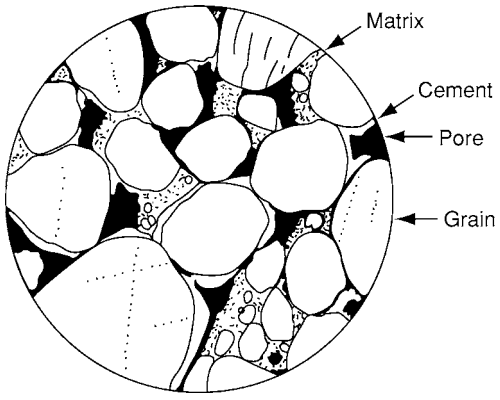

Figure 1 Diagram of a thin section of sandstone showing the four components of framework grains, matrix, cement, and pores. Only the first of these is always present. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

The syndepositional matrix that may occupy some of the space between the framework sand grains consists of silt, clay, and organic matter. Heavy mineral grains are commonly silt sized, and so technically they may form part of the matrix.

The composition of typical sandstone may be as follows. Framework grains: quartz, 45%; rock fragments, 5%; feldspar, 10%; mafics, 5%; mica, 5%; heavy minerals, 2%. Matrix: clay, 7%. Cement: calcite, 5%. Porosity, 16%. Total: 100%.

Two parameters are used to name and classify sandstones: chemical mineralogy and physical texture. When sediment is first eroded from its parent outcrop, it is generally immature in both its composition and texture. That is to say, it will still contain a range of chemically unstable mineral grains that surface processes have yet to break down and dissolve. Similarly, the debris first transported down a hillside will be very poorly sorted, consisting of a range of particles, varying in size from boulders to clay. When looking at an ancient lithified sandstone, its maturity may be described in terms of its chemical and physical properties (mineralogy and texture). Four main types of sandstone may thus be recognized as shown in Table 2. This table also employs four commonly used names to describe sandstones.

Table 2 A classification of sandstones based on textural and mineralogical maturity

	Mineralogical maturity	
	Immature	*Mature*
Texturally immature	Greywacke **Figure 2**	Quartz wacke **Figure 3**
Texturally mature	Arkose **Figure 4**	Quartzite **Figure 5**

'Greywackes' are poorly sorted sandstones with a large component of chemically unstable grains, not only feldspars, but also rock fragments and ferromagnesian minerals (Figure 2). 'Quartz wackes' are also texturally immature, but the framework grains are composed largely of quartz and lithic (rock) fragments (Figure 3). 'Arkoses' are texturally mature, but contain a large percentage of chemically unstable grains, principally feldspar (Figure 4). Quartzites, also termed quartz arenites (from the Greek '*arenos*' for sand), are texturally and mineralogically mature, being well sorted, and composed of little but quartz (Figure 5).

Mudrocks

There is little unanimity over the terminology for the argillaceous detrital sedimentary rocks. The easiest to name objectively are siltstone and claystone, being

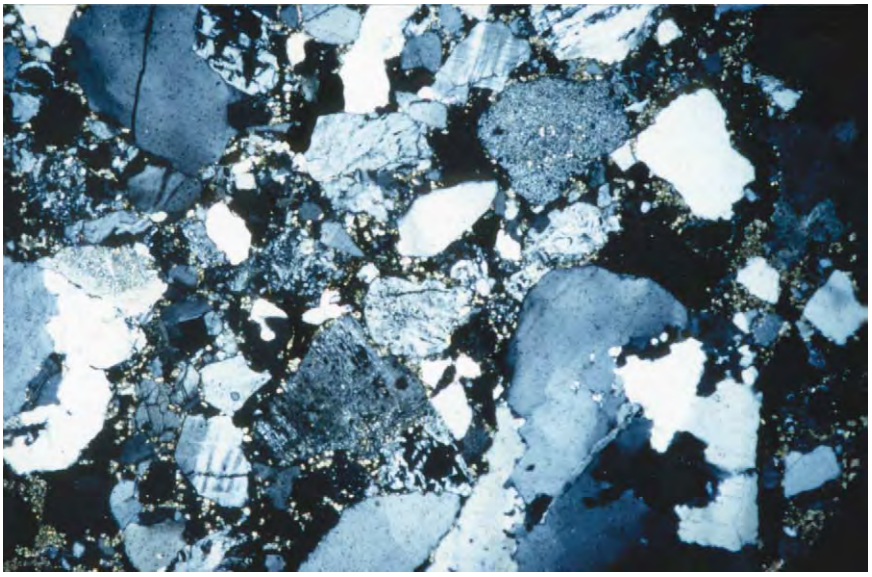

Figure 2 Photomicrograph of a greywacke under polarized light. Jurassic, UK North Sea. Note the poorly sorted texture and abundance of matrix and twinned feldspar. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

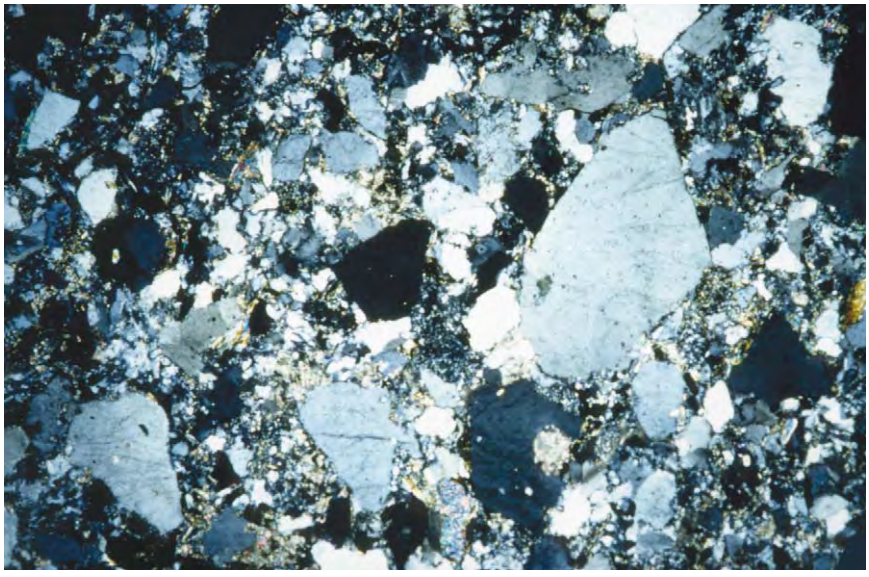

Figure 3 Photomicrograph of quartz wacke under polarized light. Carboniferous, Chios, Greece. Note the poorly sorted texture and abundance of matrix. composed, by definition, of predominantly silt or clay, respectively. They are easy to identify in the field. Siltstones have an unpleasant gritty feel between the teeth, clays a pleasing plastic texture. When sufficiently indurated, both siltstones and claystones may be termed 'shales'. The term 'shale' was defined by Pettijohn as "a laminated or fissile claystone or siltstone". This is a widely used term, and with good reason: siltstones are commonly argillaceous and claystones silty, and so the term shale covers all variations. The term 'mudrock' or 'mudstone' has been applied to siltstones and claystones (and their admixtures) that do not possess the fissility of shale. Siltstones are composed of detrital quartz, shell fragments, assorted heavy minerals, and, often, mica, which imparts the fissility to shale. Siltstones

also commonly contain varying amounts of clay matrix and organic matter.

Claystones are composed largely of the clay minerals, kaolin, illite, montmorillonite, and chlorite. Clay mineralogy is described in detail in **Clay Minerals**. Lime and organic matter may also be present in claystones. With increasing lime content, shales grade into marls, argillaceous limestones, and limestones. With increasing organic content, shales grade into sapropelite. Detrital grains of silt, mica, plant debris, and shell fragments may occur in mudstones as impurities. Clays and their diagenesis are described in **Sedimentary Rocks:** Clays and Their Diagenesis.

Autochthonous or Chemical Sediments

It has already been noted that the classification of sediments into detrital and chemical categories is somewhat artificial. Both are composed of chemical or biochemical components, and of particles of varying sizes. Nonetheless, it is a convenient grouping. The chemical sediments are those that principally precipitate out of solution, although thereafter they may become detrital in some instances. Table 1 shows that seven types may be recognized: carbonates, evaporites, residual deposits, kerogen, ironstone, phosphate, and silica. These are now described briefly.

Carbonates

The carbonate chemical sediments include a wide range of rocks, of which limestone and then dolomite are volumetrically the most important, whilst siderite and magnesite, although rare, are economically important. The mineralogy of carbonates is described in detail in **Minerals:** Carbonates. Limestone is composed largely of the mineral calcium carbonate ($CaCO_3$). Limestones may be made up of many different types of grain that originate in different ways in a range of depositional environments (Figure 6). Thus grain type is one of the keys to interpreting their depositional environment. Limestones form, almost without exception, from the aqueous precipitation of calcium carbonate, aided by some organic process or other, most obviously as shells secreted by invertebrates, but also as nodules, laminae, and clouds whose origins owe much to biochemical reactions. Limestones are described in greater detail in **Sedimentary Rocks:** Limestones.

Dolomite is composed of the mineral dolomite, $CaMg(CO_3)_2$, named by and from the eponymous French Count Dolomieu (1750–1801). Geopedants restrict the term dolomite to the mineral, and dolostone to the rock. This was not the Count's original intent. Like limestone, dolomite forms in several different ways, from penecontemporaneous cryptocrystalline mudstones in sabkhas, to coarsely crystalline varieties during late diagenesis. In the latter case, dolomite is virtually a metamorphic rock (Figure 7). Dolomite is an important petroleum reservoir, and occurs as a gangue mineral with lead–zinc sulphide ores (*see* **Mining Geology:** Hydrothermal Ores). It is described more fully in **Sedimentary Rocks:** Dolomites.

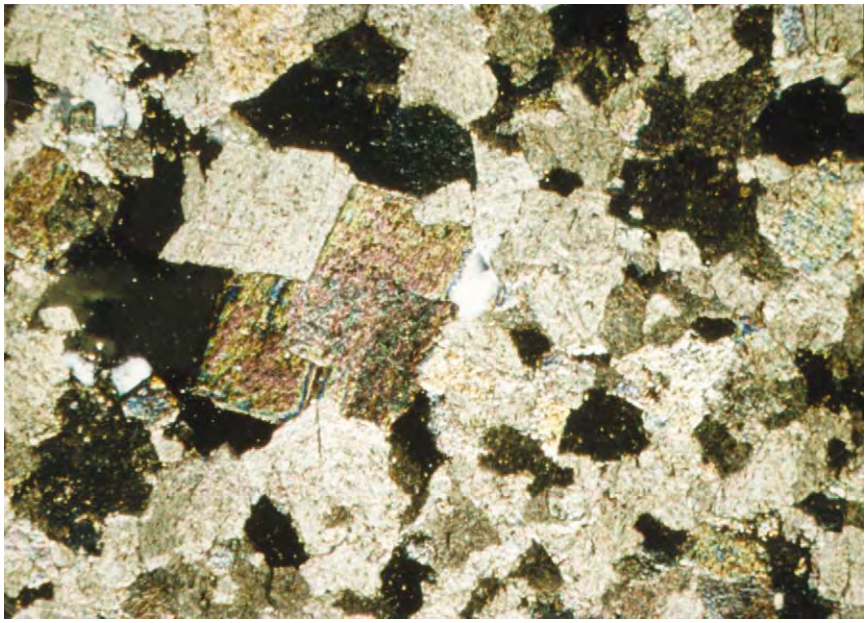

Figure 7 Photomicrograph of dolomite under ordinary light. This is a coarsely crystalline variety from the Zechstein (Upper Permian) of the UK North Sea. Some porosity (pale blue) is visible. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

Siderite is composed of iron carbonate ($FeCO_3$). It occurs commonly in shales as early cement and as concretions. It occurs as crystalline cement in sandstones, and occasionally in spherulites (sphaerosiderite) in lacustrine deposits. Here, it may be sufficiently abundant to become an iron ore (described below).

Magnesite ($MgCO_3$) is the name for the mineral magnesium carbonate, as well as the rock. It forms both as an alteration product of dolomite, and from the action of magnesium-rich fluids on limestone. Magnesite is rare, but occurs in commercially important deposits at Radenhein (Austria), Liaotung (China), and Clark County, Nevada (USA).

Evaporites

The evaporite chemical sedimentary rocks are rare, but extremely important commercially as the raw materials for the chemical industry. As the name suggests, the evaporites consist of a suite of minerals formed from the evaporation of sea water. They tend to occur in restricted sedimentary basins in cyclic sequences that begin with carbonates (limestone and/or dolomite), overlain by sulphates (gypsum and/or anhydrite), halite (sodium chloride), and then a range of potassium salts, including carnallite and polyhalite (Figure 8).

As the name suggests, it was once thought that evaporites formed exclusively from the drying out of enclosed marine basins. This required improbably large volumes of sea water to provide the resultant evaporites. It is now realized that many evaporites actually form in sabkhas (Arabic for salt marsh) from the replacement of pre-existing rocks, principally carbonates, by circulating brines. Evaporites should thus more correctly be termed 'replacementites'. Evaporites are described in more detail in **Sedimentary Rocks:** Evaporites.

Residual Deposits

Residual deposits are a variety of rocks produced by *in situ* chemical alteration or weathering (*see* **Weathering**). They include three economically important rocks: laterite, china clay (kaolin), and bauxite. These are now described in turn.

The word 'laterite' is derived from the Latin '*later*', a brick, as this rock has been widely employed for this purpose, being soft when quarried, but hardening on exposure. The term was first employed by a British geologist of the Raj, working in India, where laterites are exceptionally well developed. Laterites result from the intense weathering in many parts of the world of rocks of diverse ages and types, but particularly iron-rich rocks such as basalts. Laterites thus occur as laterally extensive residues up to 10 m in thickness above the bedrock. They require thousands of years to form, a humid climate, and a well-drained terrain. The resultant laterite is rich in hydrated iron and aluminium oxides, and low in humus, silica, lime, silicate clays, and most other minerals. Laterites are red and argillaceous in appearance, but often possess

Figure 8 Photomicrograph of nodular anhydrite ($CaSO_4$) from the sabkha of Abu Dhabi, United Arab Emirates. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

a nodular pisolitic texture. They are often termed ferricrete (etymologically, although not genetically, comparable with silcretes and calcretes). Laterites are important sources of iron in West Africa and Western Australia, and of nickel in Cuba. Further details are given in **Soils:** Modern and **Soils:** Palaeosols.

China clay, or kaolin, is the name given to rock composed almost entirely of the clay mineral kaolinite, $Al_2Si_2O_5.(OH)_4$ (*see* **Sedimentary Rocks:** Clays and Their Diagenesis). Kaolin and kaolinite are occidental corruptions of Kauling, a hill in China, from whence the first samples to enter Europe were shipped by a Jesuit missionary in 1700. Some kaolinite is produced by the *in situ* hydrothermal alteration of feldspar in granites, as for example that of south-west England. Kaolinite may then be reworked from such a source, and re-deposited in lacustrine environments, as for example the Oligocene 'Ball Clay' deposits of Bovey Tracey, Devon.

Kaolin also forms, however, as a residual deposit due to the intense weathering of aluminosilicate-rich rocks. These include feldspar-bearing igneous rocks, such as granites and gneisses. Kaolin can also be produced from sedimentary rocks, including arkosic sandstones and shales. The general chemical reaction leading to the production of kaolinite is:

$$KalSi_3O_8 + H_2O \rightarrow Al_2Si_2O_5(OH)_4$$
$$\text{Feldspar} + \text{Water} \rightarrow \text{Kaolinite}$$

Kaolin forms as a residual deposit in the soil horizons of warm humid climates, where erosion rates are low, and there is plenty of time for leaching to take place. Kaolin has many important industrial uses (see **Clays, Economic Uses**). Notable commercial deposits occur in China, naturally, south-west England, Saxony (Germany), Bohemia (Czech Republic), and Georgia, USA.

The third type of residual deposit is bauxite, hydrated aluminium hydroxide ($Al_2O_4.nH_2O$). Bauxite takes its name from Le Baux, near Arles in France. Bauxite is the end result of the intensive and prolonged weathering of soils that commences with laterite, and proceeds, via kaolin, to bauxite. These changes reflect the progressive leaching of silica, iron, and kaolinite (Figure 9).

The chemical reaction that finally leads to the formation of bauxite is:

$$H_2O + Al_2Si_2O_5(OH)_4 = Al_2O_4.nH_2O + 2SiO_2.2H_2O$$

$$\text{Water} + \text{Kaolinite} = \text{Aluminium Hydroxide} + \text{Silicic Acid}$$

Bauxites tend to be reddish or pink in colour due to some residual iron oxide. They may also possess a pisolitic texture inherited from an earlier lateritic phase (Figure 10).

Bauxite is very important as the ore for aluminium. Bauxite occurs as residual deposits on limestone, as for example in France and Jamaica. It also occurs as a residual soil on Precambrian igneous and metamorphic rocks, as in Surinam.

Kerogenous Chemical Sediments

Kerogen is defined as hydrocarbons that are insoluble in normal solvents, such as carbon tetrachloride, but which yield liquid or gaseous petroleum when heated. Chemically, kerogen includes a range of complex hydrocarbons, with traces of many other elements, including sulphur, nitrogen, and various radioactive and heavy metals. Kerogen is generally deposited in anoxic reducing stagnant conditions, most commonly found in marshes, swamps, meres, salt marshes, and lagoons, and is particularly characteristic of deltas (*see* **Sedimentary Environments:** Deltas). In these environments, vegetation may accumulate as laterally extensive horizons of peat many metres thick. During subsequent burial, peat undergoes extensive compaction and diagenesis, changing first into brown coal (lignite), then bituminous coal, then anthracite, and finally graphite, as it enters the realm of metamorphism. The variety of kerogen termed coal is, of course, a very important source of energy. Less conspicuously, although equally important, kerogen occurs in varying amounts in mudstones. Originating as plant and animal detritus, this disseminated kerogen is the mother of petroleum (Figure 11). When kerogen constitutes >1.5%, or thereabouts, of a shale, the shale becomes a potential petroleum source rock, subject to sufficient thermal maturation. Depending both on its chemistry and the level of maturation, kerogen generates petroleum gas and oil (*see* **Petroleum Geology:** The Petroleum System).

Ironstones

Iron is widespread in sedimentary rocks, but is concentrated in economic amounts in very few. A distinction is made between the Banded Ironstone Formations (colloquially referred to as BIFs), and ironstones *sensu stricto*. Banded ironstones are widespread around the Earth, but they are all of Precambrian age, and are curiously interbedded with

chert. They formed when the Earth's atmosphere was significantly different from that of today (*see* **Sedimentary Rocks:** Banded Iron Formations). The term ironstone is now restricted to Phanerozoic sedimentary rocks consisting of at least 15% by weight of iron, either 19% FeO, or 21% Fe_2O_3, or an equivalent admixture.

Ironstones consist of a range of iron minerals, including oxides (magnetite, haematite, and goethite/limonite), carbonates (siderite), and silicates (chamosite and berthierine). Three main types of ironstone are recognized: blackbands, claystones, and ooidal. Blackband and claystone ironstones are organic-rich sideritic mudstones. They commonly occur in deltaic deposits associated with peat and coal. Intraformational conglomerates composed of ironstone clasts and horizons of brittle fractured ironstone in slumped delta slope shales indicate that the ironstones formed during early shallow burial.

The origin of the third type of ironstone is more controversial. The ooidal ironstones are composed of several types of iron mineral (Figure 12). Ooid formation is normally associated with high-energy depositional environments (*see* **Sedimentary Rocks:** Limestones). The ooidal ironstones, however, are often poorly sorted wackes. Thus, argument has raged as to whether ferruginous ooids formed in high-energy environments, and were then dumped as poorly sorted wackes. Alternatively, did iron minerals replace quotidian lime ooids during subsequent diagenesis?

The data and arguments are examined more fully in **Sedimentary Rocks:** Ironstones, but it is probably as true today as it was in 1949, when Taylor wrote in his seminal memoir on the Northampton Sand Ironstone, that: "Conditions of deposition of the sedimentary iron ores are still to some extent a mystery".

Phosphates

The penultimate group of chemical sediments to consider are the phosphates. Phosphates are an extremely important mineralogically complex group of rocks that are essential as plant fertilizers. About three-quarters of the world's supply of phosphates comes from sedimentary deposits. Sedimentary phosphate deposits are of three types: bedded, placer, and guano. Bedded phosphates are formed by the replacement of limestone, and of teeth, bones, and coprolites, to form the mineral phosphorite. Factors that favour phophoritization include a broad shelf adjacent to an ocean, slow shallow marine sedimentation, low terrigenous input, and high organic productivity. Once phosphorite has formed, it is stable in sea water, and sparingly soluble in fresh water. Thus, phosphate pebbles occur, not only as intraformational conglomerates intimately associated with bedded phosphate, but also as placer deposits that are sometimes far removed from their parent body. Bedded phosphates formed during several geological periods on ancient shelves around the world. The Cretaceous phosphate belt of the southern shores of Tethys is noteworthy. This stretches

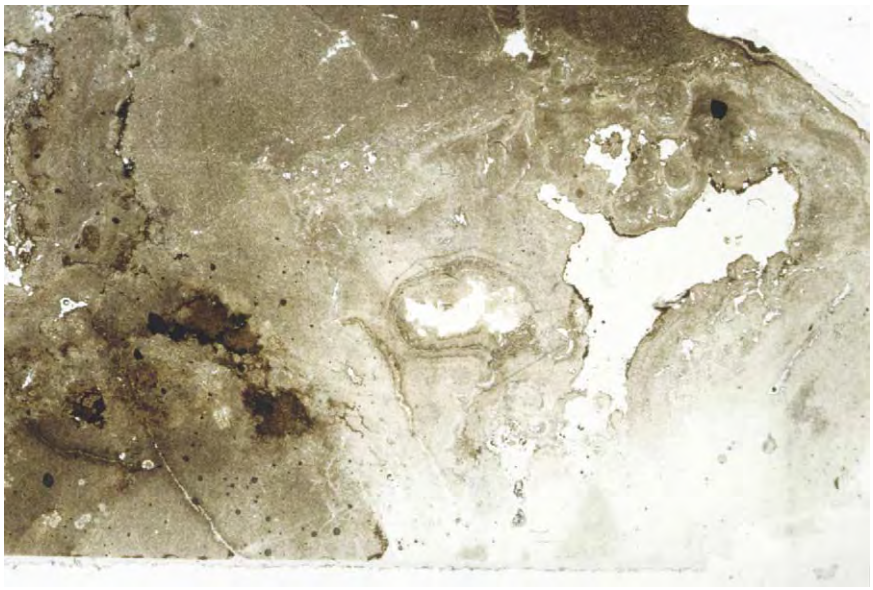

Figure 13 Photomicrograph, under ordinary light, of guano phosphate deposit. This is formed by the phosphatization of bird droppings. St Helena, South Atlantic. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

from Bu Craa in the western Sahara, through Morocco and Algeria to the flanks of the Red Sea, Jordan, and Jabal ash-Sharki in Syria. Younger placer phosphate deposits of note include the alluvial phosphate gravels of South Carolina and Florida in the USA.

Guano is the youngest phosphate rock (Figure 13). This is a fertilizer rich in phosphates and nitrates that forms from the accreted excreta of birds and bats. Whole Pacific Islands, such as Nauru, are, or rather, were composed of guano that has subsequently been quarried away.

Phosphates are described in greater detail in **Sedimentary Rocks: Phosphates.**

Siliceous Deposits

The last group of chemical sediments to describe are those composed of silica (SiO_2), not the detrital sands, but those that formed by organic secretion, replacement, or, possibly, by direct precipitation from water.

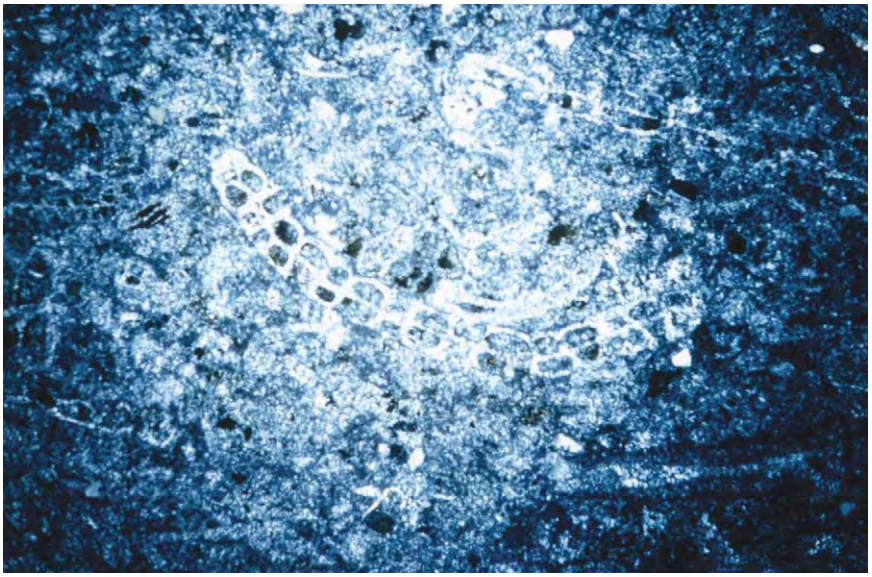

Figure 14 Photomicrograph, under polarized light, of chert (colloquially, flint) from the Chalk (Upper Cretaceous), Dover, UK. This formed by replacement of pre existing limestone. Some silicified bioclasts can be detected. Reproduced with permission from Selley RC (2000) *Applied Sedimentology*, 2nd edn. London: Academic Press.

Various organisms secrete silica. Radiolaria and diatoms secrete silica shells, whilst some sponges secrete internal spicules of silica. Deposits of radiolarian and diatom shells may accumulate under water in sufficient amounts to constitute sedimentary rocks in their own right, termed 'radiolarite' and 'diatomite', respectively. Organically precipitated silica disseminated in sediments may undergo dissolution and reprecipitate as cryptocrystalline silica. This variety of silica is termed 'chert', often referred to colloquially as 'flint' by the aboriginal inhabitants of the Cretaceous Chalk downlands of south-east England. Chert is a non-clastic cryptocrystalline variety of silica that occurs as nodules and horizons in limestones and sandstones (Figure 14). Chalcedony is a radial or fibrous variety of chert that infills fossils and other pores. Opal, sometimes termed opaline silica, is a hydrated variety of silica, amorphous and isotropic, with the chemical formula $SiO_2.nH_2O$, sometimes also written $SiO_2.nSi(OH)_4$. It occurs only in Tertiary to Recent sediments, having dehydrated to chert in older rocks. Opal is a semiprecious stone.

Cherts pose three main problems. What is the source of the silica? What is the environment of deposition of bedded cherts? How do nodular cherts replace their host sediments? These questions are discussed in **Sedimentary Rocks:** Chert.

Conclusion

The primary aim of this overview of the sedimentary rocks has been to simultaneously point the reader in two different directions: to the tranche of articles dealing with mineralogy, and to the tranche of articles that describe the various sedimentary rocks in more detail. The article offers a simple classification of the sedimentary rocks, but at the same time points out the problems and inconsistencies of any scheme of rock classification. Sediments can be broadly grouped either by their physical attributes, principally grain size, but also by their chemistry or mineralogy. A detailed analysis of any scheme shows its inconsistencies. To call a group of rocks 'chemical' is nonsensical, because it implies that others are 'non-chemical', whatever that might mean. Evaporites should really be called 'replacementites,' but who would dare to argue for such a change. Siliceous chemical rocks include detrital sediments, primary precipitates, and also some of diagenetic origin, yet they are placed in one single group. Classification is purely a pedagogical framework, like the chrysalis from which exegesis may emerge like a butterfly.

Banded Iron Formations

A Trendall, Curtin University of Technology, Perth, Australia

Introduction

Banded Iron Formation, normally abbreviated to BIF, is a type of sedimentary rock commonly present in Precambrian sedimentary successions of specific ages. Apart from this time restriction it has a number of characteristics which make it unique among sedimentary materials. Firstly, there is nothing chemically similar to it being laid down in the waters of the modern Earth, so that its origin cannot be deduced by directly observing the formation of similar materials in the present-day environment. Secondly, it has virtually none of the textural features common in other sedimentary rocks that give a clue to the conditions under which it was laid down; theories for its origin, therefore, have to be argued from various indirect lines of evidence, and there is still no complete agreement on its significance in the stratigraphic record. A third feature is that it is exceptionally hard, tough, and dense, making it instantly recognisable in field exposures, where it commonly forms resistant ridges standing out from more easily eroded rocks. Finally, it is a sedimentary rock in which fine details of stratification have been shown to persist over exceptionally large distances, arguing for depositional conditions free from disturbance by currents. BIF also has great economic importance because it is the source, either directly or indirectly, of most of the iron ore presently mined; and as the main source of raw material for the world's iron and steel industries, underpins the physical fabric of the developed world.

Nomenclature, Classification, Definition

Before describing the characteristics of BIF in more detail, it is worth reviewing the different names that have been applied to it on different continents and at different times, so that there is a clear understanding of how the name is applied in this article. The first formal geological descriptions of BIF were made in the latter part of the nineteenth century, focusing on occurrences in parts of the USA south of Lake Superior, where iron ore mining was established in areas of outcrop known as 'ranges', such as the Mesabi, Marquette, Cuyuna, Gogebic, and Menominee Ranges. The rock was then called 'jasper', 'jaspilite', or 'iron-bearing formation', which was later shortened to 'iron-formation'. The name 'taconite' was also used, and because many of the rocks had conspicuously multicoloured banding the term 'banded iron-formation' also became common. During the early twentieth century, other names came to be used for similar rocks of other continents. For example, 'itabirite' was used in Brazil, 'ironstone' in South Africa, and 'BHQ' ('banded haematite quartzite') in India. Studies in all these places tended to assume that the iron-rich rocks to which these names were applied were identical with those that had been well documented from the Lake Superior ranges.

As more detailed studies were made later in the twentieth century, it was realized that many extensive occurrences of BIF, and especially those of South Africa and Australia, were distinctively different from those of the Lake Superior area. In particularly, they lacked the granular structure that was generally present in the latter, and had a different pattern of banding. The term 'granular iron-formation', or GIF, is now preferred for the type of BIF to which the name was first applied in the USA. In a perfectly rational classification it would

probably be best to restrict the names BIF and GIF to two types of iron-rich sedimentary rock with separate textural features, and to use the name 'iron-formation' (IF) as a generic name for both. But because the use of BIF is so strongly entrenched, it is used here as the general term, and GIF is regarded as a particular type of BIF.

BIF is therefore defined as a chemically precipitated sedimentary rock containing at least 15% of iron, typically thin-bedded or laminated, and commonly containing layers of chert.

Chemical and Mineralogical Composition

Although the definition above requires a minimum iron content of 15%, the great majority of rocks that would be called BIF contain between 25% and 35% Fe. About half of the rock by weight consists of iron oxides, while the remainder is mainly silica. Carbon dioxide (as carbonate) is present as a minor constituent in many BIFs, and is a major component in some, but all other oxides (e.g., Al_2O_3, MgO, Na_2O, K_2O, P_2O_5) are relatively minor, and trace elements are insignificant. Haematite (Fe_2O_3) and magnetite (Fe_3O_4) are the most abundant iron minerals. Others that may be present are carbonates (ankerite, siderite) and silicates (stilpnomelane, greenalite, riebeckite). The silica normally occurs as microcrystalline quartz, usually called chert. Neither the chemical nor mineralogical composition of GIF differs significantly from that of BIF.

The Banding

The banding of BIF, with the exception of the type known as GIF, which is dealt with later, may best be described by reference to that of the well preserved BIFs which were laid down in the Hamersley Basin of north-western Australia between about 2650 Ma and 2450 Ma. Apart from very low-grade metamorphism, open folding, and gradual uplift and exposure, the rocks of this basin remain essentially unaffected by post-depositional events; the basin had a depositional area of at least $10^5\,km^2$. The 1.2 km (compacted thickness) of BIF present within the 2.5 km-thick median sequence of this basin forms five main units interstratified with shales and carbonate sediments. One of these units, the *ca*. 140 m-thick Dales Gorge Member, is particularly useful for stratigraphic study in that it has 33 internal alternations, termed macrobands, of BIF and shale. The banding of the BIF of each of the 16 BIF macroband is termed 'mesobanding', and is defined by sharply defined alternations, on a centimetric scale, of dark iron-rich (silica-poor) mesobands and light silica-rich (iron-poor) mesobands; the latter are usually called chert. Chert mesobands of the Dales Gorge Member BIF are normally between 5 mm and 15 mm thick, with an average thickness about 8 mm; they constitute about 60% of the total BIF volume; the intervening iron-rich mesobands have a mean thickness of about 10 mm, and make up about 20% of the total BIF volume. A minor proportion of mesobands of magnetite and/or carbonate make up the remainder of the volume. All the mineral components of all mesoband types are made up of fine-grained closely crystalline material that shows no evidence of a clastic contribution to the formation of the rock.

The monotonously repetitive alternation of iron-rich and iron-poor mesobands, on the same centimetric scale as those of the Dales Gorge Member, is an easily identifiable characteristic of BIF wherever it occurs, and is the scale of banding from which the name BIF derived. In field exposures the alternating bands may be coloured black and white, red and white, or red and black, largely according to the weathering of the rock, and often give it a spectacularly striped appearance (Figure 1).

Within many chert mesobands of the Dales Gorge Member there is a regular small-scale lamination defined by a concentration of some Fe mineral within the pervasive matrix of microcrystalline quartz. The Fe mineral may be either hematite, magnetite, carbonate (siderite or ankerite), stilpnomelane, or some combination of these. This lamination within individual chert mesobands has been called microbanding. The iron-rich laminae that define microbands are normally separated by thicknesses of between 0.2 mm and 1.6 mm of virtually iron-free chert. Within a microbanded chert mesoband the microband thickness tends to vary only slightly, but from one such mesoband to another there may be significant variation. Since its identification in the Dales Gorge

Figure 1 Hand specimen (15cm wide) of folded Archaean BIF from the Yilgarn Craton, Western Australia. The conspicuous red and black banding is mesobanding; the red mesobands are chert and the black mesobands consist mainly of iron oxides and microcrystalline quartz. (Photograph by GJH McCall).

Member, it has been identified in a number of other well-preserved BIF units elsewhere.

The characteristic mesobanding of BIF is not present in GIF. GIF also has alternations of iron-rich and iron-poor material, but these are typically coarser and much less regular. The coarsely crystalline chert bands are commonly wavy or lenticular. Both iron-rich and silica-rich bands may be granular, more particularly the latter. The iron-rich bands of GIF, as the name implies, often consist of a close-packed and lithified mass of granules or ooliths, averaging about a millimetre in diameter. They are made up of iron oxides, with or without quartz, and the intergranular material consists mainly of the same minerals, but usually with a lower iron content.

Continuity of Banding

A remarkable stratigraphic feature of Hamersley Basin BIF is its exceptional lateral continuity. Thus the Dales Gorge Member, used above as a model for the description of banding, and the other main BIF units, are easily identifiable over the entire basin area. BIF macrobands within the Dales Gorge Member are similarly recognisable through their constant relative thicknesses, and within BIF macrobands both individual centimetre-scale mesobands, as well as sub-millimetre microbands within them, have been correlated over 300 km. This degree of fine-scale lateral stratigraphic continuity is reminiscent of evaporites, particularly in the Permian of Europe and the United States.

Metamorphic and Tectonic Modification

Because of their exceptional freedom from post-depositional metamorphism and tectonic deformation, the BIFs of the Hamersley Basin have been used as 'type examples' for the introductory descriptions above; the BIFs of the Transvaal and correlative Griqualand West basins of South Africa, which are of similar age, also have the same excellent preservation. But in this respect they are atypical of the majority of BIF occurrences. Many Early Precambrian examples have suffered significant metamorphic modification, which begins with coarse-grained recystallisation (annealing) of both the initially microcystalline chert and fine-grained iron oxides, and continues with the growth of iron-rich silicates (e.g., grunerite, ferrohypersthene, fayalite). Even in early metamorphic stages the delicate fine textures within the banding tend to become blurred, but the essential iron-rich/iron-poor alternation of the mesobanding shows a robust resistance to complete obliteration. Most metamorphism of BIF appears to be isochemical, but there is some evidence of chemical modification at higher grades.

Older Precambrian BIFs also tend to have undergone significant tectonism, particularly those of Archaean greenstone belts of all continents, where the BIFs often form curvilinear steeply dipping units which are useful in deciphering complex structures. It is characteristic of deformed BIF in these belts that it appears to have reacted sensitively to tectonic stress, forming complex internal flowage folds defined by the banding.

Distribution Over the Earth

BIFs are widely distributed throughout the Precambrian areas (cratons and shields) of all continents except Antarctica, where only one occurrence is so far known. BIFs of the older cratons include the oldest known example, at Isua, in Greenland, aged about 3.8 Ga. They are consistently present in the greenstone belt sequences of all the main old cratons. Examples include the Abitibi Belt of the Superior Province of Canada, the greenstone belts of the Yilgarn and Pilbara Cratons of Australia, and the those of the Baltic Shield, the North China Craton, the Amazon Craton of Brazil, the Kaapvaal and West African Cratons, and the BIFs of the Ukraine Craton, notably at Krivoi Rog; most of these are relatively thin, tectonised, and metamorphosed. Most of these greenstone-associated BIFs have ages between 2.8 Ga and 2.5 Ga. A different style of BIF occurrence is present in four of the Gondwana continents (South America, southern Africa, India, and Australia). In this type the BIFs occur as well preserved, gently dipping supracrustal sequences, which may form conspicuous topographic plateaus. The Carajás Formation of the Amazon Craton, the Cauê Itabirite of the São Francisco Craton (both in Brazil), the Kuruman Iron Formation and Penge Iron Formation of South Africa, and the Mulaingiri Formation of the Indian Karnataka Craton all belong to this group, which includes the BIFs of the Australian Hamersley Basin, already mentioned above; these occurrences have been called the Great Gondwana BIFs, and are mostly younger than those present in greenstone belt occurrences. Further mention of a final distinct category of BIF occurrences, which includes Rapitan in the Yukon, and those of the Damara Belt, in Namibia, is made below the next heading.

Distribution in Time

Mention has already been made not only of the general restriction of BIFs to the Precambrian, but also to

specific intervals within that Eon. This topic needs closer attention, since it is critical for understanding the genesis of BIF, and has been a subject of strong controversy. A relevant point to be made is, of course, that the topic could not be discussed at all without the availability of the precise isotopic dating techniques that have established, only in the last couple of decades, a reliable time-scale for the entire span of Precambrian time.

An age of about 3.8 Ga has already been noted for the oldest BIF, from Isua. This is still the oldest known sedimentary (or more accurately metasedimentary) succession, so that BIF is included among the oldest sedimentary rocks. The abundance of BIF in Archaean greenstone belts indicates that it continued to be deposited intermittently until the end of that Era, which by convention is accepted as 2.5 Ga. By far the two largest basins of BIF deposition on Earth, in terms of contained Fe, are the Hamersley Basin and the Transvaal/Griqualand West Basin, and in these, massive deposition of BIF continued until ~2450 Ma. There is then a paucity of BIF occurrences until the Lake Superior GIFs, at ~1850 Ma, which represents a global peak for this type. A long interval in which no BIF deposition is known then followed, and it was not until the end of the Precambrian, in the Late Neoproterozoic, that there is a final burst of BIF deposition, which includes the Rapitan and Damara examples.

In summary, the overall picture is of a long early period of intermittent BIF deposition, culminating in a peak at ~2500 Ma, after which there was a smaller burst at ~1800 Ma, and finally, after a long hiatus, another significant depositional event at the end of the Precambrian. It has been pointed out that some iron-rich Phanerozoic rocks closely resemble Precambrian BIFs, but these exceptions only prove the rule, and indicate that there were special environmental conditions during the Precambrian, and particularly during the Early Precambrian, which led to the deposition of BIF.

Association with Other Rocks, and with Volcanism

BIFs do not, of course, exist in isolation, but occur in association with other lithologies as components of sedimentary, or volcanosedimentary, sequences. Two general stratigraphic points are worth making: in the first place, BIF tends to form discrete, clearly demarcated, units of significant thickness and wide lateral extent – it does not form thin or discontinuous beds interlaminated, or interdigitated, with other lithologies; and in the second place, BIF has never been demonstrated to grade imperceptibly into another lithology, whether laterally or vertically. It is as though the conditions for BIF deposition, in any given basin, were intermittently switched on and off abruptly, rather than by any gradual change in the depositional environment.

Within those two overarching generalisations, BIF has not been demonstrated to occur in immediate sedimentary contact with any preferred lithology. Examples can be found of association with both fine-grained (shale) and medium-grained (quartzite) epiclastic sediments, with turbidites and with carbonates. For BIFs in Archaean greenstone belts, there is a common association with mafic volcanic rocks, but an immediate and local genetic link between the two has never been unequivocally demonstrated. While it is true that volcanic rocks, both felsic and mafic, are commonly present as components of depositional basins in which BIF occurs, the fact remains that no volcanic rocks at all are closely associated with one major BIF of Brazil – the Cauê Itabirite of the Quadrilátero Ferrífero. There is abundant trace element and isotopic evidence that BIFs have an igneous connection, but an immediately local association cannot be inferred from this.

Theories of Origin

From direct observation of the present environment it is easy to see that lithostratigraphic units of, say, sandstone are likely to have been formed by the transport of sand in rivers to the sea. There is no such direct way to determine how BIF formed, and a credible hypothesis for its origin must be built up step-by-step, from various lines of evidence. An early suggestion in the Lake Superior area was that BIF may be an acid lava, and more recently it has been proposed that BIF was initially a carbonate rock which had been replaced by iron and silica.

Most workers now accept that BIF is a chemically precipitated sedimentary rock, but that acceptance does not remove the need to explain many associated problems, including:

i. what was the source of the materials (both iron and silica)?
ii. how were they transported to the basin?
iii. did deposition occur in a lake or in the ocean?
iv. what caused precipitation?
v. what does the banding represent?
vi. to what degree does the final rock differ from the precipitate?

The first two of these questions were at one time debated in terms of two radically opposite concepts. One suggested that the iron and silica were derived from deep weathering of continental crust, and were

selectively carried to the adjacent basin by rivers; the other proposed that the source of the the iron and silica was fumarolic volcanism very close to or within the basin, obviating the need for significant transport. As the debate progressed both ideas were generally abandoned, in favour of a model in which both iron and silica were in very dilute solution in ocean water, and were precipitated from the water of marginal basins kept supplied with both materials by appropriate circulation; in this model the primary source of iron and silica was ocean-floor volcanism or volcanic rocks, either at mid-ocean ridges or more generally from the ocean floors. As far as the third question is concerned, the abundance of BIF in the Precambrian stratigraphic record, its frequent association with clearly marine lithologies, and the difficulty of forming such immense thicknesses of iron-rich material in lakes, jointly make the lacustrine hypothesis untenable.

The fourth question then arises from a model involving precipitation from the water of an ocean margin basin which has low levels of dissolved iron and silica. Attention here has focused on the iron component, and specifically on the fact that dissolved iron will be in the ferrous state, and that oxidation will lead to precipitation in some ferric form. A variety of mechanisms for this oxidative precipitation has been proposed, including algal photosynthesis, anoxygenic bacterial photosynthesis, photo-oxidation by sunlight, and decomposition of water by ^{40}K radiation. Current research increasingly involves attention by microbiologists to the detailed mechanisms by which early biota could have effected precipitation. From a sedimentological viewpoint, the key point is that such mechanisms are quantitatively viable for precipitation of iron from small basin water concentrations.

The fifth question is one which received little early attention. Although it was generally agreed to represent the stratification of the BIF there was virtually no analysis of how the mesobanding was generated. A structured model was first proposed in respect to the BIFs of the Hamersley Basin. There it was argued that the microbands, whose presence has been noted within the chert mesobands, probably represent annual layers, or chemical varves: the thin iron-rich laminae of microbands may be presumed to represent summer seasons of high photosynthetic activity. Acceptance of this hypothesis permits calculation of the quantity of iron precipitated in the Hamersley Basin per unit area each year ($225\,t \cdot km^{-2} \cdot yr^{-1}$), and hence, from knowledge of the bulk composition of the rock, an estimate of the compacted depositional rate. But these arguments have still not addressed the fifth question, which asks about mesobanding, not microbanding. So an additional step of this model added the proposal that the initial precipitate was a collloidal silica ferrihydrate gel which was compressed to about 10% of its initially deposited thickness during burial and diagenesis; and its final step was the suggestion that the mesobands developed during this stage by differential compaction. These last two steps, of course, address the sixth question also.

Some aspects of this depositional model have been challenged. Most workers on BIF agree that an annual (varve) significance for microbands is likely, although a diurnal or even tidal origin has been suggested. Others have preferred to see a direct link between mesobanding and iron supply from mid-ocean ridge activity, the mesobands representing pulsed variations in supply, with microbanded chert mesobands representing stable periods of perhaps of tens of years of relatively low iron availability. The origin of mesobanding still remains uncertain.

Unsolved Problems

Apart from the origin of mesobanding, the uncertainty of whose origin has just been noted, three other still-unsolved questions of BIF genesis are worth emphasizing in conclusion. The possible involvement of biotic processes in the precipitation of the iron of BIFs has already been noted; further studies related to this question are clearly not only significant for understanding BIF but for understanding important processes of biochemical evolution. The distribution of BIF in time has already been described, but its significance was not discussed. An early hypothesis tied the Late Archaean peak closely into a step in the biochemistry of photosynthesis, but additional geochronological work has lessened support for that proposal. A recent suggestion that the deposition of BIF is related to deep-water phases in basin development, and that this development shows systematic tectonically controlled secular changes, has yet to be fully debated. And finally, the place of BIF in the chemical evolution of the atmosphere and oceans has yet to be fully understood. Research on this uniquely puzzling sedimentary rock still holds many challenges.

Chalk

J R Ineson and L Stemmerik, Geological Survey of Denmark and Greenland, Geocenter Copenhagen, Copenhagen, Denmark
F Surlyk, University of Copenhagen, Geocenter Copenhagen, Copenhagen, Denmark

Introduction

Chalk is a familiar rock type, particularly amongst Europeans, forming spectacular white cliffs along coastlines flanking the North Sea, the English Channel and the Baltic Sea. The essential characteristic of a true chalk is its microscopic composition – being composed predominantly of the skeletal remains of tiny calcareous marine algae known as coccolithophorids (Figure 1). Following their appearance in the Jurassic, these haptophycean algae became a common constituent of marine sediments and remain important components of the marine ecosystem today. Only during specific periods of Earth history and in certain palaeogeographic areas, however, were conditions such that pure carbonate oozes accumulated and were preserved on continental shelves and in vast epeiric seas. Chalk is thus most characteristic of the Upper Cretaceous (and in places the Danian) of north-west Europe and North America. This review focuses on these typical chalks, particularly from north-west Europe (Figure 2).

Chalk as a Sediment

Composition

A typical chalk is a fine-grained carbonate rock (a lime mudstone or micrite), the lithified equivalent of pelagic carbonate oozes recorded from ODP boreholes in present-day oceans. The sediment is dominated by debris derived from coccolithophorid algae that comprise a spherical calcareous test (coccosphere) up to several tens of microns in diameter. The test is made up of overlapping circular or elliptical discs or rings (coccoliths), which are 1–20 μm in diameter and are, in turn, constructed of tiny calcite platelets, laths or rays ranging from 0.1 to 2.5 μm across (typically 0.5–1 μm; Figure 1). The complete coccosphere is only rarely preserved and the chalk consists largely of coccoliths and their disaggregated platelets and spines (rhabdoliths). Despite being dominated by coccolithophorid debris, planktonic foraminifers and calcispheres are also common in chalks, together with coarser skeletal elements from both pelagic and benthic organisms such as belemnites, bryozoans, echinoids, bivalves, brachiopods, serpulids and sponges.

Mineralogically, pure chalks are composed of low magnesium calcite; this is the stable form of calcite

seen in most ancient limestones and is commonly the result of diagenetic modification of unstable carbonate precursors (e.g., high magnesium calcite, aragonite). In the case of chalks, however, this composition is essentially primary since coccolithophorids secrete low magnesium calcite. The chalk is thus not prone to significant diagenesis under normal marine conditions, imparting a chemical stability to the chalk that

is unique amongst limestones. This is a major factor in its utility as a reservoir both for hydrocarbons and water (see below). The content of siliciclastic detritus in chalk is typically low, but clay-rich chalks are observed at certain stratigraphic and palaeogeographic positions and clay content is often instrumental in highlighting a distinctive cyclicity in the chalk succession. Primary biogenic silica may be present in the form of opaline radiolarians, diatoms and sponge spicules, but more characteristically silica in the chalk is represented by bands of nodular flint or its precursor, cristobalite lepispheres. Glauconite and phosphorite are also important authigenic minerals in chalks, particularly over structural highs or associated with hiatal surfaces.

Facies and Processes

Typical fine-grained coccolith-dominated chalk forms one, deeper-water variant within a spectrum of facies referred broadly to the chalk family (Figure 3). The faunal content increases towards the basin margins and over structural highs, and in the shallowest parts of the north-west European chalk sea coarse-grained, shallow marine carbonates were deposited. These are dominated by skeletal carbonate sands with abundant bivalves, brachiopods and echinoderms. Basinwards, this facies belt may pass into a zone dominated by bryozoan mounds before entering the area of true chalk deposition (Figure 3). The marginal facies of the chalk sea are known mainly from onshore outcrops in Denmark and southern Sweden; the Danian-age bryozoan mound complexes exposed in eastern Denmark are particularly impressive (Figure 4).

The pelagic chalk was initially deposited as an ooze consisting of coccoliths with a variable content of foraminifers and calcispheres, and a landward increasing content of invertebrate fossils, including bryozoans, echinoderms, brachiopods, and bivalves. The chalk seafloor was a unique, long-lived macrohabitat and a remarkably well-adapted, highly specialized fauna gradually developed, dominated by millimetre-sized suspension-feeding invertebrates. This reached a climax in the Late Campanian–Maastrichtian with a diversity of several thousand benthic species. Most epifaunal species were very small allowing attachment to very restricted hard substrates such as individual skeletal fragments. Other organisms developed 'snowshoe' strategies (a flat profile, often with long marginal spines, or hemispherical with the convex valve downwards) permitting the organism to 'float' on the soft substrate.

The coccolithophorid algae lived largely within the photic zone near the sea surface, and their skeletal debris settled slowly to the seafloor from suspension, most likely in the form of faecal pellets. At the sea floor, the ooze was watery with a primary porosity of 70–80%. The grain size was extremely fine, probably about 1 μm, since the coccolithophorid tests readily disaggregate into their component coccoliths and platelets. The pelagic ooze typically accumulated under well-ventilated conditions on the sea floor where sufficient oxygen was available to support a diverse fauna of burrowing benthic invertebrates – the pelagic chalks are thus characteristically intensely bioturbated. Studies of the onshore chalk exposures have revealed composite ichnofabrics that reflect the succession of diverse benthic communities that occupied the uppermost layers of the ooze as it experienced gradual dewatering and changed from a soupground to a softground (Figure 5). The trace fossils in pelagic chalks reveal much information about substrate conditions, sedimentation rates and oxygenation as well as evidence of non-deposition and the development of firmgrounds and hardgrounds. This is based on the recognition of characteristic groups of trace fossils, known as tiers, that characterize different levels in the ooze from the sea bed down to a metre or more below the sediment surface (Figure 6). The shallowest tier completely obliterated the primary fabric and only rarely are discrete trace fossils recognizable (e.g., diffuse *Planolites*). Downwards, trace fossils are better preserved and define a succession of tiers characterized by forms such as *Thalassinoides*, *Zoophycos* and *Chondrites*. Nodular chalks and hardgrounds are distinctive features of shelf-sea chalks and record decreasing rates of sedimentation and consequent increasing intensity of cementation at or near the sea floor. True hardground surfaces (i.e., cemented layers exposed on the seafloor) may show evidence of encrustation of the hardened surface by bivalves, serpulids and bryozoans and boring by sponges, algae and bivalves. The hardground surface may also be impregnated by phosphorite or glauconite.

Resedimentation of pelagic chalks has been documented on all scales from both onshore and offshore areas, and it is widely recognized that intrabasinal slides, slumps, turbidity current and debris flow deposits form an important part of the chalk depositional system (Figure 3). The largest slides occur close to tectonic inversion or salt structures and involved downslope movement of slabs of semi-lithified chalk, tens of metres thick. They may be identifiable on seismic data, but can be difficult to recognize in core since there is little or no internal deformation within the slide masses. Such allochthonous sediment slices have, however, been recognized on the basis of anomalous biostratigraphic data, a Maastrichtian interval sandwiched between Danian chalks for example. In contrast, slumps are more readily recognized by the presence of pervasive deformation

structures such as isoclinal folds and stratigraphically inverted successions. Chalk debrites, comprising chalk pebbles or slabs supported in a fine-grained chalk matrix, form a significant part of the Maastrichtian–Danian succession in the North Sea Central Graben. Most resedimented chalk clasts are plastically deformed, implying that they were poorly lithified at the time of deposition. However, the presence of angular clasts in some debrites indicates that some of the material originated from lithified chalk, either from penecontemporaneous firmgrounds/hardgrounds or from exhumed more deeply buried chalks, for example at fault scarps. Sand-grade 'classical' turbidites are uncommon in the chalk, most likely due to the scarcity of sand- and silt-sized material, although dilute low-density turbidity currents were important in the redistribution of mud-grade sediment.

The Chalk Sea

In the Late Cretaceous, pelagic carbonate oozes extended far onto the European craton and formed the dominant facies for tens of millions of years. This was the result of a unique coincidence of global and regional factors. The chalk sedimentary record attests both to such long-term controlling factors as eustatic sea-level and regional tectonics and to the influence of short-term climatic variation controlled by orbital forcing mechanisms.

Palaeogeography

The chalk sea of north-west Europe existed for more than 35 Ma, from the Cenomanian to the Danian, at a time when global sea-level was at its highest during the Phanerozoic and relative tectonic stability prevailed in the region. Much of the north-west European craton was flooded to depths in excess of 50 m. Hinterland relief was low and potential source areas were restricted in extent so siliciclastic supply was limited and a pelagic carbonate drape accumulated, extending from a palaeolatitude of 35° N northwards to 50° N where the carbonates passed into siliciclastic muds (**Figure 2**). The biogenic components largely belonged to the heterozoan association that today characterizes cool-water, temperate carbonate systems; typical Cretaceous tropical organisms, such as reef corals, large foraminifers and rudist bivalves are absent or rare in the chalk of north-west Europe. However, direct latitudinal comparison with present-day seas are invalid since the Cretaceous was one of the 'greenhouse' phases of Earth history when equable temperatures extended further poleward than in our present 'icehouse' situation. The chalk sea is thus probably best characterized as ranging from warm temperate to sub-tropical, despite its mid-latitude

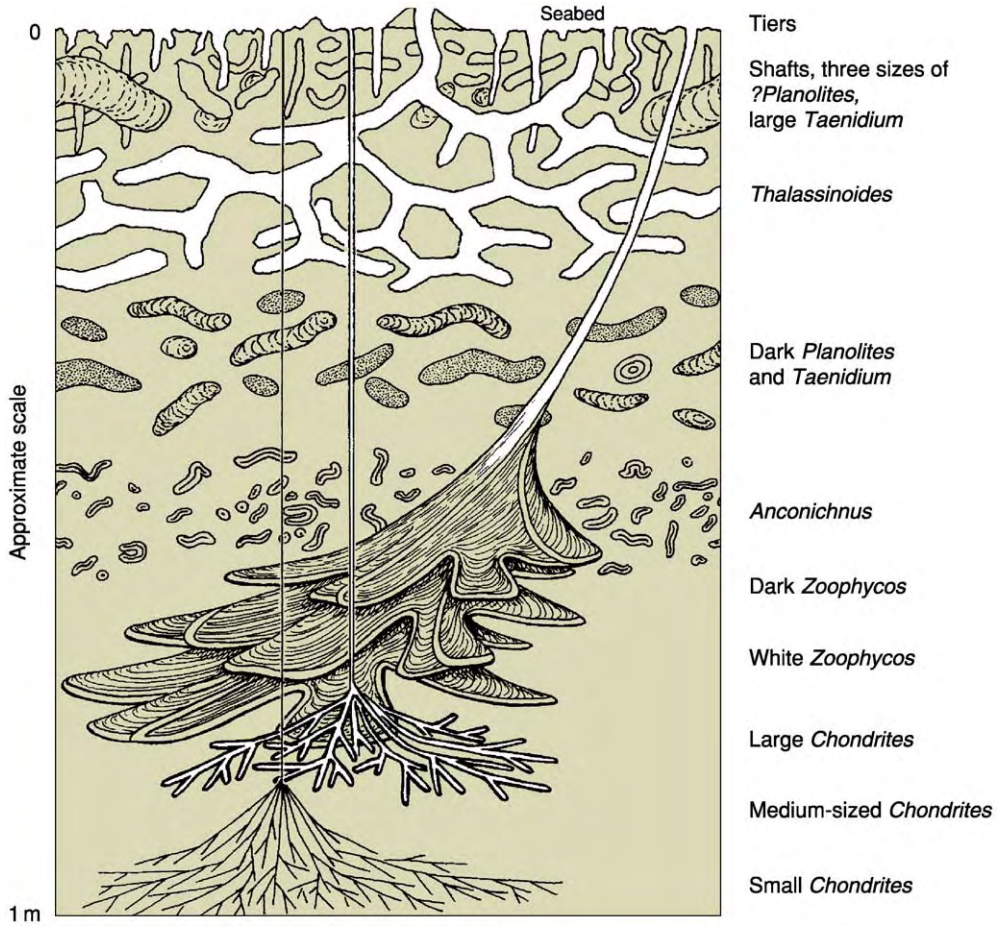

Figure 6 Schematic 'snapshot' of a Cretaceous ooze profile showing the various trace fossil tiers at different levels beneath the sea floor. Modified from Ekdale AA and Bromley RG (1991) Analysis of composite ichnofabrics: an example in uppermost Cretaceous chalk of Denmark. *Palaios* 6: 232 249.

setting. The overwhelming dominance of coccolithophorid skeletal material suggests that overall the chalk sea was a low nutrient (oligotrophic) setting. Today, shelf seas are separated from the open ocean by shelf break fronts that isolate inshore waters from the open ocean. During maximum sea-level highstand in the Late Cretaceous, the high water depths over the shelf break precluded the development of an effective shelf front and oceanic conditions extended far onto continental shelves and into epeiric seas.

Late Cretaceous pelagic sedimentation rates are estimated at 2–2.5 cm per thousand years. The Upper Cretaceous–Danian chalk succession is typically a few hundred metres thick where exposed in countries bordering the North Sea (Figure 2), but can be over a kilometre thick within major graben structures in the central North Sea and thicknesses in excess of 2 km are found in the Danish Basin. Chalk deposition was interrupted at the Maastrichtian–Danian boundary due to the mass extinction, which included coccolithophorids and foraminifers with only a few surviving species. The mass extinction severely affected all carbonate-shelled organisms and some, such as the ammonites, became totally extinct. The boundary is marked by a thin clay layer in all complete sections (Figure 4); this layer shows enrichment in iridium, forming the basis for the hypothesis that the mass extinction owed its origins to the impact of a giant meteorite. Carbonate deposition, however, rapidly resumed; the surviving microplankton and benthic invertebrates soon regained high diversities and the Danian ecosystem closely resembled that of pre-extinction, Cretaceous times.

Sea-floor relief in the NW European chalk sea was subdued and the carbonate system is best considered overall as a gently shelving ramp (Figure 3). However, significant depositional relief was developed along structures inherited from Jurassic rift events or related to localized Cretaceous inversion or salt movements. The North Sea Central Graben, for example, was a north–south-trending trough with a complex morphology formed both by the marginal slopes and by

Figure 7 Cliff section, *ca.* 50 m high, at Port d'Amont, NE of Etretat, France, showing prominent chalk flint cycles. Note slump sheet (right) and coalescing hardgrounds at beach level. Photo: F Surlyk.

intra-basinal ridges and domes along inversion axes and atop salt structures, respectively. Such relief led to sediment instability and instigated sediment slumps and gravity flows, resulting in redeposition of the coccolith ooze in deeper depocentres. The depositional relief may also have inhibited bottom water circulation and promoted the periodic development of anoxia/dysoxia in the deeper parts of the Central Graben.

In marginal settings, over intrabasinal highs and in areas of focussed, amplified bottom currents, the chalk sea floor locally developed marked depositional relief, both in the form of aggradational mounds and ridges, and erosional features. Thus, seismic data from the Danish Basin, the North Sea and onshore UK reveal ridges and valleys with a relief of up to 150 m and width of several kilometres. These features are combined constructional/erosional structures and were probably controlled by long-lived contour current systems. On a smaller scale, well-developed bryozoan-rich mounds in the Maastrichtian–Danian of eastern Denmark show amplitudes of 50–100 m, heights of 5–9 m and flanks dipping up to 20°; they show a marked asymmetry recording lateral (southwards) migration of the mounds (Figure 4). At Etretat, in northern France, Coniacian–Santonian chalks exposed in dramatic cliff sections (Figure 7) display a complex array of erosional and constructional architectures that record enhanced current activity in a tectonically constrained setting close to the margin of the chalk sea.

Cyclic Sedimentation and Orbital Forcing

Chalk successions are often overtly cyclic in nature, the typical decimetre- to metre-scale cyclicity being picked out either lithologically, as in chalk/flint and chalk/marl cycles (Figure 7), or due to changes in the fabric of the chalk, as in laminated/bioturbated cycles and those revealed by variation in the intensity or type of bioturbation. Detailed correlation of such small-scale cycles in the Cenomanian, constrained by biostratigraphy, has demonstrated their lateral persistence across the basin – at certain levels, individual cycles have been correlated from southern England, over northern Germany to southern Crimea, a distance of nearly 4000 km! This small-scale cyclicity records recurrent change in a number of interrelated factors including carbonate productivity, the balance between productivity and siliciclastic input, and bottom-water conditions, factors that are thought to have been ultimately controlled by subtle fluctuations in climate dictated by orbital fluctuations in the Milankovitch frequency band. The precession signal (mode at 21 ka) dominates, at least in the Cenomanian where the most detailed studies of small-scale cyclicity have been undertaken. Sequence-scale sea-level changes were driven by the long eccentricity cycle of 400 ka, allowing sequence stratigraphic correlation from north-west Europe to Kazakhstan and south-east India.

Chalk as a Hydrocarbon Reservoir and Aquifer

The Upper Cretaceous–Danian chalk forms significant reservoirs both for hydrocarbons, as in the North Sea Central Graben, and for groundwater, for example in Denmark, England, France and Belgium. Hydrocarbons are also produced from older, Barremian–Aptian marly chalk facies in the Danish Valdemar Field and from the Upper Cretaceous Austin Chalk in Texas. Indeed, the first hydrocarbon discovery in the North Sea, in 1966, was in chalk – the A-1 well of the Danish Kraka Field. Since that first discovery, the number of chalk fields in the North Sea has increased to nearly 30, containing almost 5 billion barrels of recoverable oil and more than 16 000 billion cubic feet of gas. Production of hydrocarbons from these fields is still a major challenge, since the chalk forms a unique family of very fine-grained reservoir rocks, characterized by high matrix porosity and low permeability, differing from most other carbonate reservoirs. The minute coccolith platelets making up the chalk are typically 0.5–1 μm across, and pores and pore throats are on the order of a micron in size, reducing the matrix permeability to a few millidarcy even at porosities of more than 35%.

The North Sea chalk is composed almost entirely of the stable low magnesium variant of calcite and has not been subjected to freshwater diagenesis.

Diagenetic modifications of the chalk were controlled by early processes at or near the sea floor and by the later burial history. The chalk ooze had an initial porosity of 70–80%, but dewatering due to bioturbation rapidly reduced porosity to about 50%. The porosity declined further to 35–40% at depths of around 1000 m due to compaction. At greater burial depths, the effects of pressure solution became more important and under normal conditions the matrix porosity is around 10% at burial depths of 2000 m. The permeability of the chalk is directly related to the porosity, so reduced porosity also means lowering of permeability and thereby hydrocarbon productivity (Figure 8). The relationship between porosity and permeability is not constant, but varies with the stratigraphic age of the chalk (Figure 8). The best chalk reservoir properties in the North Sea are found in the Maastrichtian Tor Formation where the matrix permeability for a given porosity is almost 10 times that of the Danian Ekofisk Formation. As seen in the figure, Lower Cretaceous chalks form even poorer reservoirs due to their high content of clay. The differences in reservoir properties between the Maastrichtian and Danian chalks are not fully understood, but it has been suggested that a change in the coccosphere flora across the Cretaceous–Palaeogene boundary resulted in changes in the detailed texture of the coccolith-rich sediment thereby affecting the size/geometry of pores and pore throats.

Other factors that are known to influence the quality of the chalk reservoirs are the content of clay and silica, and the mode of deposition. It was long a common belief that reworking of the chalk was the key to preservation of anomalously high porosities, a belief possibly driven by the fact that allochthonous chalks form the main reservoirs in the Norwegian North Sea sector. This view has changed, however, and although resedimentation locally has a positive effect on porosity preservation this is not always the case. On a metre-scale, however, it has been shown that facies have a major control on porosity in cyclically interbedded successions of bioturbated and laminated chalk, the highest porosities being in the laminated units. The development of firmgrounds and hardgrounds is also important since early cementation reduces primary porosity, so these layers form characteristic low-porosity zones in the chalk and may create barriers to fluid flow in the reservoir. On structural highs, several hardgrounds may coalesce, leading to a major negative effect on reservoir quality. This is particularly true for the complex hardground that developed at the Maastrichtian–Danian boundary over most of the North Sea highs. The best reservoir properties are found in the purest chalks, and the Maastrichtian Tor Formation is particularly pure with less than 5%, commonly only 1–3%, non-carbonate fraction. The Danian Ekofisk Formation has a more variable content of clay and silica throughout the North Sea; the lower Danian forms a more clay- and silica-rich (up to 20%), non-reservoir interval known as the 'Danian tight zone'. The reason for the strong negative influence of clay on reservoir quality seems to be that its presence inhibits the growth of early cement between carbonate grains, thereby preventing early lithification. As a consequence, the more weakly lithified clay-rich intervals are more easily compacted during deeper burial.

North Sea chalks are extremely fine-grained and have low permeabilities so that porosities of more than 25% are required to allow commercial

production. Since matrix porosity is reduced to 10% at burial depths of around 2000 m, preservation of such substantial porosity requires unusual conditions, and the North Sea chalk fields are all located in areas with significant overpressure. Another process that may result in the retention of high porosities is early oil migration into the reservoir, since the oil prevents further cementation during burial. The overpressured chalk reservoirs maintain porosities of up to 45–50% and matrix permeabilities in the 3–10 mD range at burial depths of 1700–3300 m. The effective permeability is commonly much higher due to fracturing since many North Sea chalk fields are localized over salt structures.

During the last two decades, the recovery factors in the chalk fields have increased significantly as the result of horizontal drilling, water injection and stimulation of artificial fractures. In the Danish Dan Field, the initial recovery factor of 10% has increased to 35%, and in the Norwegian Ekofisk Field estimates have increased from 18% to 38%.

In north-west Europe, chalks and other Upper Cretaceous–Danian limestones form important aquifers, both where they outcrop at the surface and in areas where they are covered by thin Cenozoic or Quaternary deposits. The chalk is the most important unconfined aquifer in the Paris Basin, both in terms of areal extent and size of resources, and production from the aquifer is *ca.* $10^9\,m^3$ per year. In Denmark, about 35% of the annual water consumption (*ca.* $0.4 \times 10^9\,m^3$) is derived from the chalk, largely in the north and east of the country, whereas south-east England is particularly dependent on chalk aquifers, accounting for 55% of the groundwater utilized in the UK. The uppermost 50–60 m of the saturated chalk forms the principal aquifer since water flow at reasonable rates relies on the presence of open, commonly solution-modified fractures and fissures. The permeability of fissured chalk is 10^{-5}–$10^{-3}\,ms^{-1}$ whereas that of the chalk matrix is in the order of 10^{-9}–$10^{-8}\,ms^{-1}$ and thus has a negligible contribution to the transmissivity of the aquifer. As in hydrocarbon reservoirs, therefore, the matrix porosity provides the volume for storage of groundwater and the fractures provide the distribution system that drains the matrix and allows the water to flow.

Chert

N H Trewin and S R Fayers, University of Aberdeen, Aberdeen, UK

Introduction

The term chert is currently used for any microcrystalline siliceous rock containing only minor impurities. In the early nineteenth century, hornstone and chert were names used for rather non-descript splintery siliceous rocks, but chemically similar material with specific features of colour and texture received a plethora of names, largely based on ornamental value. It is usually the minor impurities that impart colour, such as the red of haematite in jasper, and the green of chrysoprase assigned to nickel. Differing textural features produce the banding seen in agates. Porcellanite is a white variety containing clay inclusions and resembling porcelain, and flint refers to the nodules from the Cretaceous Chalk that produce superb conchoidal fractures, and were certainly one of the earliest geological industrial materials, being used by Palaeolithic man.

Cherts occur in low abundance in a variety of geological settings, and have a variety of origins. In many cases, the chert product is the result of maturation by time and the diagenesis of precursor silica phases. The diagenetic pathway of silica is controlled by phase solubility, a function of crystal structure and size, and usually proceeds from amorphous opal through intermediate stages to quartz by dissolution–reprecipitation reactions. Amorphous silica may have its origin in biogenic skeletal material (radiolaria, diatoms, siliceous sponge spicules), or in volcanic glass, or in sinter deposited from hydrothermal solutions.

Chert Composition

Chert is seldom uniform in texture and, in young material, transitions from opal are frequent. The grain size and texture are related to the origin of the silica and the diagenetic history of the rock.

The Main Constituents of Chert

Microquartz Microquartz is the main constituent of chert. It occurs as equant crystals in a solid mosaic (Figure 1), and often has a porous, spongy texture. Spongy forms are frequently dark in thin section due to included pores. Crystals are generally less than 5–20 μm in diameter. Microcrystalline quartz comprising individual crystals below the resolution of a standard petrographical microscope is termed cryptocrystalline.

Megaquartz Megaquartz occurs as a mosaic quartz fill to cavities and veins in chert, often displaying a drusy fabric (Figure 1A and B). It may also occur as a replacement fabric in carbonate fossils or fossil wood. Crystals are tens to hundreds of micrometres in diameter.

Chalcedony Chalcedony has a fibrous texture, with fibres tens to hundreds of micrometres in length. It occurs in radiating spherulitic textures and has overlays, frequently brown and zoned in thin section. Chalcedonic quartz is length-fast. Quartzine is length-slow. Leutecite is intermediate between chalcedonic quartz and quartzine, with the fibre axis oriented approximately 30° to the crystallographic *c*-axis. Chalcedonic quartz and quartzine both form cement and replacement fabrics (Figure 1C and D), whereas leutecite typically occurs as a replacement fabric in carbonate fossils. Together with quartzine, other fibrous types, namely zebraic chalcedony and microflamboyant quartz, are most common in chert-replaced evaporites.

Opal Opal occurs as amorphous to cryptocrystalline forms. The crystallinity increases from opal-A to opal-CT to opal-C; these phases can be distinguished by X-ray diffraction. Opal-A is amorphous, opal-CT comprises disordered interlayers of cristobalite and tridymite, and opal-C comprises cristobalite.

Silica Solubility and Precipitation

Biogenic opal-A has a solubility of 120–140 ppm in normal marine sediment pore water, cristobalite 25–30 ppm, and quartz 6–10 ppm. The dissolution of opal-A generally results in supersaturation with respect to opal-CT, which is precipitated in preference to quartz. Opal-CT typically consists of small bladed crystals that form spherical lepispheres 5–10 μm in diameter. Quartz precipitation generally takes place from dilute solutions over longer periods of time. The solubility in water of both amorphous silica and quartz increases rapidly above pH 9, and thus a sharp reduction in alkalinity from pH $>$ 9 results in silica precipitation.

The precipitation of silica, particularly around hot springs, occurs due to the evaporation of silica-saturated water. Silica solubility is higher in hot water, and thus cooling results in silica deposition. Boiling is also a trigger for silica precipitation in hydrothermal systems.

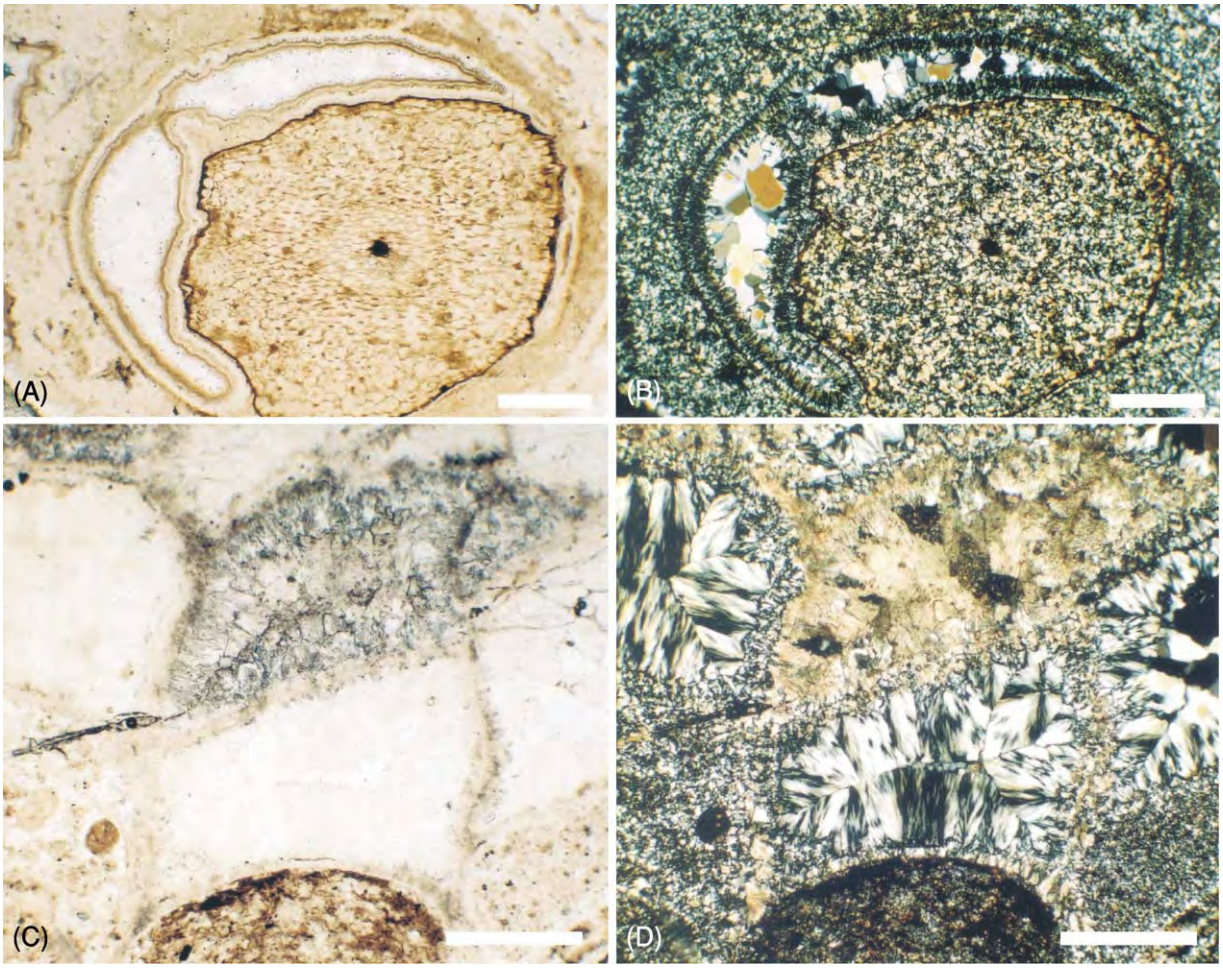

Figure 1 Examples of chert constituents and textures in thin section. (A) Transverse section through a shrunken plant stem (*Rhynia gwynne vaughanii*) in Early Devonian Rhynie Chert (Rhynie, Scotland), observed in PPL (plane polarized light) (plane polarized light). (B) Same view as (A) in XPL (cross polarized light). The plant and surrounding organic rich matrix is preserved in microcrystalline quartz. The void created by the shrunken stem is lined by zoned chalcedonic quartz and occluded by later megaquartz cement. (C) Cross section through dissepiments of the coral *Dibunophyllum* viewed in PPL. Hob's House Coral Bed, Viséan, Carboniferous, Derbyshire, UK. (D) Same view as (C) in XPL. Sediment filled voids are replaced by microcrystalline quartz (below); those above are occluded by chalcedonic quartz cement. One dissepiment is occluded by calcite spar (top, centre). Scale bars 500 μm.

Textures

In many cherts, there is a clear textural sequence in which microquartz, a transformation of original silica gel or opal, is overlain by chalcedonic layers, and the remaining space is filled by megaquartz. The full maturation sequence of opal to quartz is not the only route to chert; amorphous opal can transform directly to quartz and, in diagenetic cherts, microquartz or chalcedony may be the primary crystallization phase.

Sources of Silica

Biogenic

Two groups of common micro-organisms and one group of sponges build skeletons of opal, thus fixing silica from solution. The main groups with their ranges and environments are as follows:

- Radiolaria – Cambrian–Holocene – plankton, marine.
- Diatoms – Jurassic–Holocene – plankton, marine.
- Diatoms – Tertiary–Holocene – planktic–benthic, non-marine.
- Siliceous sponges – Cambrian–Holocene – benthic, dominantly marine.

These organisms can extract silica from water that is undersaturated with respect to silica by one or two orders of magnitude. For example, diatoms have been recorded to reduce the Si content of aquarium water from 0.95 ppm to 0.075 ppm. Thus, these organisms are important in fixing silica in a particulate form that

can be sedimented, and provide a concentration of metastable biogenic opal. This opal can then be converted to chert *in situ* to produce bedded cherts, or be dissolved and transported to a site of diagenetic deposition to produce chert cement and replacement nodules.

Volcanic

There is a strong association between chert and submarine volcanics in the geological record. Thus, it has been postulated that silica is derived from the devitrification of volcanic glass, leading to the production of smectite and silica. However, it is likely that the higher Si contents of water in volcanically active areas result in population explosions ('blooms') of diatoms and radiolaria, and that the silica is fixed by organisms.

Hydrothermal Silica

Hydrothermal systems, developed in the waning phase of volcanicity, produce hot springs and geysers that frequently deposit silica in the form of amorphous siliceous sinter. The silica is dissolved from hot rocks at depth and, as water is circulated through the convecting hydrothermal system, hot silica-saturated water is brought to the surface where silica is deposited due to cooling.

Silica Precipitation in Lakes

The sources of silica resulting in cherts in non-marine lakes are various. In sediment-starved Tertiary to Holocene lakes, diatoms can accumulate to form a siliceous sediment (diatomite) that can be converted to chert through time and diagenesis. Lakes (e.g., Lake Magadi) in volcanically active areas of the African Rift Valley contain sodium carbonate brines with $pH > 10$. Silica is leached from volcanic rocks and Si concentrations can rise to 2500 ppm. Seasonal evaporation and dilution of the brine by river waters causes the deposition of hydrated sodium silicates that are converted to chert during diagenesis. In the Coorong region of South Australia, the pH in some Mg-rich carbonate lakes can rise above pH 10 due to algal photosynthesis. Silica is derived by the corrosion of detrital minerals, resulting in Si supersaturation of the lake waters. Subsequently, the silica is deposited in lake carbonates as a gel, giving the potential for conversion to chert during diagenesis.

Occurrence of Chert

There are a number of modes of occurrence of chert, the most common, and volumetrically the most important, being bedded cherts and nodular cherts in limestone sequences.

- Bedded cherts in ocean basins.
- Nodular cherts in limestone sequences.
- Cherts of hydrothermal origin, both surface and subsurface.
- Cherts in lake basins.
- Silcrete, chert in palaeosols.
- Silicified wood.

Bedded Cherts

Bedded cherts have been formed through the burial and diagenesis of siliceous oozes throughout Phanerozoic time (Figure 2). However, the Palaeozoic is dominated by radiolaria, and diatoms do not make a significant contribution until the Late Mesozoic. There are also extensive bedded cherts in the Precambrian, at a time from which no silica-secreting organisms are known. Thus, it is pertinent to consider the mechanisms and environments of accumulation of siliceous oozes through time.

At the present time, siliceous oozes are accumulating in deep ocean basins, in areas starved of detrital supply. A broad band of siliceous diatom-dominated deposits surrounds Antarctica, and similar deposits are accumulating between North America and Asia in the northern Pacific to the south of the Aleutian Island chain. An equatorial belt of radiolarian-dominated ooze is present in the Pacific and Indian Oceans. Drilling by the Deep Sea Drilling Project has shown that, in some oceanic areas, the siliceous oozes are converted at depth to bedded cherts, the chert generally being of Tertiary age.

The conditions considered to be favourable for the accumulation of siliceous ooze are summarized below (Figure 3).

- High organic productivity in surface waters due to upwelling of nutrient-rich oceanic currents.
- Lack of significant input of land-derived detritus that would dilute the deposit. Such material is carried by the wind from deserts, and by ocean currents from sources of clastic input.
- Limited presence of calcareous plankton. Calcareous oozes are accumulating at present at rates of 10–50 mm Ka^{-1}, compared with <10 mm Ka^{-1} for siliceous oozes. Modern siliceous oozes tend to occur in oceans below the carbonate compensation depth (CCD), the depth at which carbonate dissolution balances the oceanic carbonate rain. The CCD varies in the oceans, but is generally at about 4 km. Siliceous oozes are associated with, and diluted by, red clays derived from aeolian desert dust and volcanic fallout.

Siliceous oozes can also accumulate in shallower oceanic settings if conditions are suitable. Small,

sediment-starved basins and submerged carbonate platforms on passive continental margins are potential sites for deposition when upwelling currents bring nutrients and calcareous plankton is scarce. The Gulf of California (<1.5 km deep) is an area in which siliceous oozes are accumulating in association with distal turbidites and organic-rich shales.

Tertiary bedded chert Tertiary bedded chert derived from diatomaceous ooze occurs in the Miocene–Pliocene of the Pacific margin, and formed in small rifted and back-arc basins where there was strong nutrient supply, high phytoplankton activity, and a lack of detrital sediment input. The Monterey Formation (Miocene, California) contains chert derived from diatomaceous sediments (Figure 2A and B), and is associated with hydrocarbon source rocks. The maturation process from diatomaceous sediment to chert involves porosity loss to the extent that the cherts can form a diagenetic reservoir seal at depth.

In the Mediterranean, cherts occur in the Late Miocene at the time when the area was characterized by small, restricted basins in the build-up to the Messinian salinity crisis at the end of the Miocene. In general, cherts of Tertiary age are widespread in oceanic areas, and occur in a wide variety of settings satisfying the conditions described above.

Mesozoic and Palaeozoic bedded cherts Mesozoic and Palaeozoic bedded cherts can be divided into those that are associated with volcanics, usually of ocean floor origin, and those that have no relationship to volcanicity. Prior to the expansion of planktonic diatoms in the Late Mesozoic, the radiolaria were the main contributors to siliceous ooze. The major calcareous planktonic organisms, coccoliths and planktonic foraminifera, did not appear in abundance until the Late Mesozoic. Thus, it can be postulated that siliceous radiolarian ooze would have been more abundant in the Palaeozoic and Early Mesozoic, and that radiolaria provided the main source for biogenic silica. It is likely that radiolarian ooze accumulated over a greater depth range, extending into shallower water above the current level of the CCD, in the absence of, or at least the reduction of, the diluting effect of calcareous plankton.

Volcanic association There is a common association of bedded cherts with black shales, pillow lavas, and volcaniclastic rocks. In some cases, sheeted dykes and ultramafic rocks are present, and the whole assemblage is typical of the ophiolite suite: a preserved ocean floor succession. The cherts are usually dark in colour, and may contain recognizable ghosts of radiolaria (Figure 4). The presence of radiolaria points to a biogenic origin for the silica, although elevated Si in seawater from the volcanics may have been responsible for the proliferation of radiolaria. Mesozoic examples occur in the Troodos Massif in Cyprus, the Franciscan of California, and the Khabarovsk area of the Russian Far East (Figure 2C). Palaeozoic examples associated with the margin and closure of the Iapetus Ocean occur in the Ordovician of Scotland, from the Girvan–Ballantrae area in the

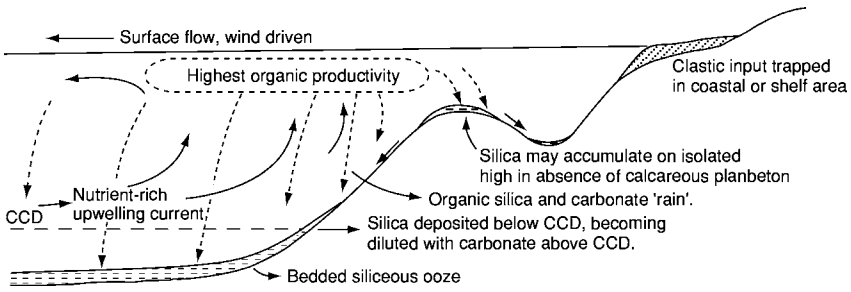

Figure 3 Diagram illustrating the production and deposition of organic silica under the influence of an upwelling nutrient rich current at an ocean margin. CCD, carbonate compensation depth. Not to scale.

west, through to Stonehaven in the east, where the chert is present as jasper. Similar developments occur in Newfoundland (Canada) and Maine (USA). The jasper in these instances lacks recognizable biogenic material and is frequently attributed to the hydrothermal alteration of sediments and hydrothermal vent deposits. It is not always possible to distinguish biogenic and volcanic/hydrothermal origins.

No volcanic association Many Palaeozoic and Mesozoic cherts have no volcanic association, and occur with black shales, pelagic limestones, and turbidites. Passive continental margins with small rifted basins are a common setting. Water depths were typically less than oceanic. Radiolarian cherts in the Lower Carboniferous of south-west England and Germany provide an example. Submarine rises, starved of land-derived detritus, formed a typical location. Resedimentation of siliceous material from shallow-water areas by turbidity currents provided a concentration mechanism in deeper basinal areas. The Caballos Formation of the Marathon Basin, Texas, USA, is a widespread bedded chert (part termed novaculite). It is of Devonian age and marine in origin, containing sponge spicules and radiolaria. The chert is interbedded with shale, and some sandstone beds and chert conglomerates are present. Arguments have been presented for both shallow marine to restricted lagoonal and deep marine environments.

Precambrian cherts Precambrian cherts are abundant, particularly in association with Precambrian 'iron formations'. However, no silica-secreting organisms are known from the Precambrian and it cannot be assumed that Precambrian cherts have a biogenic origin. There is a concentration of these deposits dated at around 2 Ga, and these cherts contain fossils of coccoid and filamentous bacteria. In the absence of silica-fixing organisms, it is likely that Si concentrations in water were high, and Si precipitation may have occurred initially as a gel in the large iron formation basins. It is possible that photosynthetic cyanobacteria played a significant role in silica deposition as in Coorong-type lakes. Texturally, the presence of algal stromatolites, ooids, and intraclasts implies shallow water, and Si replacement of carbonates. Shallow extensive shelves and large lake basins are postulated environments.

Classic examples at around 2 Ga are the Gunflint Chert of Ontario (Canada) (Figure 5), and the Biwabik Chert of South Africa. These deposits may mark the period in the Earth's history when oceans were changed from reducing to oxygenated conditions by the action of photosynthetic bacteria, and consequently vast amounts of iron were deposited that had previously been held in solution in ocean waters. Even older, at about 3.5 Ga, are the cherty rocks of the north pole region in Western Australia containing silicified stromatolites that are possibly the oldest morphological fossils on Earth (there is older geochemical evidence).

Nodular Cherts

Chert is common as a nodular and, occasionally, 'bedded' replacement feature in limestone sequences,

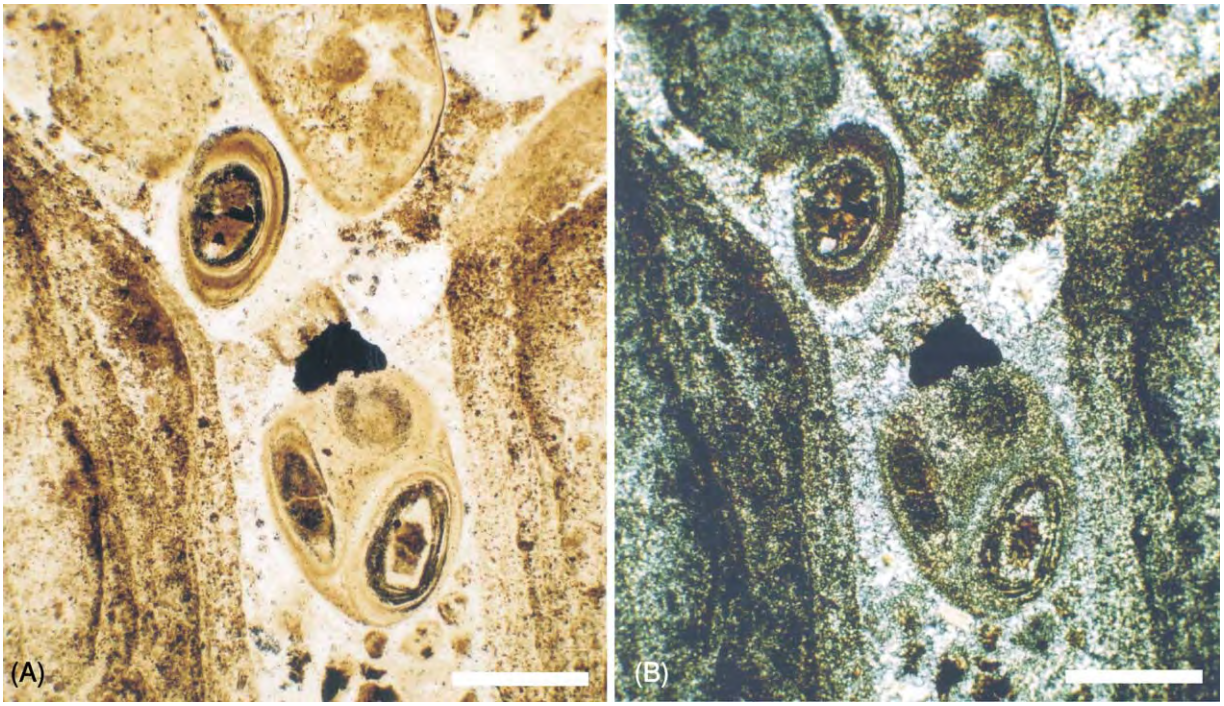

Figure 5 Photomicrographs of Gunflint Chert in thin section showing chert replaced intraclasts and ooliths within a crack between stromatolites. (A) Viewed in PPL (plane polarized light). (B) Viewed in XPL (cross polarized light) showing replacement mainly in the form of microcrystalline quartz. Precambrian, Ontario, Canada. Scale bars 500 μm.

and occurs to a lesser extent in mudstones and evaporites. The apparently bedded cherts in this situation are the result of the replacement of original sedimentary beds by chert (Figure 6). The source of the silica is considered to be biogenic, with the dissolution products of biogenic opal being redistributed in solution and precipitated as cement and replacement during diagenesis. The replacement nodules show a great variety in form, ranging from irregular forms with smooth curved margins (Figure 7), to more tabular and diffuse cherts seen in Carboniferous limestones, and the generally spherical nodules (geodes) representing the replacement of original anhydrite nodules.

Both chalcedony and microquartz are present (Figure 6), and there is frequently evidence for the direct precipitation of quartz in the rock in the form of isolated bipyramidal crystals. The general process of formation of the nodules involves the dissolution of biogenic opal, present in low abundance in the deposited sediment (*ca*. 1%). The mobilized silica is then deposited at suitable nucleation sites, probably as opal-CT. Such sites are controlled by rock texture and biogenic content; hence, silica deposition may favour specific beds. The opal-CT fills the pore space and replaces carbonate, and, with burial, is converted to chert. The silicification appears to be a relatively early diagenetic event, taking place during shallow burial.

In marine phreatic conditions, silica precipitation and replacement of carbonate tend to occur along redox boundaries between aerobic surface sediments and underlying sediments dominated by sulphate-reducing bacteria. The degradation of organic material by sulphate-reducing bacteria releases carboxyl and sulphide ions. Many carbonate sediments contain very little iron; therefore, very little sulphide is precipitated as pyrite. The rest is hydrolysed to hydrogen sulphide which then diffuses to more oxic conditions. Oxidation produces sulphate and hydrogen ions; the former diffuse back into the sulphate reduction zone, whilst the increased acidity causes carbonate dissolution at the redox boundary. The high concentration of carbonate ions, organic matter, and the reduced pH promote silicification.

Early silicification may also take place in emergent areas where marine pore waters in carbonate sediments mix with meteoric pore waters. In these 'mixing zones', the mixing of waters with suitable differences in PCO_2 provides ideal conditions for carbonate dissolution with contemporaneous silica replacement and precipitation.

The concentration of chert replacement nodules at specific horizons, often on a basin-wide scale, can be

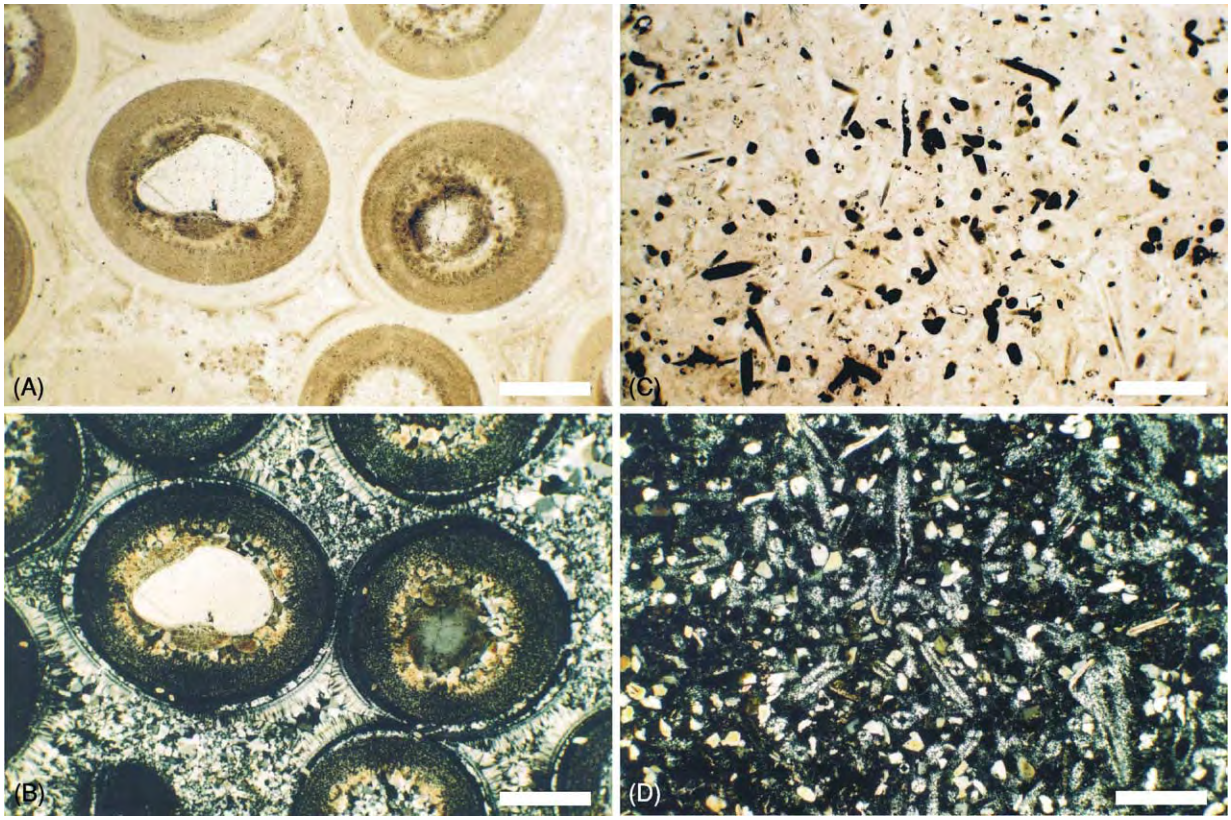

Figure 6 Photomicrographs of chert replaced and cemented sedimentary rocks in thin section. (A) Silicified oolite in PPL (plane polarized light). (B) Same view as (A) in XPL (cross polarized light) showing a variety of silica cement and replacement fabrics after the original carbonate sediment. Trenton Series, Ordovician, Centre County, Pennsylvania, USA. (C) Silicified bioclastic sandstone with abundant sponge spicule tetraxons, viewed in PPL. (D) Same view as (C) in XPL. Both the matrix and sponge spicules are replaced primarily by microcrystalline quartz. Upper Greensand, Cretaceous, Ventnor, Isle of Wight, UK. Scale bars 500 μm.

related to redox boundaries in the original sediment (Figure 8). The spacing of chert bands reflects abrupt, stepwise rises of the redox boundary related to pulses in sedimentation and hiatuses. The geometry of the redox boundary (governed by permeability and porosity contrasts in the sediment) generally determines the chert morphology, accounting for the spectrum of burrow-form and tabular cherts commonly observed in the field.

The replacement by chert can be remarkably selective, with preferential replacement of limestone matrix, or of biogenic debris of a particular original composition, such as high-Mg calcite. Very often the earliest stages of silicification in carbonate sequences occur in shell material in which localized silica precipitation/carbonate dissolution is promoted by the bacterial breakdown of organic matter, particularly conchiolin within the shell matrix. Thus, as well as the nodular form of chert, selective silicification may result in scattered silicified fossils within limestone.

In the Cretaceous Chalk of Europe and the USA, flint nodules of irregular form occur at specific widespread stratigraphical horizons, but also in sheets and pipes that cross-cut bedding. Flint is generally dark grey, and contains carbonate inclusions, particularly of bivalves and echinoderms. Flint nodules have a thin white crust, or patina. Many echinoids from the Upper Chalk are filled with flint, the silica having nucleated within the urchin, but without replacing the shell. Sponges and burrows are also selectively silicified, with the shape of many flints in the chalk reflecting the morphology of *Thalassinoides* burrows in which they nucleated (Figure 9). Siliceous sponge spicules probably provided much of the biogenic silica for the formation of flint.

There are also nodular chert-bearing beds within the Portlandian (Late Jurassic) limestones of southern England (Figures 7 and 8), where bioturbation textures and diagenetic redox boundaries controlled silica precipitation and replacement. Siliceous sponges were the main biogenic silica source.

Figure 7 Nodular cherts replacing bioclastic and spicule wack estones. Cherty Beds, Portland Stone Formation, Upper Jurassic, Isle of Portland, Dorset, UK.

Figure 8 Laterally persistent beds of nodular and tabular chert (dark bands) concentrated within the Cherty Beds (Ch) of the Upper Jurassic Portland Stone Formation. Isle of Portland, Dorset, UK.

The Carboniferous limestones of Europe and the USA contain abundant chert as nodules and as silicified fossils (Figures 1C,D, and 10). The chert is generally black and has a splintery fracture, rather than the conchoidal fracture of flint. Silicification can affect specific beds, such that chert nodules may link up to form a diagenetically bedded chert.

Chert in Lakes

Modern examples of lacustrine chert deposition comprise the Lake Magadi type, where the lake is Na-rich and alkaline and has pH > 9 in the dry season, leading to silica dissolution, and a pH that fluctuates below

pH 9 in the wetter months, resulting in silica precipitation. Silica is initially deposited as magadiite (hydrated sodium silicate), which is subsequently replaced by silica. Thus, the controlling factors are evaporation and freshwater input to the lake.

In the Coorong type from South Australia, Mg-rich carbonate lakes acquire a high pH due to the seasonal activity of photosynthetic algae, resulting in the dissolution of silicates; with a seasonal reduction in pH, direct precipitation of mixed opal and cristobalite takes place.

The Cretaceous Uhangri Formation of southwest Korea was deposited in an alkaline lake surrounded by alkaline volcanics. The sequence includes couplets of sandstone overlain by chert, and of laminated chert with black shale. The sandstone/chert couplets were deposited following episodic influxes of fresh, less alkaline water. The influxes carrying sand produced density-current underflows in the stratified lake, depositing sand followed by opaline silica, caused by the fall in pH due to the influx of freshwater. The laminated cherts are interpreted to be the result of interflows causing silica precipitation. The chert beds show soft-sediment deformation and injection features, indicating a gelatinous consistency for the deposited silica. Thus, with regard to the feature of direct silica deposition, this example has similarities with the Coorong type.

Ancient deposits interpreted as belonging to the Magadi type are more common, and range in age from the Precambrian Reitgat Formation, Hartbeesfontain, South Africa, to the present day. In typical examples, there is an association with contemporaneous volcanics, and evidence for evaporite minerals.

Chert of Hydrothermal Origin

Silica-rich fluid expulsion from basins Basin marginal faults are commonly the site of chert deposition as veins and porosity-filling cement. Chert is deposited as a result of the cooling of silica-rich water expelled from the basin and rapidly rising up marginal fault zones. Silica is more soluble at high temperatures, and hence cooling results in silica precipitation. Chert may seal a fault, and subsequent fault movement may result in new fractures, which themselves become sealed; the result is a chert-cemented and veined fault zone.

Cherts resulting from hydrothermal systems Hydrothermal systems associated with volcanic activity are seen today at Geysir in Iceland, Yellowstone National Park in the USA, and North Island, New Zealand. At these, and many other localities, hot springs and geysers deposit large quantities of silica both in the subsurface and at the point of eruption, which may be on land or under water. Silica is deposited from cooling waters that have dissolved silica from hot rocks at depth (**Figure 11**).

In the subsurface, the result is the silicification of country rocks, particularly along fluid pathways such as faults. Cherty rock may develop on a large scale in the subsurface above a hydrothermal system, resulting in chert cement and cherty veins. The silica is initially deposited as amorphous silica, and this matures to chert with time, heat, and burial.

Hot springs and geysers bring hot water to the surface that cools rapidly on eruption, resulting in the instant deposition of amorphous silica in the form of sinter. Sinter may form mounds around geyser vents, or the outflow from a hot spring may result in sinter terraces or a low-angle sinter outwash apron (**Figure 12**). Under water, sinter chimneys may form above vents as occurs in Lake Yellowstone. The silica is deposited as highly porous amorphous opal-A, which is transformed to opal-CT, and later to chert, with a loss of porosity.

In New Zealand, the stages of mineral transformation are well documented. The Umikiri sinter is up to 15 m thick, can be dated to between 27 000 and 200 000 years BP, and shows a preserved silica maturation stratigraphy of opal-CT to opal-C to quartz with depth, all original opal-A having already been converted to opal-CT. Thus, the textural features associated with phase changes and solution–precipitation phenomena occur in a geologically short period of time in near-surface environments.

Probably the best-known fossil hot spring deposit is the Early Devonian Rhynie Chert of north-east Scotland (**Figures 1A,B, and 13**). The chert beds were deposited as sinters on a low-angle run-off apron from hot springs fed along a marginal fault to the Rhynie Basin of Old Red Sandstone. The beds are up to 0.5 m thick, laterally non-persistent, and with interbedded shale and sandstone of an alluvial plain environment. The chert is generally bluish to brown in colour, and is remarkable for the early terrestrial and freshwater biota it contains. The plants in some beds are preserved in three dimensions, with perfect cellular preservation, with plant axes still in the position of growth (**Figure 13**) to a height of 15 cm. This chert has yielded the most diverse terrestrial and freshwater arthropod fauna of any locality of similar age in the world. The detail of preservation is remarkable, including germinating plant spores and even sperm in the process of release from the male fertile organ of a gametophyte plant. Such features require virtually instant preservation, and point to a silica gel as the primary silica deposit. The presence of framboidal pyrite and the preservation of organic matter suggest reducing conditions during silicification. The textures within the Rhynie Chert are closely comparable with

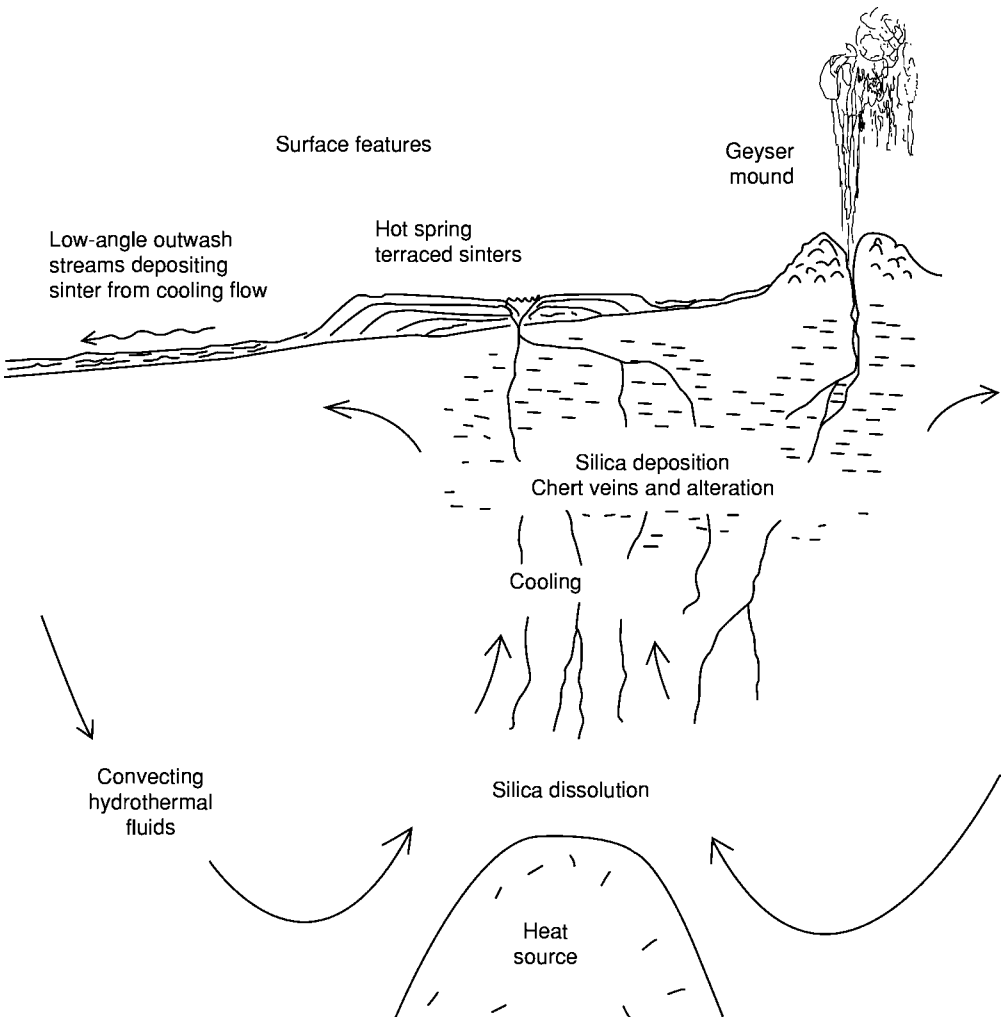

Figure 11 Diagram of a convecting hydrothermal system above an igneous heat source to illustrate surface and subsurface deposition of silica. Not to scale.

those of modern siliceous sinters, but the maturation process to quartz is complete, and the chert comprises microcrystalline quartz, chalcedony, and macroquartz (Figure 1A and B).

Also found in the same area is a remnant of a geyser vent, with the typical geyserite texture preserved in chert. The country rocks in the area of this ancient hot spring system are also silicified, and a cherty breccia occupies the hot spring feeder zone along the marginal fault. More uncommon are silica deposits resulting from submarine exhalations; examples are the Cretaceous ochres of Cyprus, and the cherty ironstones of Tynagh, Ireland.

Agates with concentric and layered textures of microcrystalline quartz, chalcedony, and megaquartz

are mainly found in gas cavities (amygdales) in lavas. The silica is sourced from the volcanic rock, and deposited from hydrothermal and later diagenetic solutions migrating through the rock.

Chert in Soil Profiles – Silcrete

Silica is precipitated in soil profiles forming a hard chert-cemented rock known as silcrete. Most silcretes form in arid to semiarid climatic regions in which silica-saturated, alkaline groundwater with $pH \geq 9$ is evaporated from the surface, or mixes with surface water of lower pH. The presence of iron, aluminium, and magnesium oxides, and also NaCl, appears to encourage silica precipitation. The microquartz occurs as a mosaic cementing any detrital material present. Some replacement by chert is usual, particularly affecting carbonate and micaceous minerals. Silcretes are present in parts of Australia and in both northern and southern Africa. Silica is present in the form of microcrystalline quartz, chalcedony, and, to a lesser extent, opal. Silcrete horizons up to 10 m thick occur; the degree of silicification decreases with depth, with isolated silcrete nodules in the lower part of the profile, and massive silcrete at the top.

The 'Hertfordshire Puddingstone' of southern England is a Tertiary silcrete containing rounded pebbles of flint derived from the chalk, and cemented with chert. It closely resembles examples from the Lake Eyre region of Australia. Silcrete has also been described from the Proterozoic of north-west Canada, where it formed from the weathering of acid volcanics.

Silicified Wood

At many localities throughout the world, fossil wood is preserved in microcrystalline quartz with excellent preservation of the cellular structure of plant tissue. Woody material is a favoured site for silica deposition; in some cases, organic cell walls are preserved; in others, all organic material is lost. The Eocene fossil forests of Yellowstone National Park comprise a succession of 27 forests that were buried by volcanic ash, and occur in a 400 m thick sequence. The silicified trees are preserved as upright stumps several metres high. The silica source was the volcanic ash. In contrast, the Petrified Forest in the Painted Desert region of Arizona represents logs transported to the depositional site, where they occur in alluvial mudstones of Late Triassic age. Silica was probably derived from migrating groundwater, and nucleated in the acidic environment of the decaying wood structure.

Clays and Their Diagenesis

J M Huggett, Petroclays, Ashtead, UK and The Natural History Museum, London, UK

Introduction

Clay diagenesis is the process of clay transformation (layer by layer replacement) and authigenesis (or neoformation) in buried sediments. Diagenesis commences with the onset of burial and ends with the onset of metamorphism. These boundaries are defined in a variety of ways, including clay mineral crystallinity. Although, in the nineteenth century, microscopists were able to observe euhedral stacks of kaolinite platelets in sandstones, it was not until the early 1970s that it became apparent just how widespread and significant are clays that form after burial. Until this time, geologists had argued over 'the greywacke problem', i.e., how was it possible that clay, and sometimes quite high proportions of clay, could be present in sandstones deposited in high-energy environments? The realization that many sandstones contain authigenic clays came about largely as a result of the arrival of the scanning electron microscope in geological research. This allowed the examination of rocks in three dimensions at magnifications (typically $<1000\times$) ideal for imaging clay particles. Clay diagenesis is not restricted to sandstones; similar processes occur in mudrocks, although transformation reactions and reaction pathways may differ. At around the same time, X-ray diffraction (XRD) was being used to measure changes with depth in clay and non-clay mineralogy with depth in mudrocks, and it was through the pioneering work of John Hower that this was shown to be due to diagenesis (Figure 1). This difference in approach resulted in some rather different perceptions regarding the nature of diagenesis in sandstones and mudrocks.

Factors controlling clay diagenesis include the detrital sediment composition, environment of deposition, temperature, permeability, and burial history (rate of burial, overpressuring, faulting, uplift). Diagenesis typically involves a simplification of the mineralogical suite of a sedimentary rock unit. As the temperature and pressure increase, so too does the tendency towards an equilibrium assemblage, provided that the pore fluid remains aqueous. Most diagenesis occurs at less than 160°C (although the cut-off is not determined by temperature; it is more likely to be determined by the exhaustion of reactive minerals, loss of permeability, or the cessation of movement of aqueous fluids for other reasons).

The movement of ions in solution from argillaceous sediment to coarser sediment has been widely invoked to account for the lack of an obvious internal source for the authigenic minerals present. This has partly come about through a lack of petrographical studies of mudrocks. However, it is now apparent that interbedded mudrock/sandstone can contain the same authigenic minerals, but in very different proportions. This is because, although the same or similar detrital minerals are present in both lithologies, their proportions can be quite different. In argillaceous rocks, there may be more organic matter diagenesis driving particular reactions, and the higher proportions of clay will result in much lower fluid flow rates and water/rock ratios than exist in sandstones. In Tertiary sediments from the North Sea, qualitative mass balance calculations have demonstrated that cross-lithology (sandstone/mudrock) flow can be insignificant for either clay or quartz diagenesis. Backscattered scanning electron microscopy (SEM) provides unequivocal evidence for coarsely crystalline authigenic clays in mudrocks, as well as in sandstones, and with the high resolution and magnifications possible by field emission SEM, it is possible to image overgrowths on clays and small packets of authigenic clay enclosed in detrital clay.

Clay Diagenesis in Mudrocks

Detailed investigations of diagenesis in argillaceous sediments in a wide variety of sedimentary basins have shown some consistent patterns of clay diagenesis. Variations in diagenetic clay assemblages result from differences in detrital assemblages and burial history. The bulk composition of most mudrock results in illite as the predominant end product of diagenesis. For

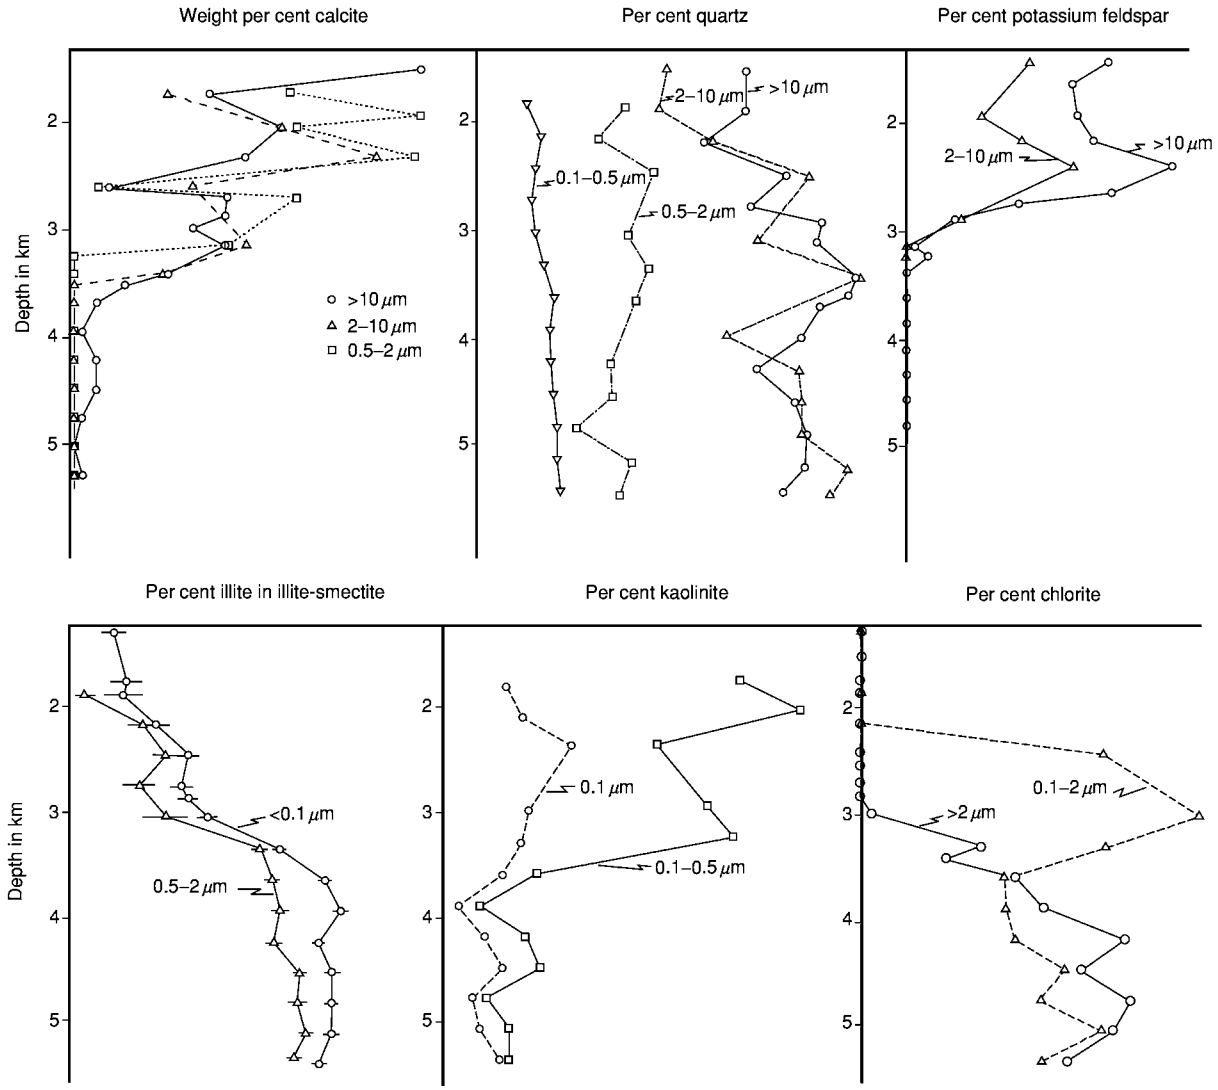

Figure 1 Change in percentage of calcite, quartz, K feldspar, illite, kaolinite, and chlorite with depth. Adapted from Hower J, Eslinger EV, Hower ME, and Perry EA (1976) Mechanism of burial metamorphism of argillaceous sediments: 1: Mineralogical and chemical evidence. *Geological Society of America Bulletin* 87: 725 737.

kaolinite or chlorite to be the predominant clay, special conditions are required, whilst the preservation of smectite at depth requires the inhibition of diagenesis, usually through overpressuring.

Illitization of Smectite

The most studied and first recognized aspect of clay diagenesis is the illitization of smectite with increasing depth. This has been most intensively studied in the Gulf Coast region of the USA, where Tertiary smectite-rich argillaceous sediments have undergone progressive burial. With increasing depth (i.e., increasing temperature), K feldspar, kaolinite, and smectite decrease, whilst illite and chlorite increase. In its simplest form, this reaction can be written as the dissolution of K feldspar to yield Al^{3+} and K^+, which react with smectite to form illite–smectite and ultimately illite:

$$\text{smectite} + Al^{3+} + K^+ \rightarrow \text{illite} + Si^{4+} + Fe^{2+} + Na^+ + Mg^{2+}$$

or

$$\text{smectite} + K^+ \rightarrow \text{illite} + Si^{4+} + Fe^{2+} + Na^+ + Mg^{2+}$$

The second reaction conserves aluminium and requires the dissolution of some smectite. The rock evidence suggests that both reactions are possible. K feldspar may also react with kaolinite to form illite. It is widely claimed that the K^+ for these reactions is a

result of acid dissolution, especially by organic acids. However, feldspar dissolution can occur at low, neutral, or high pH. Indeed, the rate of feldspar dissolution is kinetically controlled. Hence feldspar (and mica) dissolution increases with increasing temperature, and therefore depth. Moreover, organic acids have low buffering capacities and therefore do not influence pH greatly. It should be noted that the reaction results in the release of silica and, through smectite dehydration, the release of water. The source of aluminium is probably mostly feldspar, but the means of transporting sufficient dissolved aluminium to the reaction site has not been entirely resolved, as the aluminium solubility varies enormously with pH, but in most geological situations is rather low. Carboxylic acids are claimed to have the capacity to complex with aluminium, thereby increasing the amount that can be held in solution. However, such acids are unlikely to have much effect on aluminium solubility in complex (i.e., natural) systems. It should also be noted that the reaction yields a potential source of quartz cement. It is largely agreed that the reaction is kinetically controlled, although, if the proposed kinetic equations are applied to the older sedimentary basins, the amount of illitization is vastly overestimated; this may be because the total heating to which they have been exposed has been overestimated. How close K feldspar needs to be to the site of illitization probably depends on the fluid flow, the degree of sandstone/mudrock interbedding, and the overpressure. In the Mahakam Delta Basin in Indonesia, it has been shown that the K feldspar alteration in both sandstone and mudrock is restricted to the upper 2 km of sediment, whereas illitization occurs at greater depths, thus necessitating an open system for K^+ transfer at depth. In contrast, in the Gulf Coast and the Tertiary mudrock/sandstones of the North Sea, diagenesis may be a nearly closed system.

The illitization of smectite commences at approximately 70°C, and peaks at approximately 120–130°C. However, in sedimentary basins with high geothermal gradients, this will occur at shallower depths than in those with lower geothermal gradients. Time, overpressure, pore fluid composition, and hydrothermal activity are also important factors in clay burial diagenesis. In general, there is sufficient K feldspar and mica for this not to be an inhibiting factor; clay diagenesis in clay-rich basins is most likely to be inhibited by overpressure which restricts fluid movement. If a source of K^+ is lacking, illite will not be formed, except where intense organic diagenesis releases NH_4, which is able to form ammonium illite. The illitization of smectite in mudrocks proceeds via random, mixed-layer, smectite-rich, illite–smectite to ordered, illite-rich, illite–smectite. Ordering commences at about 35% expandable layers. The maximum illite content is typically 80%. This sequence has been recognized in a wide variety of settings. The analysis of the expandability and thermal histories of basins ranging in age from Precambrian to Quaternary has indicated that the composition of illite–smectite in mudrocks is primarily controlled by the maximum palaeotemperature. Hence, illite–smectite may be used as a geothermometer for mudrocks, although, as pore fluid overpressure and a lack of K^+ may occasionally be more than minor controls on the illitization process, this should always be performed with caution. The interpretation of mixed-layer illite–smectite in terms of fundamental particles and interparticle diffraction, in the early 1980s, triggered much research into the true nature of illite–smectite. The concept of interparticle diffraction implied that, during illitization, mixed-layer crystals were not two chemically distinct clay minerals, but single illite layers 10 Å thick (Figure 2). When these fundamental particles were analysed by XRD, diffraction between particles created the illusion of smectite interlayers. With increasing diagenetic maturity, these particles grow in three dimensions and the apparent smectite layers decrease. This interpretation is not intended to imply that smectite does not exist! The mechanism implies the dissolution of smectite and the precipitation of illite, which initially exists as fundamental particles. However, it is still argued from transmission electron microscopy (TEM) data that layer-by-layer replacement of smectite by illite occurs. High-resolution investigations of the illitization of smectite have shown coherently scattering domains of interstratified illite-expandable layers (Figure 3), expandable layers within coherently scattering domains of illite, and domains of illite within

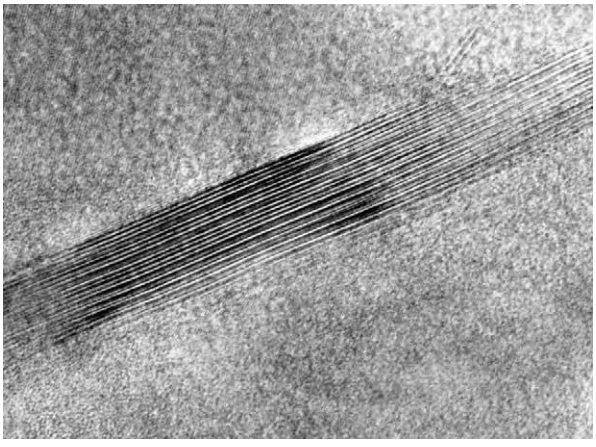

Figure 2 Lattice fringe transmission electron microscopy (TEM) image of interstratified illite expandable clay (the expandable layers have been fixed to prevent collapse in the electron beam).

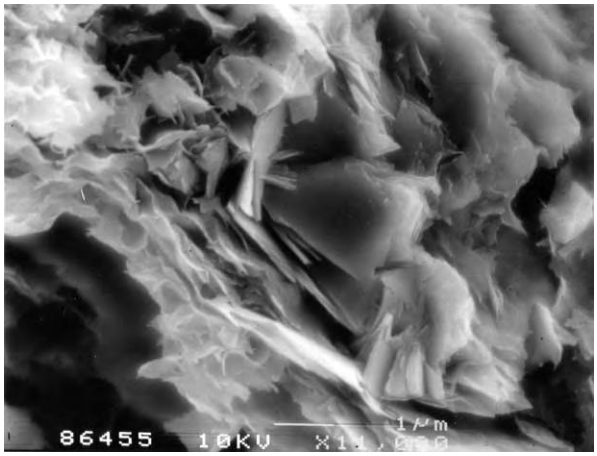

Figure 3 Field emission scanning electron microscopy (SEM) image of authigenic chlorite enclosed by detrital clay in mudrock.

smectite. It is also probable that both dissolution/precipitation and layer transformation occur in different settings. In both bentonites and mudrocks, most smectite is dioctahedral, which appears to be more prone than trioctahedral smectite to illitization. The latter is more likely to react to form chlorite via interstratified chlorite/smectite minerals.

Illitization in Bentonites

Bentonites are ash falls that have undergone extensive devitrification to dioctahedral smectite (usually montmorillonite). Because they have a very simple mineralogical assemblage (most mudrocks contain not only more than one clay type, but a mixture of smectites and illite–smectites), and are often almost monomineralic, ancient bentonites have been extensively used to study the process of illitization of smectite. Comparison of different bentonites, or single bentonites which have undergone variable heating during burial, shows that Si^{4+}, Ca^{2+}, and Na^{+} are lost from the bed and K^{+} is gained as the smectite is illitized. It should be noted that the supply of K^{+} is the rate-limiting step in the illitization of most bentonites because they are K^{+} deficient. Thus, the most potassic (illitized) portions of many bentonite beds are frequently the margins. Where the enclosing sediment is limestone, illitization will be restricted to any K^{+} present within the bentonite bed.

Illite Crystallinity and Illite Sharpness Ratio

With increasing temperature, illite in mudrocks undergoes an increase in crystallinity, as measured by the 001 reflection sharpness on XRD traces. This is due to the loss of smectite layers, increased particle size, and a reduction in abundance of crystal lattice defects. This property has been widely used as an indicator of diagenetic grade, and the results may be correlated with vitrinite reflectance. The Kubler crystallinity index is a measure of the width at half height of the glycol-solvated illite 001 reflection. The Weaver sharpness ratio is the ratio of the illite 001 (10 Å) reflection to the height of the low-angle side of the reflection at 10.5 Å, also on the glycol-solvated trace. The validity of using illite crystallinity or the sharpness ratio has been much debated, but the recent finding that the thickness of fundamental illite particles follows a unique evolution has permitted the refinement of illite crystallinity into a precise measurement of mean crystal thickness. It should be noted that the inclusion of detrital metamorphic mica in the analysis will result in an overestimation of crystallinity.

Chlorite

Si^{4+}, Al^{3+}, Fe^{2+}, and Mg^{2+}, released from the dissolution of smectite and kaolinite, may react to form chlorite. This is usually detected as a down-hole increase in chlorite, although it can be argued that mineralogical changes may also result from a shift in provenance or climate. To obtain unequivocal evidence of authigenesis, it is usually necessary to use an imaging technique, such as SEM or TEM analysis, to demonstrate the face-to-edge arrangement of euhedral platelets. The chlorite shown in Figure 4 was investigated because XRD patterns for a Tertiary mudrock sequence showed unusually high chlorite concentrations at around 2.6 km burial depth. A sample from the same depth, analysed by TEM, confirmed the presence of 14 Å and 7 Å lattice fringes, and X-ray analyses confirmed that it was an iron-rich chlorite. Authigenic chlorite in mudrocks can also form by the replacement of biotite; commonly, replacement is partial, resulting in chlorite–biotite 'stacks'.

Kaolinite

Authigenic kaolinite in mudrocks is much more abundant than was previously thought before backscattered electron imaging made mudrock petrography a real possibility. Previously, a high kaolinite content in an argillaceous rock was assumed to indicate that the clay was formed through tropical weathering, and that it was consequently a climatic indicator. Kaolinite in mudrocks typically replaces muscovite and phengite mica, and cements microfossil cavities. Replacement of detrital mica by kaolinite is a hydrolysis reaction that releases K^{+}. It characteristically occurs during early diagenesis, whilst the

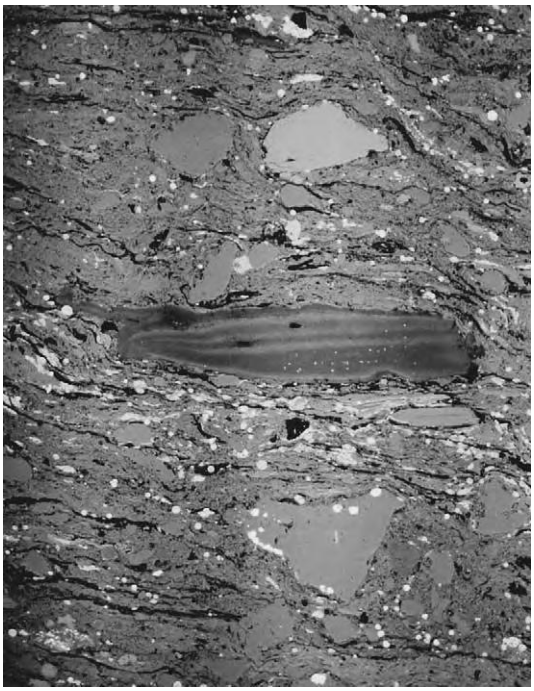

Figure 4 Backscattered scanning electron microscopy (SEM) image of kaolinite pseudomorph after mica in the London Clay Formation (Eocene).

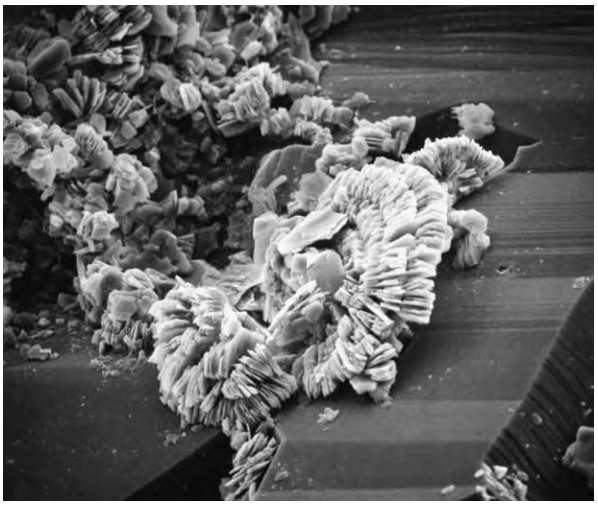

Figure 5 Fracture surface scanning electron microscopy (SEM) image of pore filling kaolinite.

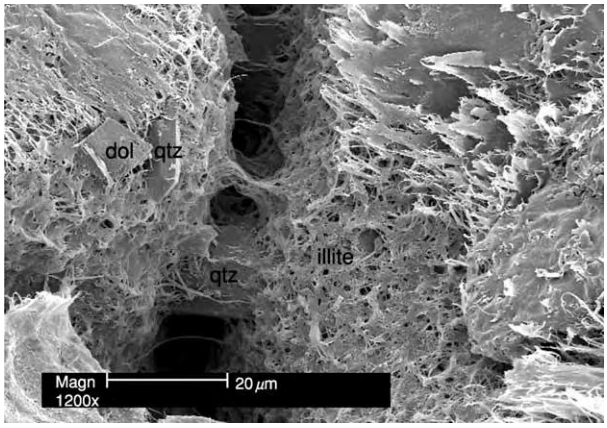

Figure 6 Fracture surface scanning electron microscopy (SEM) image of wispy illite in Rotliegendes Sandstone (Permian). The clay has constricted the pore throat.

fluid/rock ratio is still high, and the K^+ can be removed from the site of dissolution, allowing the reaction to continue. A tentative reaction is deduced from the common association of kaolinite pseudomorphs after mica with mica/quartz pressure solution contacts:

$$\text{muscovite} + H_4SiO_4 + K^+ + H^+ \rightarrow \text{kaolinite} + \text{K feldspar} + Na^+ + Mg^{2+} + Fe^{2+} + H_2O$$

However, in the Eocene of the London Basin, where burial has never been greater than 1 km, probably much less, kaolinite pseudomorphs after mica are widespread (Figure 5), and evidence for pressure solution is minimal. This particular reaction mechanism may be more applicable to sandstones than mudrocks. The fate of the K^+ that is released at shallow depths is not clear; certainly, it is not normally needed for the illitization of smectite at such low temperatures.

Clay Diagenesis in Sandstones

Kaolin Clays

Authigenic kaolinite in sandstones forms stacks of euhedral pseudohexagonal platelets, with the *c* axis parallel to the stacking direction (Figure 6). Very long stacks are called vermicules (Figure 6).Typically, this clay has a pore-filling habit. Kaolinite also forms pseudomorphs after detrital mica, usually muscovite and chlorite. It should be noted that this kaolinite forms particles far larger than the 2 μm maximum defined for clay particles. Pore-filling authigenic kaolinite is often linked to the dissolution of feldspar at temperatures of less than 100°C. Although it is commonly assumed that a high aH^+ is necessary for significant feldspar and mica leaching, the stability field of kaolinite extends to the greatest range of $[K^+]/[H^+]$ values at a pH close to neutral. It should be noted that, for significant kaolinite to precipitate, K^+ and Na^+ from feldspar and mica need to be removed, or illite rather than kaolinite will become the stable clay mineral. The implication is that kaolinite will form at higher fluid flow rates (or a higher water/rock ratio) than illite, i.e., in the most porous parts

of a sandstone, in the most coarse-grained beds, and at a time when a sandstone is less cemented. This is likely to be an important reason why kaolinite almost invariably precipitates before illite in a paragenetic sequence, and why it is often interpreted as a product of meteoric flushing. Meteoric flushing can be an effective mechanism for the replacement of feldspar by kaolinite if the water is sufficiently acidic, which effectively restricts the mechanism to the tropics. Early authigenic kaolinite in sandstones is most abundant in nearshore sediments, because these are most prone to meteoric flushing. Late (or relatively late) authigenic kaolinite is often associated with unconformities, and uplifted fault blocks. A meteoric origin for authigenic kaolinite can be demonstrated through $\delta^{18}O$ stable isotope measurements.

Dickite in sandstones typically forms larger crystals than kaolinite, which are thicker in the direction of the *c* axis. Dickite has been observed to replace kaolinite in reservoir sandstones at approximately 120°C (typically at 2500–4000 m burial depth), most notably where a high water/rock ratio has been preserved. The scarcity of dickite relative to kaolinite is probably due to the rarity of a high water/rock ratio in deeply buried sediment.

Smectite

Authigenic smectite in sandstones is fairly uncommon. Most smectite forms in surface sediments or through the alteration of ash layers. Where it does occur, it characteristically forms early diagenetic rims of crenulate, 'honeycomb', interlocking crystallites. The fusing of adjacent crystallites and the undulose morphology serve to distinguish smectite rims from chlorite rims in SEM images. It should be noted that SEM qualitative X-ray analyses are not always sufficiently accurate to distinguish between smectite and Mg chlorite. Smectite formation is associated with the dissolution of acid volcanic rock fragments and biogenic silica, because smectite formation is favoured by a high Si^{4+} activity. During burial, dissolved Si^{4+} is removed by quartz precipitation (greater than approximately 65°C), making smectite unstable.

Illite

Illite in sandstones has a range of morphologies, from undulose platelets ('cornflake' texture) at one end of the spectrum to laths, fibres, wisps, or ribbons ('hairy' illite) at the other. In fact, the elongate form is not fibrous, but sometimes the particles are so long that they appear so. Wispy illite particles are typically only a few 100 Å thick and 0.1–0.4 μm wide. Their length varies enormously, but can be tens of micrometres. There is no general agreement on any relationship between authigenic illite morphology, the timing of precipitation, chemistry, or structure (although this does not preclude the existence of such relationships). Certainly, with increasing burial depth, the morphology becomes increasingly that of rigid laths, i.e., the width and thickness increase (reflected in an increase in illite crystallinity). Wispy illite is bad news for hydrocarbon reservoir quality. Its high surface area and pore-throat constricting habit (Figure 7) can

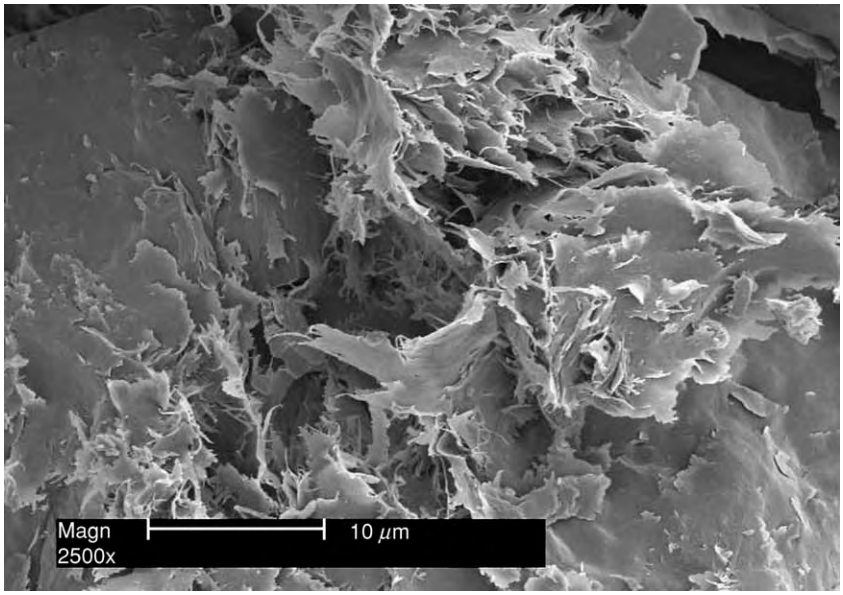

Figure 7 Fracture surface scanning electron microscopy (SEM) image of illite lath overgrowths on infiltrated illitic clay in Rotliegendes Sandstone (Permian).

drastically reduce the permeability (without causing much porosity reduction, because the actual volume of illite is small in proportion to the pore volume). Furthermore, injection wells may suffer a loss of permeability if the injected water breaks up the illite, which then migrates to pore-throats. Not uncommonly, authigenic illite forms short wispy overgrowths on platey detrital illite or illite–smectite, whilst, in some non-marine settings, authigenic illite preferentially nucleates on infiltrated illitic clay (Figure 8). With increasing temperature, pH, and $[K^+]/[H^+]$, kaolin and smectite minerals become unstable and are replaced by illite (Figure 9). In simple terms, the reactions may be shown as:

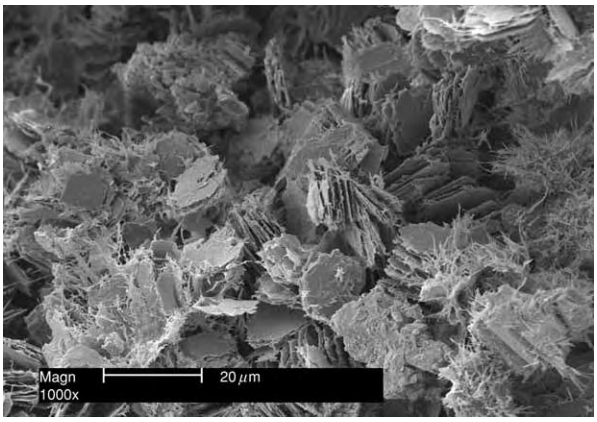

Figure 8 Fracture surface scanning electron microscopy (SEM) image of illite pseudomorph of kaolinite.

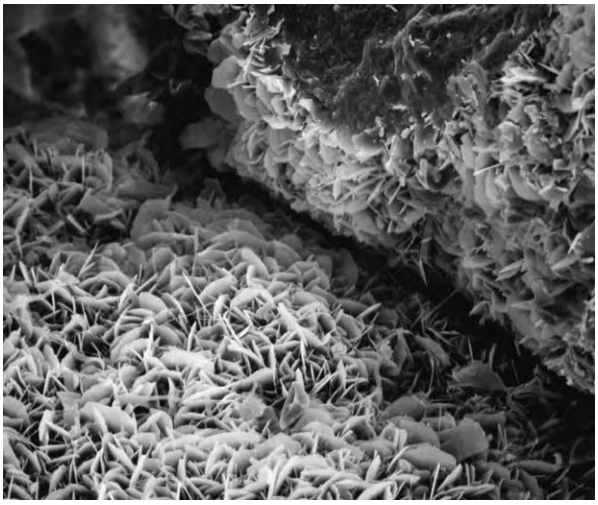

Figure 9 Fracture surface scanning electron microscopy (SEM) image of grain rimming Fe chlorite.

$$\text{smectite} + K^+ \rightarrow \text{illite} + \text{silica (approximately } 80 - 100^\circ\text{C)}$$

$$\text{kaolinite} + \text{K feldspar} \rightarrow \text{illite} + \text{quartz (greater than } 120^\circ\text{C)}$$

This reaction involves an increase in layer charge to accommodate the K^+ in place of the more weakly bonded exchangeable cations in the smectite. This is achieved through substitution of Al^{3+} for Si^{4+} in tetrahedral sites and a reduction in octahedral iron. In fact, many sandstones have pore fluid in thermodynamic equilibrium with illite, but little precipitation occurs due to an extremely low kinetic precipitation rate at temperatures of less than 120°C. Kaolinite is illitized at burial depths in the region of 3–3.5 km, whilst, at greater depths, the thermodynamically more stable dickite is also replaced by illite. Sometimes the mass balance (based on petrographical data) shows that sufficient K^+ can be obtained from locally dissolved K feldspar; in other instances, insufficient K feldspar dissolution has occurred (K feldspar may even be absent) to account for all the illite present, and external sources need to be invoked. It should be noted that the illitization of kaolin minerals is not inevitable above 120°C; there are many instances in which kaolinite coexists with authigenic illite and unleached K feldspar at burial depths ranging from 3 to 4 km. This is because significant illite precipitation requires a higher $[K^+]/[H^+]$ value than that which can occur in a closed system, in which $[K^+]/[H^+]$ is controlled by K feldspar solubility. Hence, the fact that sufficient K^+ can be locally derived does not mean that it is. In the North Sea, authigenic illite abundance is often highest close to major faults, suggesting that the K^+ is derived from the dissolution of K feldspar in deeper parts of the basin. In parts of the North Sea Basin, extensive illite cementation of the Rotliegend Sandstone has been linked to the dissolution of Zechstein salt deposits. Hence, in sandstones, the degree of illitization may reflect the temperature of migrating fluid rather than, as is the case with mudrocks, the maximum burial temperature. Consequently, illite geothermometry is not so reliable a tool for sandstones as it is for mudrocks. The dissolution of K feldspar releases more silica than is required for either kaolinite or illite precipitation. This is thought to be one of the main sources of quartz cement in sandstones. Indeed, textural relationships between kaolinite, illite, and quartz are frequently suggestive of the coprecipitation of one or other clay with quartz cement.

Table 1 Differences between Fe chlorite and Mg chlorite. Adapted from Hillier (1984)

	Fe chlorite	*Mg chlorite*
Morphology	Pseudohexagonal, planar	Cornflake like
Arrangement	Individual plates and rosettes, face to edge contacts	Boxwork, face to face and edge to edge contacts
XRD	Interstratified with 7 Å layers at <200°C	Often interstratified with corrensite or smectite
Polytype	Ib transforming to IIb	IIb only
Occurrence	Marginal marine sandstones offshore from major river systems in tropical climates	Coastal aeolian dunes and sandy sabkhas, any facies associated with evaporite brines
Facies associations	Oolitic ironstone	Evaporites
Associated early authigenic minerals	Siderite, calcite, phosphates	FeO rims, anhydrite, K feldspar, calcite, dolomite
Precursor		

XRD, X ray diffraction.

K/Ar dating allows the determination of the mean age of an authigenic illite occurrence. Although contamination of data by detrital illite and K feldspar can be a problem, this technique is much used in unravelling burial histories. The method is based on the known rate of decay of radioactive ^{40}K to stable ^{40}Ar. Important advantages of this method are that it is generally reasonable to assume that no argon was present in the mineral at the time of its formation, whilst illite has excellent Ar retention at burial temperatures of less than 175°C. Illite ages generally decrease with increasing burial depth. In sandstones, smaller sized fractions may give younger dates than coarser ones, as contamination by detrital illite decreases with decreasing particle size. However, in bentonites, smaller sized fractions can give older dates than coarser ones, which is consistent with the growth of fundamental particles as described above. In the Jurassic of the North Sea, most illite dates are in the range 50–30 Ma, coincident with the onset of rapid burial in the Late Cretaceous–Early Tertiary.

Glauconite

Although glauconite forms only at the sediment–water interface, with increasing burial temperature, aluminium is partly substituted for iron.

Chlorite

In sandstones, authigenic chlorite typically forms grain-coating rims of radial, interlocking platelets. Such rims have been the focus of petroleum company research, due to the inhibiting effect they have on quartz overgrowth cementation. The result of this inhibition can be sandstones with excellent reservoir quality at 4–5 km burial depth. Textural relationships indicate unequivocally that such chlorite forms very early in diagenesis. As with chloritic green clay pellets, early Fe chlorite rims are associated with sandstones offshore from major river systems within the tropics. Examples of this occur in the Jurassic Åre Formation in the Norwegian sector of the North Sea and the Miocene off the Niger Delta. It is now thought that Fe chlorite (chamosite) originates as odinite or a similar 7 Å iron-rich clay, although recent examples of odinite are rare. One line of evidence for a 7 Å clay precursor is that the proportion of 7 Å interlayers in 14 Å chlorite decreases with depth and burial temperature. This is not the only change exhibited by chlorite with depth: a gradual Ib to IIb polytype transition has been demonstrated for Fe chlorite, and there is a strong linear relationship between tetrahedral Al in authigenic chlorites and present-day temperature in hydrothermal systems. However, there is no simple relationship between chlorite polytype and temperature, and attempts to develop a universal chlorite geothermometer have largely failed as authigenic chlorite composition is influenced by detrital sediment composition. Chlorite in sandstones also occurs as a pore-filling replacement of ferromagnesian igneous rock fragments; the composition of this type of chlorite will reflect the mineral being replaced. Chlorite–smectite and corrensite can form by a similar process. These clays typically have more undulose platelets than true chlorite and are most frequently found in volcaniclastic sediments. Mg-rich chlorite, chlorite, and corrensite also form by diagenetic replacement of Mg smectite in evaporite basins. Non-chemical differences between Mg chlorite and Fe chlorite are summarized in Table 1.

Deep Ocean Pelagic Oozes

R G Rothwell, Southampton Oceanography Centre, Southampton, UK

Introduction

Deep-ocean pelagic (from the Greek *pelagios*, meaning 'of the sea') sediments are areally and volumetrically the dominant sediment type found on the ocean floor. They comprise three main types, depending on their primary composition: deep-sea siliceous oozes, calcareous oozes, and deep-water red clays (Figure 1). Pelagic sediments mixed with terrigenous material derived from continental weathering are termed 'hemipelagic'. Siliceous and calcareous oozes are composed largely of test and test debris of planktonic micro-organisms such as foraminifera, coccolithophores, pteropods, diatoms, and radiolaria. The formation of pelagic sediments involves settling of material, that is commonly derived from biological surface productivity, but also includes wind-derived material that travels through the water column ('pelagic rain') to the seafloor (Figure 2). This process occurs throughout the world's oceans and true pelagic deposits tend to blanket seafloor topography. Local remobilization of pelagic sediments on topographic highs due to slope instability may result in pelagic turbidites (redeposited units) that pond in adjacent lows. However, the distribution of pelagic sediments is strongly depth controlled, because calcium carbonate shows increasing solubility with depth. In contrast to terrigenous sediments (the other main type of deep-sea sediment, largely composed of detrital material derived from continental weathering), pelagic sediments are characterized by low sedimentation rates and frequently contain a high proportion of authigenic minerals, extraterrestrial material, and, where physicochemical conditions allow, a substantial biogenic component.

History of Research

Although mention of marine sediments has been found in Greek and Roman texts, it was not until 1773 that the recovery of sediment from the deep sea was first recorded. In that year, Captain John

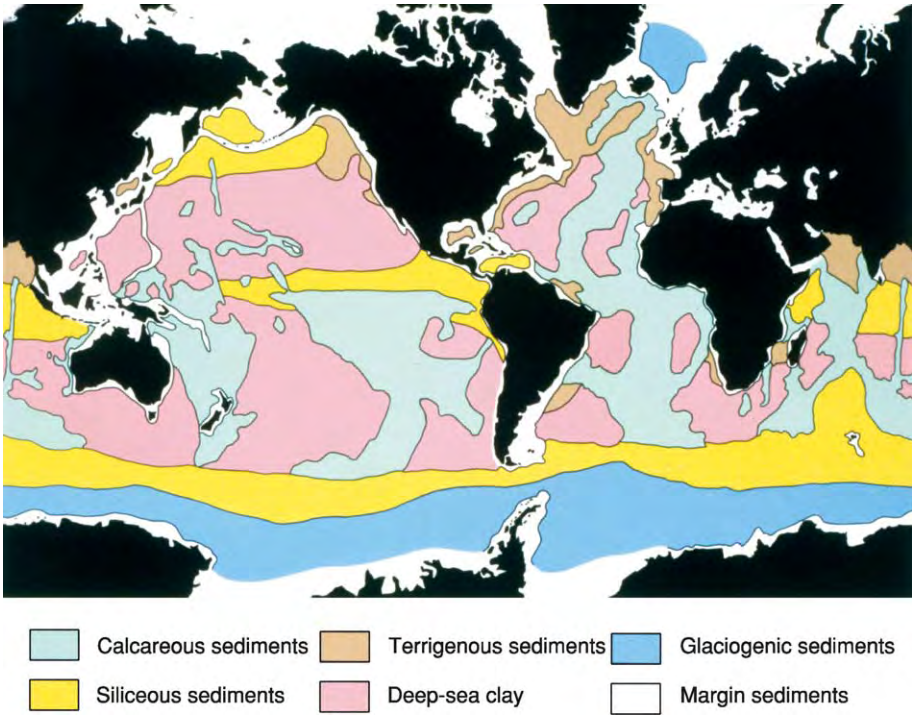

Figure 1 Distribution of the main sediment types on the ocean floor. Reproduced with permission from Davies TA and Gorsline DS (1976) Oceanic sediments and sedimentary processes. In: Riley JP and Chester R *Chemical Oceanography*, vol. 5, 2nd edn., pp. 1 80. London: Academic Press.

Phipps, on *HMS Racehorse*, bought up "fine soft blue clay" from a depth of 1250 m, the first recorded successful deep-sea sounding. The sample was taken in water on the southern edge of the Voring Plateau in the Norwegian Sea. In 1818, Sir John Ross recovered 6 lb (2.7 kg) of greenish mud from a depth of 1920 m in Baffin Bay, offshore Canada, using a deep-sea grab, representing one of the first recorded successful substantial deep-sea sediment recoveries. The laying of the first functioning submarine telegraph cable across the Straits of Dover in 1851 led to rapid expansion in the collection of deep-sea soundings and samples, driven by the prospect of the new means of intercontinental communication. However, it was not until the voyage of *HMS Challenger* (1872–76) that enough deep-sea samples were recovered to produce the first global seafloor sediment map. The voyage of *HMS Challenger*, led by Professor Charles Wyville Thomson, professor of natural history at the University of Edinburgh, was the first large-scale expedition devoted to oceanography. A wealth of seafloor samples were recovered from 362 observing stations, spaced at uniform intervals, along the 128 000-km track traversed during the voyage. John Murray, a naturalist on the *Challenger* expedition, oversaw the initial analysis of the recovered samples; Murray later edited the *Challenger Reports*, following the death of Wyville Thomson in 1882. The milestone *Challenger Report* on 'Deep-Sea Deposits' represented the first comprehensive volume on sediments of the deep-ocean seafloor. Published in 1891 with the assistance of Murray's co-worker AF Renard, this volume introduced many of the descriptive terms used today, such as 'red clay' and '*Globigerina* ooze', and provided the basis for further deep-ocean sediment studies. Murray also correctly related the distribution of shell-bearing plankton in the surface waters to the calcareous and siliceous sediments of the deep-ocean seafloor.

A major step forward in the investigation of seafloor sediments was the invention of the gravity corer by German researchers; the corer allowed continuous samples of extended lengths of sediment to be collected (but generally restricted to 1–2 m in length). The German South Polar Expedition (1901–03) collected several 2-m cores that were described by E Philippi in 1910. These cores showed that some deep-water sediments were stratified. During the period 1925–38, Germany ran a series of oceanographic expeditions using the ship *Meteor*, which recovered several 1-m-long cores from the southern Atlantic and Indian oceans. These cores, studied by Wolfgang Schott, showed changes in foraminifer species with depth and initiated the first

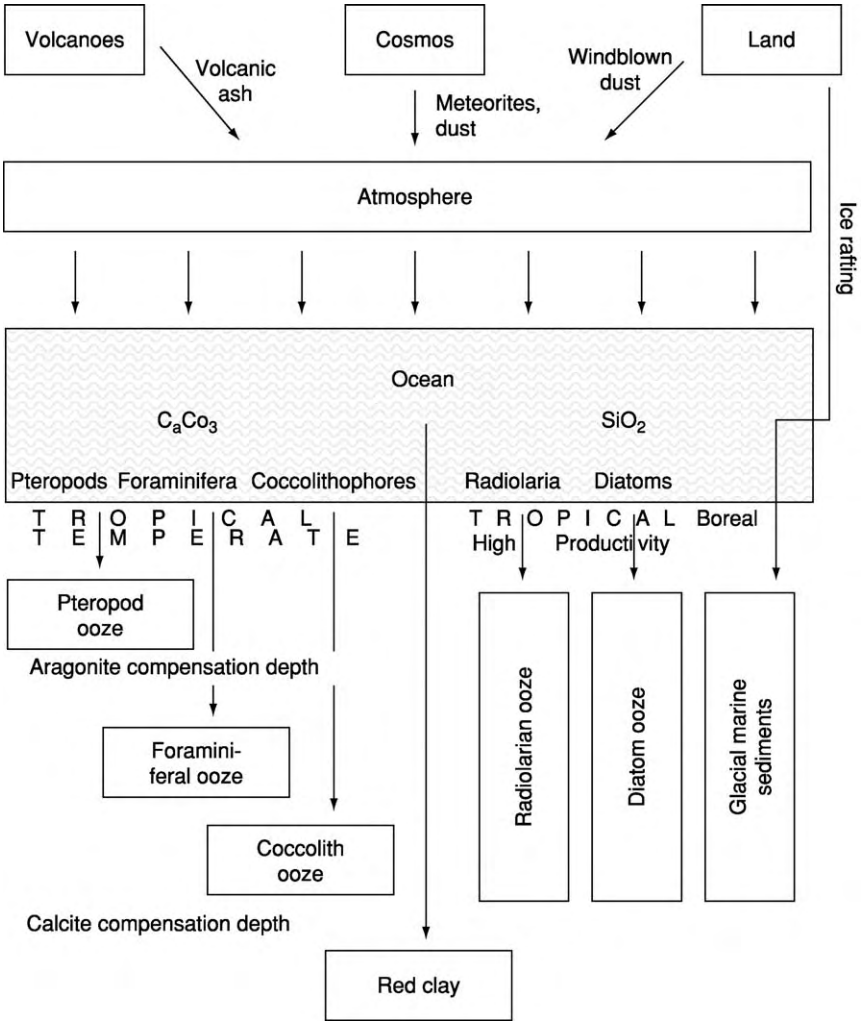

Figure 2 Sources and pathways for pelagic sedimentation in the oceans. Reproduced with permission from Hay WW (1974) Studies in Paleoceanography. Tulsa, Oklahoma: Society of Economic Paleontologists and Mineralogists.

palaeoceanographic studies. The Swedish Deep-Sea Expedition (1947–49) provided another fundamental advance in the study of deep-sea sediments. This expedition on the *Albatross* deployed a new kind of coring device, called a piston corer, which was developed by Börje Kullenberg, a marine geologist working in Gothenburg, Sweden. An innovative modification of the traditional gravity corer allowed the coring tube to fall past a stationary piston at the end of the wire, so that water was expelled from the falling tube above the piston and sediment was admitted from below. This allowed retrieval of much longer (10 m or more) and much less disturbed sediment cores. Acquisition of such long piston cores made possible the study of Pleistocene ocean history. The era of modern deep-sea sediment sampling had begun. Piston coring remains the main contemporary method of sampling the deep-sea sedimentary record, although sizing-up of the coring apparatus has led to development of giant piston corers, now capable of obtaining sediment cores up to 60 m in length. A giant piston core providing a continuous 54-m-long sediment record covering 4 million years of sedimentation was recovered from the Indian Ocean by the French ship *Marion Dufresne* in 1990; this is one of the longest piston cores ever recovered.

The advent of the Deep Sea Drilling Project (DSDP) in 1968 took deep-sea sediment sampling technology further. This programme, using the dynamically positioned drillship *Glomar Challenger*, set to recover continuous or semicontinuous sediment records from the ocean basins and heralded another new era in the exploration of the deep-ocean sedimentary record. Prior to the DSDP, the global inventory of cores recovering pre-Quaternary sediments

numbered fewer than 100. The DSDP and its successor, the Ocean Drilling Program (ODP), which began drilling operations in 1985 with a new drillship *JOIDES Resolution*, with improved capabilities, have led to major advances in our understanding of the processes of plate tectonics, of Earth's crustal structure and composition, of past changes in climate, and of conditions in ancient oceans. A vast amount of core material has been collected by the DSDP and ODP from all ocean basins (except the Arctic Ocean) and continuous sediment sequences back to Early Jurassic times have now been recovered.

Control of the Distribution of Pelagic Deposits

Pelagic sediments are defined as those formed of settled material that has fallen through the water column; their distribution is controlled by three main factors, distance from major landmasses (which affects their dilution by terrigenous, or land-derived, material), water depth (which affects sediment preservation), and ocean fertility (which controls surface water productivity). Pelagic sediments are composed largely of the calcareous or siliceous remains of planktonic micro-organisms or wind-derived material or mixtures of these. Several types of pelagic deposits can be identified on compositional grounds, and because seawater is increasingly corrosive with pressure and depth, the distribution of pelagic sediment types is strongly controlled by the calcite compensation depth (CCD), which is that depth at which the rate of supply of biogenic calcite equals its rate of dissolution (Figure 3). Therefore, below the CCD, only carbonate-free sediments accumulate. Thus the calcite compensation depth marks a major boundary defining the deposition of pelagic clays and calcareous sediments.

Another important depth in the water column is the lysocline, which lies above the CCD and is the depth at which the degree of undersaturation with respect to calcium carbonate is sufficient for dissolution of calcareous particles to become significant (Figure 3). Therefore, the lysocline is a depth that separates well preserved from poorly preserved solution-etched calcareous particles. The depth of the lysocline varies but it generally lies between 3000 and 5000 m. At water depths less than the lysocline, calcareous particles accumulate without loss through dissolution. The depth of the CCD varies as a function of a number of variables that reflect oceanic productivity patterns and the shoaling of the lysocline near continental margins. The CCD varies between 3500 and 5500 m in the Atlantic and Pacific oceans but has a mean depth of around 4500 m. The difference between the lysocline and CCD depths is also not constant, because this depends on the gradient of the concentration of carbonate ions in the water column overlying the sediments. However, the depth at which the calcite content of sediments falls to only a few percent is typically about 700 m deeper than the lysocline.

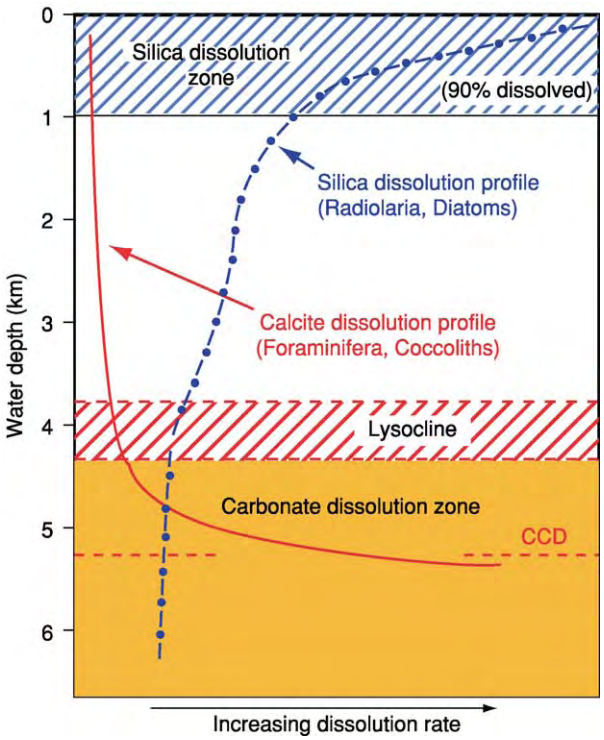

Figure 3 Generalized dissolution profiles of silica and calcite. Note that the depth of the lysocline, taken as the level below which there is rapid increase in calcite dissolution, and the calcite compensation depth (CCD), which is the depth at which the rate of supply of biogenic calcite equals its rate of dissolution, vary within and between ocean basins. Reproduced with permis sion from Douglas RG (2003) Oceanic sediments (Figure 5). In: Middleton GV (ed.) *Encyclopedia of Sediments and Sedimentary Rocks*, pp. 481 492. Dordrecht: Kluwer Academic Publishers.

Types of Pelagic Deposits

Pelagic sediments fall into two broad groups based on composition, deep-water pelagic clay and biogenic oozes. Deep-water pelagic clay is found in deep-ocean areas far from land, where solution has removed the biogenic component and only insoluble inorganic material, much of it wind-derived, remains. Biogenic oozes are composed largely of biogenic planktonic debris derived from surface water productivity (they contain more than 30% biogenic debris). Biogenic oozes are largely composed of the remains of zoo- and phytoplankton such as foraminifera,

coccolithophores, pteropods, diatoms, and radiolaria. In the upper water column, these remains are biologically 'packaged' and 'repackaged' into larger particles, which hastens their descent to the seafloor (e.g., as faecal pellets or phytoplankton aggregates). Indeed, most of the organic and skeletal matter produced in the euphotic zone is consumed and only a fraction is exported, and a fraction of this reaches the deep seafloor, where more is destroyed by dissolution. The distribution of biogenic oozes is strongly depth controlled due to dissolution of calcium carbonate with depth. Two main types are recognized, calcareous oozes, the composition of which is dominated by the remains of calcareous plankton, and siliceous oozes, which are dominated by the remains of siliceous plankton. Siliceous oozes lithify into radiolarites, diatomites, and cherts, whereas calcareous oozes lithify into pelagic chalks and limestones, and examples are well known from the geological record, well-documented examples occurring in the Troodos Massif, Cyprus, and the Ligurian Apennines in Italy.

Calcareous Oozes

Calcareous oozes may be dominated either by the tests and test debris of planktonic foraminifera (termed 'foraminiferal ooze') (Figure 4) or by the remains of planktonic plants (coccolithophores; termed 'nannofossil ooze'). In either type of calcareous ooze, the other component will often be the second most important constituent. In the modern world ocean, ~50% of the seafloor is blanketed by foraminiferal ooze (Table 1). Calcareous oozes commonly also contain a terrigenous fraction (which may amount to 10–15%), composed mainly of quartz and clay minerals, but may contain trace amounts of pyrite, iron and manganese precipitates, mica, chert, rock fragments, glauconite, feldspar, ferromanganese minerals, detrital carbonate, zeolites, volcanic glass, and cosmic spherules. Minor biogenic components may include benthonic (bottom-dwelling) foraminifera, ostracods, echinoid remains, radiolaria, silicoflagellates, diatoms, sponge spicules, pteropod shells and shell debris (in shallow water), phosphatic vertebrate remains and fish teeth.

Pteropods (pelagic gastropods) are relatively common zooplankton, especially in warm-water latitudes, and some forms secrete delicate aragonitic shells. Pteropod shells may range up to 30 mm in length, although most are in the range 0.3 to 10 mm. Aragonite is unstable and dissolves as ocean waters become undersaturated in respect to carbonate with depth. Consequently, pteropod-rich oozes are only found at depths shallower than 2500 m in the Atlantic Ocean and shallower than 1500 m in the Pacific Ocean.

Foraminifera comprise a group of protozoans characterized by a test of one to many chambers composed of secreted calcite or agglutinated grains. Test sizes are generally in the range 0.05–1 mm. Forms with agglutinated tests are typically benthonic (bottom-dwelling) and make only a very minor contribution to pelagic sediments, which are overwhelmingly dominated by the remains of globular planktonic forms. Modern species show clear latitudinal distribution patterns related to water temperature. Oxygen isotope analysis of planktonic foraminifera tests can provide estimates for past

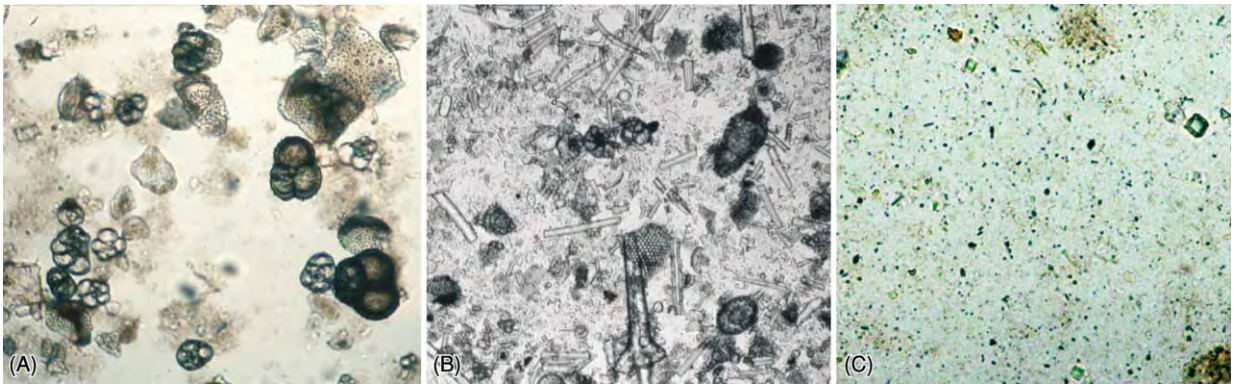

Figure 4 Illustration showing the three main types of pelagic sediments as seen under the microscope in plane polarized light. Left: Calcareous ooze from the North Atlantic Ocean, comprising mainly planktonic foraminifer tests and test fragments. The larger complete foraminifer tests are about 0.1 mm across. Centre: Siliceous ooze from the South Atlantic Ocean, comprising mainly silica sponge spicules (tubular forms), radiolaria (high relief bell shaped and circular forms, right of centre), and broken centric diatom frustules (lower left and centre). Two planktonic foraminifera can be seen in the upper centre field. The foraminifera are about 0.05 mm across. Right: North east Atlantic Ocean pelagic red clay containing rhomboid dolomite crystals. The red colour is due to the presence of amorphous or poorly crystalline iron oxide minerals and grain coatings. The largest dolomite rhomb (upper right) is about 0.01 mm across.

Table 1 Coverage of the deep ocean floor by pelagic sediments[a]

Sediment type	Seafloor coverage (%)			
	Atlantic Ocean	*Pacific Ocean*	*Indian Ocean*	*Total World Ocean*
Foraminiferal and nannofossil ooze	65.1	36.2	54.3	47.1
Pteropod ooze	2.4	0.1		0.6
Diatom ooze	6.7	10.1	19.9	11.6
Radiolarian ooze		4.6	0.5	2.6
Pelagic clay	25.8	49.0	25.3	38.1

[a]Data from Open University (1991) *Ocean Chemistry and Deep Sea Sediments*, 2nd edn. Oxford: Pergamon Press.

sea-surface temperatures and salinities. Isotope data from benthonic forms allow reconstruction of bottom-water mass histories. Foraminifera hence can provide important information on thermohaline structure and circulation patterns in ancient oceans.

Coccoliths are minute, usually oval, calcite plates produced by unicellular planktonic algae (family Coccolithophoridae); because of their small size, coccoliths are referred to as nannoplankton. In life, coccolith plates, eight or more in number, depending on the species, are attached to a membrane surrounding a living cell. Each organism (i.e., the cell surrounded by coccolith plates) is termed a 'coccosphere'. Coccospheres are generally spherical, usually 5–30 μm in diameter. The individual coccolith plates are usually around 3 μm in diameter, although some forms can be as large as 35 μm. On the death of the organism, the membrane holding the coccolith plates disintegrates, releasing the coccoliths to contribute to calcareous oozes. Coccoliths are single calcite crystals and are more resistant to dissolution than the tests of foraminifera or pteropods are. Globally, their diversity increases from a minimum in subpolar seas to a maximum in tropical and equatorial waters; and species distribution is closely linked to water masses.

Siliceous Oozes

Siliceous oozes are largely composed of the opaline silica tests and test fragments of siliceous plankton (Figure 4). Again, there are two main varieties: radiolarian ooze, composed mainly of the tests of radiolarians, and diatom ooze, dominated by the siliceous remains of unicellular plants (diatoms). Both types may contain minor amounts of silicoflagellates. Some sediments (for example, in some high-latitude abyssal environments and near spreading ridges) may also contain significant numbers of siliceous sponge spicules (Figure 4). Typically, siliceous ooze is present only in regions of high biological surface water productivity (such as the equatorial and polar belts and areas of coastal upwelling), where the depth of the seafloor is deeper than the calcite compensation depth. In the North Pacific and Antarctic belts of siliceous oozes, diatoms make up as much as 95% of the bulk sediment. The mineralogical composition of the detrital fraction of siliceous oozes is commonly similar to that of calcareous oozes, with quartz and clay minerals being the dominant detrital minerals.

Radiolaria are a diverse group of planktonic, pseudopod-bearing protozoans characterized by transparent opal skeletons. These exquisitely structured lattices are often of great complexity. Radiolarian tests show a great variety of shapes, but most are based on conical, spherical, or helmet-shaped forms. Most radiolarians are within the size range 20–400 μm. They are particularly abundant and diverse in equatorial latitudes (especially in areas of upwelling) and in subpolar seas. Radiolarian oozes occur mainly in the equatorial Pacific.

Diatoms are single-celled algae that secrete a test (called the frustule) of opaline silica. They are a major part of the phytoplankton and typically occur as pinnate (spindle-, rod-, or wedge-shaped) or centric (discoidal, spherical, elliptical, or oblong) forms. Most planktonic diatoms are centric types, although in Antarctic Seas, planktonic pinnate forms occur. They generally fall within the size range 10–100 μm. Diatoms represent most of the suspended silica in the water column and are the main contributors to deep-sea siliceous sediments. However, although in productive areas diatom concentrations are many millions of frustules per cubic metre, most tests are redissolved in the water column, because surface waters are greatly undersaturated in respect to silica due to high biological demand (Figure 3). Indeed, in areas of low silica supply, diatom assemblages in sediments are commonly biased to dissolution-resistant robust forms rather than to more fragile species. Diatoms are particularly abundant in regions of high productivity, especially in high latitudes and areas of upwelling.

Silicoflagellates are small unicellular flagellated marine plankton with internal skeletons of opaline silica. These skeletons consist of hollow rods arranged in a lattice, a common arrangement comprising a basal ring from which rods arise on one side to form an arch or dome, resulting in an overall hemispherical shape. Most silicoflagellates are in the size range of 20–50 μm. Although silicoflagellates are widespread in sediments, they are seldom abundant, so do not make a significant contribution to marine sediments.

Pelagic Clays

Deep-water pelagic clays (sometimes called 'red clay') are found only in deep-ocean areas, generally below water depths of 4000 m, far from land. Such clays cover large areas of the seafloor, particularly in the Pacific, southern Atlantic, and southern Indian oceans (Figure 1), in areas remote from terrigenous sources and below the calcite compensation depth. The reddish-brown appearance of these clays, first noted on the *Challenger* expedition, is due to the presence of amorphous or poorly crystalline iron oxide minerals and grain coatings. Pelagic clays usually contain less than 10% biogenic material and are mainly composed of fine-grained quartz and clay minerals, the bulk of which is derived from aeolian fallout and has been slowly deposited from fine suspensions. Typically, 75–95% of pelagic clay deposits consists of clay minerals with a grain size of less than 3 μm (Figure 4). These clay minerals are dominated by illite, smectite, kaolinite, and chlorite, with illite as the main type. Illite is, in fact, largely land derived and is transported to the ocean by rivers and glaciers and as windblown dust. Both kaolinite (a product of humid tropical weathering) and chlorite (typically derived from low-grade metamorphic rocks) are also mainly land derived. Smectite, however, is a low-temperature alteration product of volcanic ash and is particularly widespread on the Pacific Ocean floor. Wind transport is the major mechanism by which land-derived clay, fine-grained silt (commonly quartz), and dust reach the ocean surface, ultimately to be deposited in pelagic clays. The highest rates of aeolian dust deposition (up to 1000 mg cm $^{-2}$ ky $^{-1}$) are in the north-western Pacific downwind of far-east Asia. Substantial fluxes of windblown dust also enter the deep ocean offshore of the Sahara, South Africa, the Arabian peninsula, and the Horn of Africa and around Australia. The origin of wind-derived material in pelagic clays can be determined by rare earth geochemistry and study of Sr and Nd isotopes. Pelagic clays also commonly contain significant amounts of authigenic minerals, such as chert, zeolites, apatite, phosphorite, volcanic glass, and manganese micronodules, as well as indicators of slow sedimentation, such as fish debris and cosmic spherules. Pelagic clays may also contain varying amounts of feldspar, pyroxenes, and mica. In total, pelagic clays cover about 38% of the modern seafloor (Table 1).

Ferromanganese Deposits

New mineral phases may be formed on the seafloor (a process known as authigenesis) either by direct precipitation from seawater or by the alteration of pre-existing minerals or grains. Ferromanganese deposits are the most common and probably the most widely known authigenic deposits found on the deep-ocean seafloor. They occur as encrustations or crusts on submarine rock outcrops, or as discrete nodules and concretions on the seafloor. Ferromanganese crusts, which grow on exposed rock surfaces, acquire the elements necessary for their growth directly from seawater. Ferromanganese nodules occur throughout the sediment column, but the greatest concentrations are found on the surface; the nodules range in size from the microscopic (called 'micronodules', usually in the silt-sand size range) to the macroscopic, reaching several centimetres across (Figure 5). There are two main controls on nodule abundance: (1) the rate of accumulation of the host sediment, with the highest number of nodules being found on sediments with low accumulation rates (e.g., a few millimetres per thousand years), and (2) the presence of suitable accretion nuclei for the nodules to grow around; the nuclei may be small clumps of sediment, fragments of volcanic rock, shark teeth or teeth fragments, or even foraminifer tests. Ferromanganese nodules can show a great variety of shape and size and are found in all oceans, but are particularly common on the deep Pacific seafloor. Nodules may form by precipitation from the overlying seawater and from elements supplied from interstitial porewaters below the sediment surface, or through a combination of both element sources. The shape of the nodule may reflect the dominant source of elements available for its precipitation and growth. For circular nodules, it is thought that the dominant supply of metals is from the overlying seawater, whereas for discoidal, flattened nodules the dominant supply of metals may be via interstitial porewaters below the seabed. Nodule growth rates are slow, varying from a few to a few hundred millimetres per million years. Ferromanganese nodules are rich in iron and manganese as their name implies, but also contain relatively high concentrations of a number of trace metals, including cobalt, molybdenum, thorium, nickel, silver, iridium, and lead. Deep-sea ferromanganese nodules may someday become an important economic resource.

Metalliferous sediments, including iron and manganese-rich mudstones (termed 'umbers') and iron-rich sediments (termed 'ochres'), are frequently associated with ophiolites (fragments of oceanic crust that have been tectonically emplaced onto continental margins), well-known examples of which occur in Cyprus and Oman. These record past oceanic sediments that have contained hydrothermal minerals or authigenic ferromanganese deposits.

Figure 5 Deep sea photograph, showing a field of ferromanganese nodules over part of the Madeira Abyssal Plain, north east Atlantic Ocean. Individual nodules are a few centimetres across; water depth is 5400 m.

Biogenic Sedimentation in the World Ocean

Early researchers such as John Murray believed that pelagic sediments must accumulate slowly, but it was Wolfgang Schott, studying cores collected by the German *Meteor* expeditions of 1925–27, who was first able to demonstrate that Atlantic calcareous oozes had accumulated at rates of several centimetres thickness per thousand years. He found that the distinctive tropical foraminifer *Globorotalia menardii* was absent in glacial-period sediments in the North Atlantic, and that its appearance correlated with the start of the Holocene. Because the age of the base of the Holocene was known from land sections, Schott was able to determine accumulation rates for Atlantic pelagic calcareous oozes for this time period. Today, a wide variety of dating techniques (for example, radiocarbon dating and uranium series dating) can be used to determine accumulation rates. Pelagic sedimentation rates do vary considerably, but pelagic clays accumulate the most slowly (typically $0.1–0.5\,\mathrm{cm\,ky^{-1}}$), whereas sedimentation rates for calcareous oozes are typically in the range $0.3–5\,\mathrm{cm\,ky^{-1}}$ and siliceous oozes are in the range $0.2–1\,\mathrm{cm\,ky^{-1}}$.

Biogenic sediments show considerable variation in both space and time. In the present-day Atlantic Ocean, pelagic sediments are predominantly calcareous and siliceous sediments are virtually absent in the North Atlantic. In the Pacific, however, calcareous sediments are limited to oceanic ridges, plateaus, and seamounts (at water depths less than 3500 m) and also occur as a broad belt in the southern central Pacific. Siliceous sediments are widespread in the North Pacific, along the equator and adjacent to Antarctica. Calcareous sediments occur along the mid-ocean ridges in the Indian Ocean and siliceous sediments are widespread in the northern and southern Indian Ocean (Figure 1). Pelagic sediment distribution reflects both seafloor depth and ocean fertility. Where nutrient supply is low and surface waters are nutrient poor (especially in dissolved silica), sinking particles deliver to the seafloor more carbonate than silica (low Si/Ca ratio), which will be preserved, providing the seafloor lies above the CCD. Low nutrient supply favours production of coccolithophorids, which are fed on by small foraminifera, and long food chains develop in the euphotic zone. Foraminifera and coccoliths therefore dominate export to the seafloor. Where nutrient concentrations in surface waters are high, such as at upwelling areas and ocean divergence zones, diatoms will be the primary producers. Diatoms can reproduce rapidly and produce dense blooms (10^7 frustules per cubic metre). Food chains in these regions tend to be short because large diatoms are eaten by large zooplankton and fish (high trophic-level consumers). Export to the seafloor is high in silica and organic carbon, and flux rates are high, leading to siliceous sediment deposition. Further, bacterial decomposition of the organic carbon results in production of carbonic acid, which dissolves carbonate grains. In this way, carbonate is removed and the siliceous content as a proportion of total sediment increased. Deep-ocean circulation also leads to fractionation of silica and carbonate between ocean basins. In the North Atlantic, deep-water outflow is

exchanged for surface water inflow and bottom waters are young, nutrient poor, well oxygenated and saturated in respect to calcium carbonate. Sediments deposited here tend to be calcareous. In the North Pacific, in contrast, deep water is old and poorly oxygenated but nutrient rich, because surface water outflow is exchanged for deep-water inflow. Before reaching the North Pacific, the deep water has flowed through the southern Atlantic and Indian oceans, hence its age and low oxygen content. However, during this long passage, microbial breakdown of organic matter (which has depleted oxygen) produces CO_2 and regenerates nutrients. These waters therefore become undersaturated in regard to calcium carbonate but are enriched in nutrients and dissolved silica. Upwelling of this water will cause high surface productivity and diatom production, resulting in deposition of siliceous oozes with little calcareous content. Thus, pelagic sediment distribution is determined by bottom water circulation, which controls both the rate of particle dissolution and the productivity of surface waters through upwelling. In this way, in the modern ocean, the Atlantic is depositing carbonate and exporting silica, whereas in the Pacific, the reverse is happening. However, changes in climate and continental positioning and ocean connectivity, caused by plate motion, will affect ocean chemistry and fertility, and hence pelagic sediment deposition and distribution.

Data from the DSDP and ODP have shown that the distribution and relative abundance of seafloor sediment types have changed with time. Biogenic sediments were even more widely distributed in Cretaceous and Early Tertiary time. The deep-ocean sedimentary record provides a most important source for our knowledge of the past Earth, particularly regarding ocean fertility, geochemistry, evolution of marine biota, and past wind regimes and patterns.

Dolomites

H G Machel, University of Alberta, Edmonton, Alberta, Canada

Introduction

Dolomite was first described in 1791 as a rock by Deodat de Dolomieu, who investigated samples from the Italian Alps. Dolomites are of special interest because they often form hydrocarbon reservoir rocks. Despite intensive research for more than 200 years, the origin of dolomites is subject to considerable controversy. This is because some of the chemical and/or hydrological conditions of dolomite formation are poorly understood, and because the available data often permit more than one viable genetic interpretation. This article covers the thermodynamic and kinetic conditions that favour dolomitization, mass balance considerations for the generation of massive dolostones, dolomite textures and pore spaces in dolostones, geochemical methods that are used in dolomite case studies, an overview of the various dolomitization models, and a brief section on secular variations in dolomite abundance.

Basics

Ideal, ordered 'dolomite' has a formula of $CaMg(CO_3)_2$ and consists of alternating layers of Ca^{2+}–CO_3^{2-} –Mg^{2+}–CO_3^{2-} –Ca^{2+}, etc., perpendicular to the crystallographic c axis. Most natural dolomite contains up to a few per cent Ca surplus (and a corresponding Mg deficit), as well as less than ideal ordering. 'Protodolomite' contains about 55–60% Ca, is poorly ordered, i.e., the alternating cation layer structure is poorly developed, and is common as a metastable precursor of well-ordered, nearly stoichiometric dolomite in both laboratory experiments and in nature. Good arguments have been made to abandon the term protodolomite or to restrict it to laboratory products, yet the term is useful to describe metastable precursors of dolomite in nature. The term 'dolostone' refers to a rock that consists largely (>75%) of the mineral dolomite. This term has been rejected by some, but has gained wide acceptance during the last 20 years. The term 'dolomites' is the best term to use to refer to types of dolomite that vary in texture, composition, genesis, or a combination thereof.

Two types of 'dolomite formation' are common, i.e., 'dolomitization', which is the replacement of $CaCO_3$ by $CaMg(CO_3)_2$, and 'dolomite cementation', which is the precipitation of dolomite from aqueous solution as a cement in primary or secondary pore spaces. Dolomites and dolostones that originate via replacement of $CaCO_3$ are called 'replacement dolomites' or 'secondary dolomites', especially in the older literature. A third type of dolomite formation is direct precipitation from aqueous solution to form sedimentary deposits. Dolomites that form in this way may be called 'primary dolomites'.

Genetically, all natural dolomites can be placed into two major families, i.e., 'penecontemporaneous' dolomites and 'postdepositional' dolomites. Penecontemporaneous dolomites may also be called 'syndepositional' dolomites. They form while a carbonate sediment or limestone still resides in the original environment of deposition as a result of the geochemical conditions that are 'normal' for that environment. Such dolomites are also called 'primary' or 'early diagenetic', although these terms are not strictly synonymous with penecontemporaneous. True penecontemporaneous dolomites appear to be relatively rare. Most known cases are of Holocene age, and are restricted to certain evaporitic lagoonal and/or lacustrine settings. It is quite possible, however, that such dolomites are much more common in the geological record than presently known, but their presence is hard to prove because of later diagenetic overprinting.

'Postdepositional' dolomites may also be called 'postsedimentary'. They form after a carbonate sediment has been deposited and removed from the active zone of sedimentation, which may happen via progradation of the sedimentary surface, burial and subsidence, uplift and emergence, eustatic sea-level fluctuations, or any combination of these. Such dolomites and dolostones are often called 'late diagenetic', although this term is not synonymous with postdepositional. Almost all known examples of massive, regionally extensive dolostones are postdepositional.

One aspect that transcends the above genetic grouping is that of hydrology. Whether syndepositional or postdepositional, the formation of large amounts of dolomite requires advection, i.e., fluid flow, because of chemical mass balance constraints. On the other hand, small amounts of dolomite can be formed without advection. In such cases, the Mg for dolomite formation is locally derived and redistributed, or supplied via diffusion. Examples include dolomite formed from Mg that was contained in (high-)Mg calcite, adsorbed to the surfaces of minerals, organic substances, or biogenic silica, or

that was contained in older primary or secondary dolomites.

Thermodynamic and Kinetic Constraints

The thermodynamic conditions of dolomite formation have been known quite well since at least the 1970s. The kinetics, however, i.e., the catalysts and inhibitors of dolomite formation, are relatively poorly understood and continue to be a source of controversy.

According to the present state of knowledge, dolomite formation is favoured chemically, i.e., thermodynamically and/or kinetically, under the following conditions: (1) low Ca^{2+}/Mg^{2+} ratios, (2) low Ca^{2+}/CO_3^{2} ratios (high carbonate alkalinity), (3) high temperatures, and (4) salinities substantially lower or higher than that of seawater. These constraints translate into four essential and common conditions for the formation of dolostones in natural settings:

- Settings with a sufficient supply of Mg^{2+} and CO_3^{2}. This condition favours marine settings and burial diagenetic settings with pore fluids of marine parentage, because seawater is the only common Mg-rich natural fluid in sedimentary/diagenetic settings.
- Settings with a long-lasting and efficient delivery system for Mg^{2+} and/or CO_3^{2} (also exporting Ca^{2+} in the case of calcite replacement). This favours settings with an active and long-lasting hydrological drive.
- Carbonate depositional settings and/or limestones that can be replaced.
- Settings in which fluids suddenly release CO_2, i.e., from hydrothermal solutions that ascend rapidly via fault systems.

Considering that the above chemical constraints allow dolomite formation in almost the entire range of surface and subsurface diagenetic settings, the question arises as to why there are so many undolomitized limestones. The essential conditions for the common lack of dolomitization appear to be:

- Ion pair formation (especially hydration), inactivating much of the Mg^{2+} and CO_3^{2} in solution.
- Insufficient flow because of the lack of a persistent hydraulic head, too small a hydraulic head, or insufficient diffusion, resulting in insufficient Mg^{2+} and/or CO_3^{2} supply.
- The limestones are cemented and not permeable enough, inhibiting or prohibiting the throughput of Mg-rich waters.
- The diagenetic fluids are incapable of forming dolomite because of kinetic inhibition, e.g., because the environment is too cold (most kinetic inhibitors of dolomite nucleation and growth are rather potent at temperatures below about 50°C), and the Ca^{2+}/Mg^{2+} ratio of many cold diagenetic fluids is not low enough for dolomitization.

The last point leads to kinetic factors, three aspects of which deserve special mention. Firstly, almost all researchers agree that most kinetic inhibitors that lower the nucleation rate and growth rate of dolomite are especially potent at temperatures below about 50°C. Hence, dolomite formation is easier at higher temperatures. Secondly, it is also generally acknowledged that dolomite forms via metastable precursors, but the significance of this phenomenon for the formation of massive dolostones is not clear. Thirdly, sulphate has been shown to increase as well as decrease the rate of dolomitization, and thus the role of sulphate is not clear, and may vary from place to place, depending mainly on fluid composition and temperature.

Mass Balance Constraints

Within the chemical constraints outlined in the previous section, the amount of dolomite that can be formed in a given diagenetic setting depends on the stoichiometry of the reaction, temperature, and fluid composition. Dolomitization can be represented by two equations, i.e.,

$$2CaCO_3(s) + Mg^{2+}(aq) \rightarrow CaMg(CO_3)_2(s) + Ca^{2+}(aq) \quad [1]$$

where '(s)' is solid and '(aq)' is aqueous, or by

$$CaCO_3(s) + Mg^{2+}(aq) + CO_3^{2}\ (aq) \rightarrow CaMg(CO_3)_2(s) \quad [2]$$

Reactions [1] and [2] are end members of a range of possible reaction stoichiometries, i.e.,

$$(2-x)CaCO_3(s) + Mg^{2+}(aq) + xCO_3^{2}\ (aq) \rightarrow CaMg(CO_3)_2(s) + (1-x)Ca^{2+}(aq) \quad [3]$$

Reaction [3] can be used to represent dolomitization in general, as it encompasses reactions [1] and [2]. For $x = 0$, reaction [3] becomes reaction [1] and, for $x = 1$, reaction [3] becomes reaction [2]. Dolomite cementation is most simplistically represented by

$$Ca^{2+}(aq) + Mg^{2+}(aq) + 2CO_3^{2}\ (aq) \rightarrow CaMg(CO_3)_2(s) \quad [4]$$

If dolomitization proceeds via reaction [1], and if the dolomitizing solution is normal seawater, about 650 m^3 of solution is needed to dolomitize 1 m^3 of limestone with 40% initial porosity at 25°C. Dolomitization may not take place with 100% efficiency, however, and some Mg in excess of saturation is carried away by the dolomitizing solution. In such cases, larger water/rock ratios are required for complete dolomitization. If seawater is diluted to 10% of its original concentration, as is the case in a typical seawater–freshwater mixing zone, ten times as much water is needed. On the other hand, only about 30 m^3 of brine is needed per cubic metre of limestone at 100% dolomitization efficiency in the case of a halite-saturated brine. The role of increasing temperature in the underlying thermodynamic calculations is to reduce the amount of Mg necessary for dolomitization, because the equilibrium constant (and hence the equilibrium Ca/Mg ratio) is temperature dependent. For example, at 50°C, only about 450 m^3 of seawater is needed for complete dolomitization of 1 m^3 of limestone with 40% initial porosity at 100% efficiency. The amounts of dilute and hypersaline waters change accordingly.

These calculations have two major implications. Firstly, large water/rock ratios are required for complete dolomitization, and the more dilute the solution, the larger the water/rock ratio. This necessitates advection for extensive and pervasive dolomitization, which is why all models for the genesis of massive dolostones are essentially hydrological models. The exceptions are natural environments in which carbonate muds or limestones can be dolomitized via diffusion of magnesium from seawater rather than by advection. Secondly, variable reaction stoichiometries result in variable porosity development during dolomite formation (see below).

Rock and Pore Classifications

Crystal size distributions are classified as 'unimodal' and 'polymodal', whereas crystal shapes are classified as 'planar-e' (euhedral), 'planar-s' (subhedral), and 'nonplanar-a' (anhedral). Using this semantic scheme, almost all other dolomite texture types can be named, i.e., planar-c (cement), planar-p, and nonplanar-p (both porphyrotopic). Saddle dolomite, with its distinctive warped crystal faces, is simply called nonplanar (Figure 1). A complete textural description includes recognizable allochems or biochems, matrix, and void fillings. Particles and cements may be unreplaced, partially replaced, or completely replaced. Replacement may be mimetic or non-mimetic, which can be added to a rock description, such as 'unimodal, non-mimetic, planar-s dolomite'.

Pores in dolostones are commonly addressed using the same classification as for limestones, with pore types such as mouldic, vuggy, shelter, etc. This

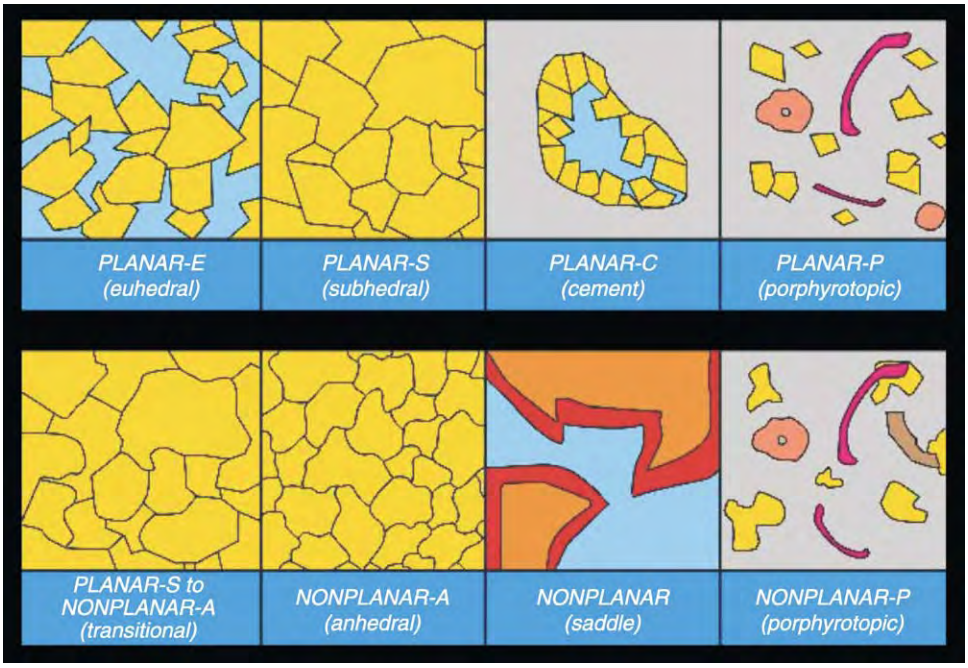

Figure 1 Dolomite textural classification combined from Gregg and Sibley (1984) and Sibley and Gregg (1997), supplemented by a 'transitional' form. Ph.D. thesis, Univerisity College Dublin, Belfield, Ireland, 407 p.

classification is independent of pore size. The latter, however, is of special interest for the petroleum industry. Another classification contains categories in size/magnitude from the very smallest to the very largest, i.e., from mercury injection capillary measurements (MICPM) and scanning electron microscopy (SEM) to karst caverns, respectively (Figure 2).

Textural Evolution

The textures and reservoir characteristics of natural dolostones are highly variable. On the microscopic scale, a unimodal size distribution generally results from a single nucleation event and/or a unimodal primary (pre-dolomite) size distribution of the substrate. Polymodal size distributions result from multiple nucleation events and/or a differential nucleation on an originally polymodal substrate. Planar crystal boundaries tend to develop at growth below about 50°C (the so-called 'critical roughening temperature'), whereas nonplanar boundaries tend to develop at $T > 50$°C and/or high degrees of supersaturation.

Within this framework, observations from many dolostone occurrences show that dolomitization often proceeds in a certain sequence of steps that correspond to certain textural types on the macroscopic scale. Within limits, these steps correspond to certain types of dolomitizing fluids (especially seawater and its derivatives) and/or meteoric water incursion. The most common sequence includes:

1. *Matrix-selective dolomitization*. Dolomitization begins as a selective replacement of the matrix (Figure 3).
2. *Vugs and moulds*. Holes resulting from the dissolution of undolomitized fossils and allochems (Figures 4 and 5).
3. *Emplacement of calcium sulphate*. Commonly anhydrite, both as a replacement and as a cement during advanced dolomitization from seawater (Figures 5 and 6).
4. *Development of two dolomite populations*. A smaller sized population with 'cloudy' centres with or without clear rims (overgrowths), and a larger population (Figures 7 and 8) resulting either from recrystallization or inherited from primary textural features.
5. *Dolomite cementation ('overdolomitization')*. Dolomite cement as overgrowth on the earlier formed dolomite crystals.

Furthermore, outcrop evidence shows that there is a distinct difference in the textures resulting from 'low-temperature' versus 'high-temperature' dolomitization of limestones. Empirical evidence suggests that the range of 50–80°C approximately marks the boundary between these two temperature realms. In the low-temperature settings, dolomitization commonly is matrix selective and at least partially fabric retentive, as discussed earlier, whereas dolomitization tends to be fabric destructive in the high-temperature settings (Figures 9 and 10). However, there are counterexamples.

Saddle dolomite (Figures 11 and 12) is a special type of dolomite. Its crystallographic, geochemical, and paragenetic characteristics suggest formation at temperatures above about 80°C. Saddle dolomite forms from stylolitization of older dolomites, as a

by-product of thermochemical sulphate reduction, and from hydrothermal fluids. Saddle dolomite commonly occurs as gangue in MVT-type metal sulphide deposits.

Porosity and Permeability

Comparison of the molar volumes of calcite and dolomite reveals that about 13% of porosity is generated in the so-called 'mole-per-mole' replacement of calcite by dolomite according to reaction [1] (whereby two moles of calcite are replaced by one mole of dolomite). However, several other processes are involved. As a generalization, dolostones can have higher, the same, or lower porosity and permeability than their precursor limestones, and the poroperm evolution has to be investigated on a case-by-case basis. Many/most dolostones have higher porosities than limestones, and this fact may be the result of one or several of six processes (**Figure 13**): (1) mole-per-mole replacement; (2) dissolution of unreplaced calcite (solution undersaturated for calcite after all Mg in excess of dolomite saturation is exhausted); (3) dissolution of dolomite (without externally controlled acidification); (4) acidification of the pore waters (via decarboxylation, clay mineral diagenesis, etc.); (5) fluid mixing ('*Mischungskorrosion*'); and (6) thermochemical sulphate reduction, which may generate porosity under certain circumstances.

Dolomitization almost invariably involves the reorganization of permeability pathways. Commonly, permeability increases along with porosity, and vice versa, such as in the Upper Devonian Grosmont Formation in eastern Alberta, which hosts a giant heavy-oil reservoir, and in the Cambrian–Ordovician Bonneterre Formation of Missouri, USA, which hosts one of the world's largest MVT-type sulphide deposits. Planar-e dolomites tend to have the highest porosities and permeabilities, the latter caused by well-connected pore systems with low pore to throat size ratios (as indicated by mercury injection curves);

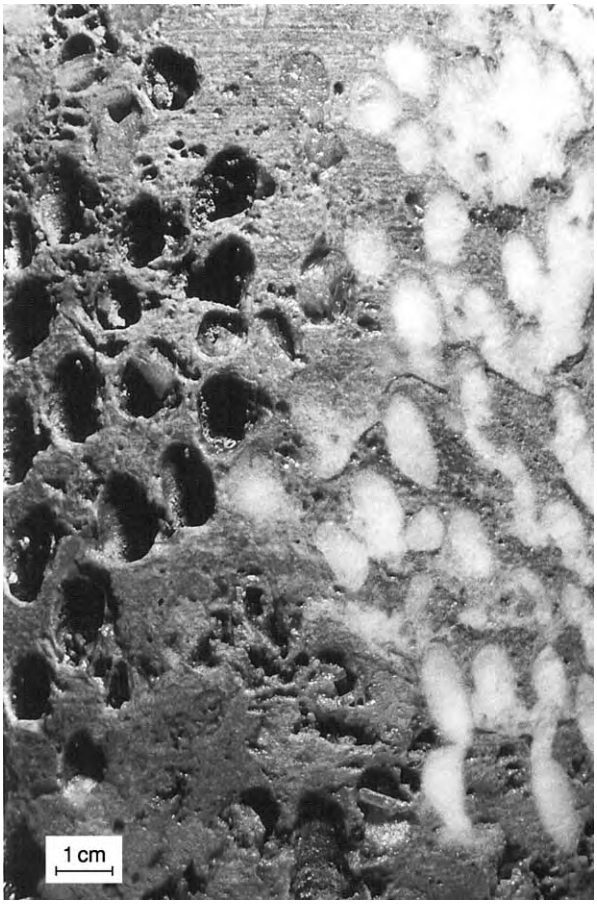

Figure 5 Coral mouldic porosity in tight matrix dolomite. White anhydrite occurs partially as a replacement (top right) and partially as a cement in coral mouldic porosity (centre and bottom right). From the Devonian Nisku Formation, Alberta, Canada.

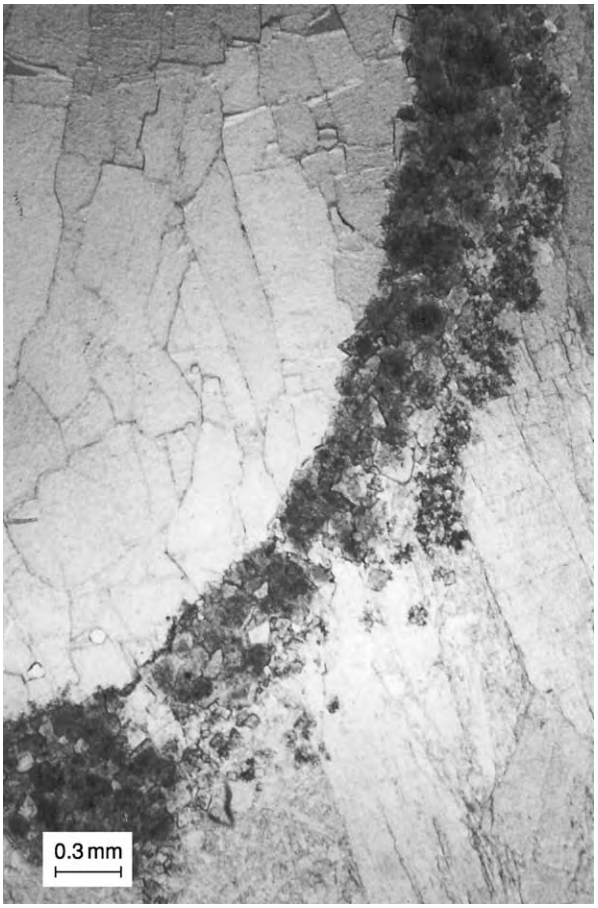

Figure 6 Thin section photomicrograph of the sample shown in Figure 5.

in planar-s dolomite, the permeabilities do not increase as rapidly with increasing porosity, corresponding to relatively large pore to throat size ratios; nonplanar dolomites have a statistically insignificant porosity–permeability relationship, whereby the pore systems have a high tortuosity and large pore to throat size ratios. Some authors have disputed that there is a systematic correlation between porosity and permeability in dolostones, or that these two petrophysical parameters are enhanced in dolostones relative to limestones. The Grosmont and the Bonneterre clearly show, however, that there is a relationship between porosity and permeability in at least some major and economically important dolostone sequences.

In cases of mole-per-mole replacement, the fabrics of the original limestone must be at least partially obliterated in order to account for the volume change during the replacement process. On the other hand, limestones dolomitized in a volume-per-volume replacement should not contain secondary intercrystal pores or dolomite cements, and the primary textures may be partially or largely, even mimetically (if the crystal size is very small), preserved. Partial or complete obliteration of primary textures can occur even in a volume-per-volume replacement, however, if there is a marked change in crystal size (usually an increase, due to Ostwaldt ripening) and/or porosity redistribution.

Dolomite Geochemistry

A wide range of geochemical methods may be used to characterize dolomites and dolostones, and to decipher their origin. One aspect of particular interest is the determination of the type of the dolomitizing fluid(s), i.e., marine, evaporitic, subsurface brine, etc., and the identification of the direction of fluid flow during dolomitization. The latter can often be ascertained by mapping a gradient in dolomite abundance, i.e., complete dolomitization near the upflow direction and decreasing abundance downflow. However, this approach necessarily fails where

Figure 7 Dolostones consisting of domains of relatively tight, light to medium grey dolomite intergrown with domains of highly porous, brownish dolomite. From the Devonian Nisku Formation, Alberta, Canada.

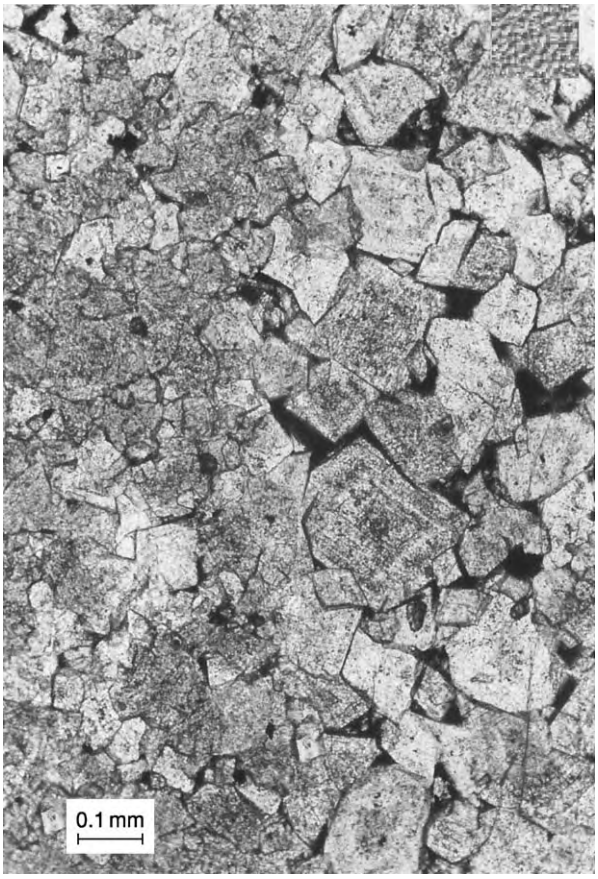

Figure 8 Thin section photomicrograph of the sample shown in Figure 7 from the boundary region between the two dolomite types.

dolomitization is 'complete' or where exposure and/or core are insufficient. In such cases, the geochemical composition of dolomites can be used, within limits, to determine the fluid composition and/or the flow direction during dolomitization.

Oxygen and carbon isotope ratios ($\delta^{18}O$ and $\delta^{13}C$) are the most widely applied and probably best understood geochemical methods in dolomite research. $\delta^{18}O$ values of carbonates can be used, within limits, to determine the $\delta^{18}O$ value and/or temperature of the fluid present during crystallization, including a possible distinction between meteoric, marine, and/or evaporitic waters.

Fluid inclusion homogenization temperatures arguably are the best method to determine the temperature of formation of dolomites (and other minerals), in addition to the highly desirable information on fluid compositions that can be gained from freezing experiments. Unfortunately, the vast majority of fluid inclusions in dolomites are too small for standard heating–freezing runs, as phase transitions within the inclusions are not observable. This is especially true of matrix-selective, replacive dolomites. On the other hand, the sparry saddle dolomite cements found in late-diagenetic dissolution vugs, but also as a replacement, commonly yield excellent fluid inclusion data.

Where possible, fluid inclusion homogenization temperatures are used in conjunction with $\delta^{18}O$ values to further characterize the conditions of dolomite formation. This type of analysis can reveal the direction(s) and temperature gradient(s) of the dolomitizing fluid flow on a local scale (a few kilometres) or on a regional scale (over several hundred kilometres). Mapping and contouring of the oxygen isotope and/or fluid inclusion homogenization temperatures have shown clear, spatially resolved gradients in some locations. Unfortunately, such gradients do not appear to be common.

The $\delta^{13}C$ values of the carbonates can be used to identify whether meteoric water (carrying soil CO_2) was involved, whether thermogenic or biogenic CH_4 was oxidized, whether CO_2 from microbial processes or organic matter maturation was available,

Figure 9 Outcrop photograph of Upper Carboniferous carbonates from the southwestern Cantabrian Zone, Spain: high temperature dolomitization of limestones. The dolostone appears dark where covered with lichen (upper right corner), yet light beige where cleaned of lichen (centre). The limestone (left) has a medium grey colour. Note the sharp contacts between limestones and dolostones, and that sedimentary and diagenetic textures visible in the limestones are obliterated in the dolostones. Hammer for scale.

Figure 10 Outcrop photograph of Upper Carboniferous carbonates from the southwestern Cantabrian Zone, Spain: high temperature dolomitization of limestones. The dolostone is light coloured and at the bottom. Note the sharp contacts between limestones and dolostones, and that sedimentary and diagenetic textures visible in the limestones are obliterated in the dolostones. Hammer for scale.

or whether thermochemical sulphate reduction contributed carbon to the carbonates. Also, there is a secular carbon isotope trend that may be used in the dating of marine dolostones, but only under very favourable circumstances.

Radiogenic isotopes are less commonly used in studies of carbonate diagenesis, mainly because they are analytically much more expensive. Yet, strontium isotopic compositions (usually quoted as $^{87}Sr/^{86}Sr$ ratios) are an excellent parameter to deduce compositional changes and, especially, flow directions of the fluids from which the diagenetic carbonates have formed. This is because strontium isotopes, as opposed to the more commonly used stable isotopes of oxygen and carbon, are not fractionated by pressure, temperature, and (as in the case of carbon) microbial processes.

The direction of fluid flow can also be determined using trace elements, which is especially attractive because trace element analysis is the cheapest of all the common geochemical methods. Trace element trends have been documented in several Phanerozoic dolostone sequences.

For all practical applications, i.e., the determination of fluid composition and/or fluid flow direction, the absence, presence, and/or degree of recrystallization is important. If changes via recrystallization in texture, structure, composition, and/or palaeomagnetic properties are so small that the total data range after recrystallization is the same as when the dolomite first formed, a dolomite/dolostone is said to be 'insignificantly recrystallized' (**Figure 14**, top), and its properties are still representative of the fluid and environment of dolomitization. On the other hand, if these changes result in data ranges that are larger than

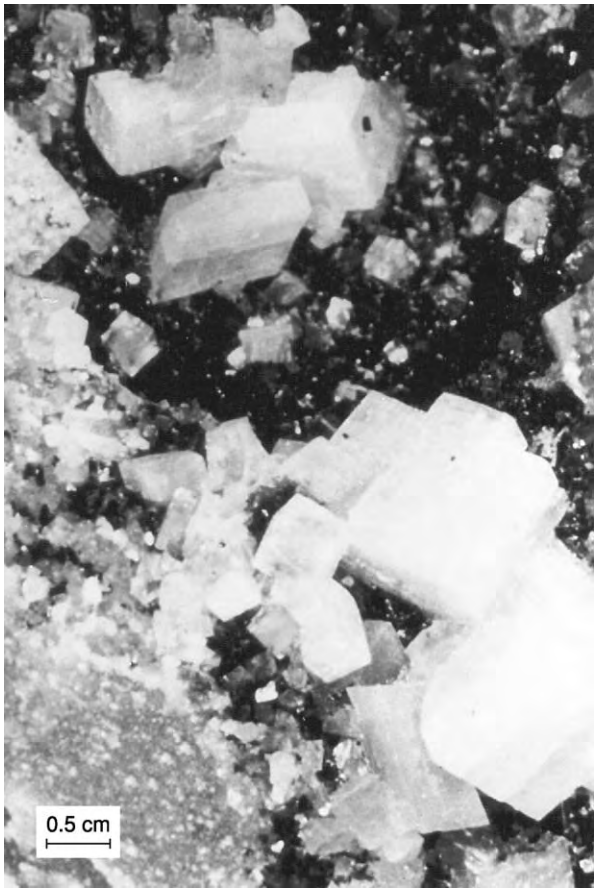

Figure 11 Core specimen of milky white saddle dolomite cement in a vug that is coated with solid bitumen ('dead oil'). Host rock is grey matrix dolomite. Saddle dolomite appears as a large crystal in the centre and lower right, with undulous extinc tion. From the Devonian Nisku Formation, Alberta, Canada.

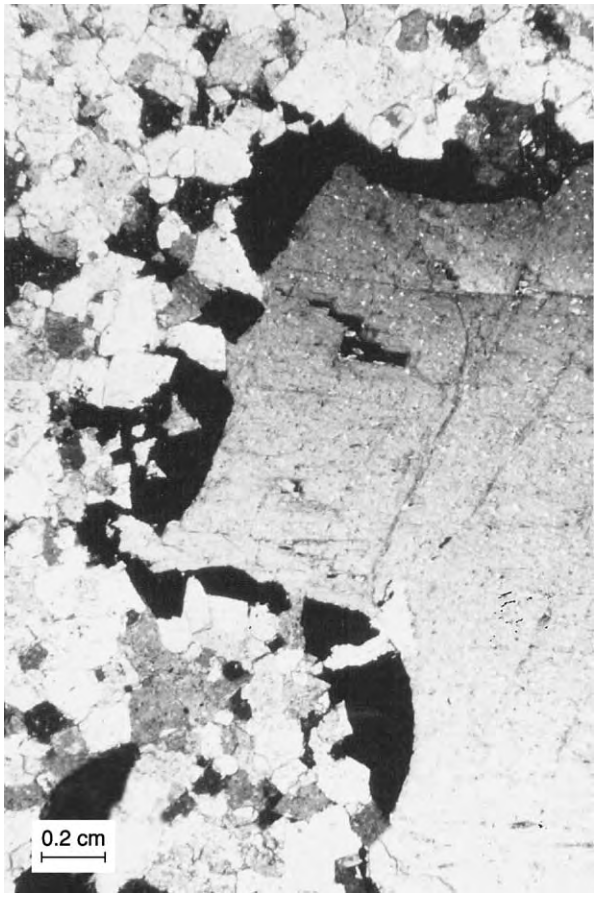

Figure 12 Thin section photomicrograph (transmitted light with crossed polarizers) of the sample shown in Figure 11.

the original ones, a dolomite/dolostone is said to be 'significantly recrystallized' (Figure 14, bottom), and its properties are no longer representative of the fluid and environment of dolomitization. In this case, the measured properties are reset and they characterize the last event of recrystallization. Furthermore, not all measurable properties must be reset during recrystallization. For a dolomite to be recognized as significantly recrystallized, only one of the measurable properties has to be modified to a range larger than the original one. In this case, inherited properties may still represent the event of dolomitization, whereas reset properties represent recrystallization.

Most dolomites that originally form very close to the surface and/or from evaporitic brines tend to recrystallize with time and during burial, because they form as metastable protodolomite phases that become thermodynamically highly unstable as a result of increasing temperature, increasing pressure, and changing fluid composition. On the other hand, dolomites that form at several hundred to a few thousand metres of depth are not or hardly prone to recrystallization, because these dolomites tend to form as rather stable (nearly stoichiometric, well-ordered) phases, whose stability does not change much during further burial and with increasing time.

Another important aspect of dolomite research requiring the application of geochemical methods is the recognition of hydrothermal activity. In many studies, the presence of saddle dolomite has been taken as an indication of elevated heat flow and/or increased temperatures during dolomite formation. However, the presence of saddle dolomite merely indicates a temperature of formation that is relatively high in the context of diagenetic studies. Its presence in uplifted dolomites, or in structurally inverted subsurface systems currently at lower temperatures, may merely reflect processes formerly operating at depths (and temperatures) at or around maximum burial and with normal geothermal gradients. Saddle dolomite may be hydrothermal, geothermal, or hydrofrigid (Figure 15). A distinction between these

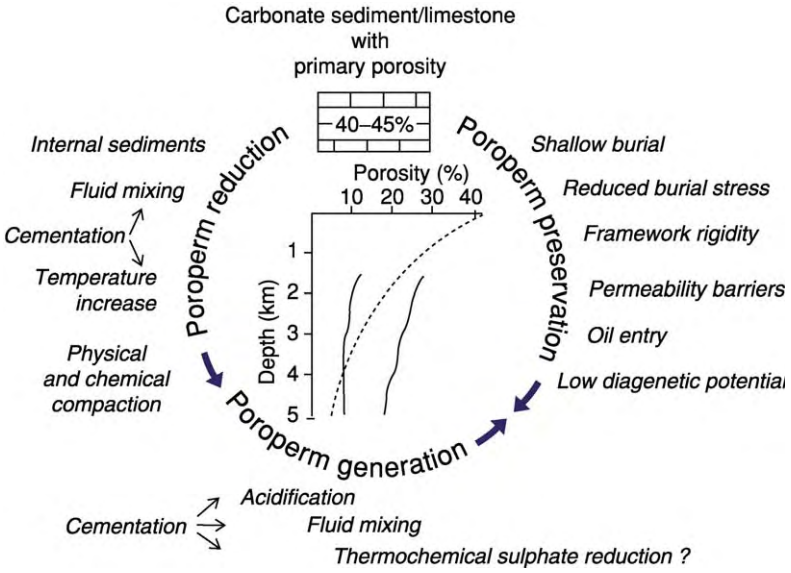

Figure 13 Major processes of porosity and permeability ('poroperm') generation, preservation, and reduction in carbonates. The inset contains averaged porosity/depth data from Mesozoic and Cenozoic limestones and dolostones in south Florida (broken curve; from Schmoker and Halley (1992)) and from the Jurassic Smackover oolite carbonate reservoirs in the southern USA (full curves, which envelop the measured maximum and minimum values below depths of about 1.5 km; from Scholle and Halley (1985) and Heydari (1997)). The Florida trend can be considered typical for most carbonates elsewhere. The large variations in Smackover carbonates at any given depth reflect highly variable degrees of porosity generation, preservation, and reduction due to various competing diagenetic processes. alternatives can only be made if the temperature of formation of saddle dolomite is considered relative to the temperature of the surrounding rocks at the time of saddle dolomite formation, e.g., via fluid inclusion data in silicates or other carbonates, vitrinite reflectance data, reconstruction of maximum burial and geothermal gradient, etc.

Environments and Models of Dolomitization

In near-surface and shallow diagenetic settings, dolomitization models are defined and/or based on water chemistry, but on hydrology in deeper burial diagenetic settings. This poses an obvious dilemma when some type of near-surface diagenetic fluid moves into the deeper subsurface, and when deeper subsurface fluids (commonly brines) ascend into shallow diagenetic settings. Research over the last 15–20 years has revealed several such 'cross-overs' or 'overlaps' between models, which has resulted in unnecessary ambiguities in semantics and classification.

Penecontemporaneous Dolomites and the Microbial/Organogenic Model

In shallow marine to supratidal environments, penecontemporaneous dolomites commonly form in quantities of <5 vol.%, mostly as Ca-rich and poorly ordered, microcrystalline to fine crystalline cements and/or directly from aqueous solution. These occurrences include: lithified supratidal crusts (e.g., Andros Island, Sugarloaf Key, Ambergris Cay); thin layers in salinas (e.g., Bonaire, West Caicos Island) and evaporative lagoons/lakes (e.g., Coorong); and fine crystalline cements and replacements in peritidal sediments (e.g., Florida Bay, Andros Island). The dolomite-forming fluids are normal seawater and/or evaporated seawater, in some cases with admixtures of evaporated groundwater. There are also cases of penecontemporaneous dolomite formation in association with volcanics or volcanic activity, dolomite as fine crystalline supratidal weathering products of basic rocks, and hydrothermal dolomite forming at submarine vents. One especially important type in this group, commonly classified under hypersaline dolomites, forms lenses and layers of up to 100 vol.% dolomite in sabkhas.

Penecontemporaneous dolomites in hemipelagic to pelagic settings commonly form in very small quantities as microcrystalline protodolomites, generally with less than 1 wt.%. However, under favourable circumstances, the amount of dolomite can reach up to 100 vol.% locally. For example, Miocene hemipelagic carbonate sediments from the margin of the

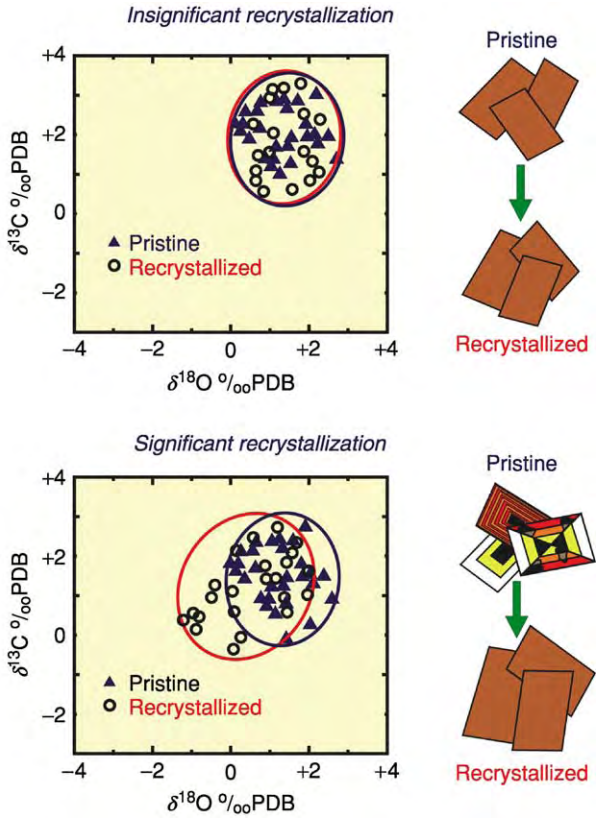

Figure 14 Schematic illustration of insignificant and significant recrystallization. For the properties shown, i.e., $\delta^{13}C$ and $\delta^{18}O$ values, crystal sizes, and luminescence, the pristine and recrystallized samples are the same in the case of insignificant recrystallization, but different, despite some overlap, in the case of significant recrystallization, i.e., at least some isotope values of the recrystallized samples fall outside the range of the pristine samples. The crystals also have increased in size and lost their respective zonations (concentric, sector, oscillatory). Reproduced with permission from Machel HG (1997) Recrystallization versus neomorphism, and the concept of 'significant recrystallization' in dolomite research. *Sedimentary Geology* 113: 161–168.

Great Bahama Bank are partially to completely dolomitized over a depth range of about 50–500 m subsea. In this setting, dolomite forms as a primary void-filling cement and by replacing micritic sediments, red algae, and echinoderm grains.

Both settings of penecontemporaneous dolomite formation mentioned above appear to be linked to the 'microbial model' or 'organogenic model' of dolomitization. According to this model, dolomite may be formed syndepositionally or early postdepositionally, i.e., at depths of a few centimetres to a few hundred metres, under the influence of, or promoted by, bacterial sulphate reduction and/or methanogenesis. The latter is indicated by organogenic $\delta^{13}C$ values. The exact role of microbial activity in reducing the notorious kinetic barriers to dolomitization is unknown, although it seems likely that the reduction of Mg and Ca hydration barriers, an increase in alkalinity, and/or changes in pH are involved. Most microbial/organogenic dolomites are cements; some are replacive, typically fine crystalline to microcrystalline (less than 10 μm), calcic and poorly ordered protodolomites. The chief modes of Mg supply are diffusion from the overlying seawater and/or release from Mg calcites and clay minerals, which obviously places severe limits on the amounts of dolomite that can be formed. Microbial/organogenic dolomites may act as nuclei for later, more pervasive dolomitization during burial.

Hyposaline Environments and the Mixing Zone Model

Hyposaline environments are those with salinities below that of normal seawater (35 g l^{-1}). These environments include coastal and inland freshwater/seawater mixing zones, marshes, rivers, lakes, and caves. Virtually all hyposaline environments are near-surface to shallow burial diagenetic settings at depths of less than about 600–1000 m.

One hyposaline environment, the coastal freshwater/seawater mixing zone (often simply called mixing zone), has given rise to one of the oldest and most popular models, i.e., the 'mixing zone model' (also called the Dorag model) for dolomitization. However, the mixing model has been overrated with regard to its potential to form massive dolostones. Not a single location in the world has been shown to be extensively dolomitized in a freshwater/seawater mixing zone, in recent or in ancient carbonates, and several lines of evidence indicate that massive dolomitization in mixing zones is so unlikely as to be virtually impossible. Rather, mixing zones tend to form only very small amounts of dolomite, commonly along with substantial dissolution porosity, up to the scale of caves. A striking example is the vast cave system with essentially no dolomite generated by mixing zone diagenesis along the coastline of the Yucatan Peninsula, Mexico. The main role of coastal mixing zones in dolomitization may be as a hydrological pump for seawater dolomitization, rather than a geochemical environment favourable for dolomitization.

Most true mixing zone dolomites are petrologically and geochemically distinct. The crystals tend to be relatively clear, planar-e or planar-s, stoichiometric, well-ordered rhombs. However, some mixing zone dolomite is protodolomite. Crystal sizes commonly range from 1 to 100 μm, but may reach several millimetres in some cases. Most mixing zone dolomite occurs as cements in microscopic interstices and macroscopic voids, moulds, vugs, and caverns, and

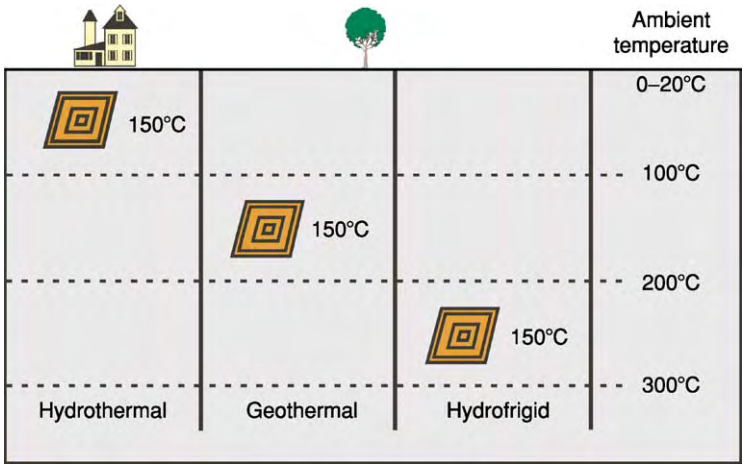

Figure 15 Hydrothermal, geothermal (formed in thermal equilibrium with the surrounding rocks), and hydrofrigid mineral formation. Reproduced with permission from Machel HG and Lonnee J (2002) Hydrothermal dolomite a product of poor definition and imagination. *Sedimentary Geology* 152: 163 171.

subordinately as a replacement. Alternating generations or growth zones of calcite/dolomite are common in coastal mixing zones with rapid and cyclical changes of salinity.

Hypersaline Environments and the Reflux and Sabkha Models

Hypersaline environments have salinities greater than that of normal seawater and are widespread at latitudes of less than about 30°, while some occur at even higher latitudes. Hypersaline environments thus defined include the so-called mesohaline (also called penehaline) environments, which are mildly hypersaline, i.e., between normal seawater salinity ($35\,g\,l^{-1}$) and that of gypsum saturation (about $120\,g\,l^{-1}$). In all these types of environment, dolomite is formed from water whose salinity is controlled by surface evaporation, that is, in near-surface and shallow burial diagenetic settings.

The (evaporative) reflux model of dolomitization was originally proposed for seawater evaporated beyond gypsum saturation in lagoonal and shallow marine settings on a carbonate platform behind a barrier, such as a reef. Surficial water circulation on the platform is severely restricted because of the barrier, which leads to evaporation and a landward salinity gradient behind the barrier. The evaporated seawater flows downwards into and seaward through the platform sediments because of its increased density (active reflux), thereby dolomitizing the penetrated sediments. Platforms can be penetrated by mesohaline reflux to depths of several hundred metres. Furthermore, numerical modelling predicts that 'latent reflux' flows the a platform after the evaporative generation of brine ceases at the platform top, which can be expected after a significant rise in sea-level with concomitant freshening of the waters on the platform. However, a platform can be dolomitized completely only if it has very high permeability and does not contain aquitards (such as shale or evaporite layers), and if reflux is permitted to persist for a very long time. The published literature provides several examples of localities that probably were dolomitized by evaporative reflux, including the Permian carbonates of west Texas and New Mexico, and the peritidal Jurassic carbonates of Gibraltar. Whether active or latent, all refluxing brines exit or even landward of the platform margin, which confines reflux dolomitization to the platform interior.

The sabkha model of dolomitization is hydrologically and hydrochemically related to the reflux model. Sabkhas are intertidal to supratidal deflation surfaces that are flooded episodically. In the sabkha of the Trucial Coast of Abu Dhabi, the type location of the sabkha model for dolomitization, Mg for dolomitization is supplied synsedimentarily/penecontemporaneously by seawater that is propelled periodically onto the lower supratidal zone and along remnant tidal channels by strong onshore winds. The seawater has normal to slightly elevated salinity (up to about $38\,g\,l^{-1}$), but becomes significantly evaporated beyond gypsum saturation on/within the supratidal flats, through which it refluxes via its increased density, similar to flow in the reflux model. Sabkha dolomite appears to form via evaporative pumping in a narrow (1–1.5 km) fringe next to the strandline, and in the flooded tidal channels that extend more landward. In

the Abu Dhabi sabkha, the best dolomitized parts contain 5 to about 65 wt.% protodolomite. Dolomite forms as a cement and aragonite is replaced, but lithification does not occur, or only partially. Furthermore, dolomitization is restricted to the upper 1–2 m of the sediments, and appears to be most intense where the pore waters become chemically reducing, which leads to enhanced carbonate alkalinity via sulphate reduction and/or microbial methanogenesis. Therefore, sabkha dolomites are texturally and geochemically similar to organogenic dolomites in some respects, i.e., they tend to form as protodolomite and may have reduced carbon isotope ratios. In most respects, the Abu Dhabi sabkha appears to be a good recent analogue for dolomitization in many ancient intertidal to supratidal flats, such as landward of the famous Permian carbonates of Texas and New Mexico. Rather than forming reservoir rocks, these dolostones – including the associated evaporites – generally form tight seals for underlying hydrocarbon reservoirs. More generally, sabkhas and similar intertidal to supratidal environments in more humid climates typically form small quantities of fine crystalline protodolomite in thin beds, crusts, or nodules, either within the upper 1–2 m of sediment, or at the sediment surface. Repeated transgressions and regressions may stack such sequences upon one another to cumulative thicknesses of several tens of metres.

Seawater Dolomitization

Most postdepositional formation of massive dolostones probably results from 'seawater dolomitization'. There are a group of models of seawater dolomitization, whose common denominator is seawater as the principal dolomitizing fluid, and which differ in hydrology and/or depth and timing of dolomitization. All dolomites belonging to this group are postdepositional.

The Cenozoic dolostones of the Bahama platform, often used as an analogue for older dolomitized carbonate platforms elsewhere, can be considered the type location for seawater dolomitization. Extensive petrographical and geochemical data indicate that seawater and/or chemically slightly modified seawater was the principal agent of dolomitization in the Bahama platform at shallow to intermediate depths and commensurate temperatures of less than about 60°C.

The hydrology of and during seawater dolomitization is still very much contested. Various hydrological systems have been invoked to drive the large amounts of seawater needed for pervasive dolomitization through the Bahama platform, i.e., thermal convection, a combination of thermal seawater convection and reflux of slightly evaporated seawater derived from above, or seawater driven by an overlying freshwater/seawater mixing zone during partial platform exposure, possibly layer by layer in several episodes.

The Bahamas' dolostones actually represent a hybrid with regard to the traditional, conventional classifications of models. Petrographical and geochemical data indicate that seawater was the principal dolomitizing agent, yet thermal convection, as a hydrological system and drive for dolomitization, is better classified under the burial (subsurface) models discussed below. Analogously, the regionally extensive Devonian dolostones in Alberta, western Canada, are also a hybrid with regard to the conventional dolomitization models. These Devonian dolostones probably formed at depths of 300–1500 m at temperatures of about 50–80°C from chemically slightly modified seawater, and have been classified as burial dolostones. Another example is represented by the regionally extensive dolostones of the Carboniferous of Ireland, which are petrographically and geochemically very similar to the Devonian dolostones of Alberta, and whose genesis has been interpreted in an analogous manner. In all cases, the hydrology that facilitated dolomitization is unclear, with thermal convection, reflux, compaction, tectonic expulsion, or a combination thereof, as alternatives. The regionally extensive dolostones of the Cretaceous Soreq Formation in Israel represent a Mesozoic example of this type of dolomitization. These Palaeozoic and Mesozoic dolostones can be (re-)classified along with the Cenozoic Bahama dolostones as 'seawater dolomites'. This classification dilemma arises from the historical evolution of our understanding of these dolostones, rather than invalidating the earlier 'burial' interpretations.

Intermediate to Deep Burial (Subsurface) Environments and Models

Burial (subsurface) environments are those removed from active sedimentation by burial, and in which the pore fluid chemistry is no longer entirely governed by surface processes, i.e., where water–rock interaction has modified the original pore waters to a significant degree, or where the fluid chemistry is dominated by subsurface diagenetic processes. The textures, porosities, and permeabilities of dolostones formed in intermediate and deep burial settings are variable. These textures in themselves are not indicative of the depth of burial. However, three specific textural characteristics may be used to indicate considerable burial: dolomites cross-cut by stylolites suggest burial of at least 600 m (stylolites in dolostones appear to require at least 600 m of burial); the absence of planar

crystals suggests temperatures of formation or recrystallization in excess of the critical roughening temperature of about 50°C; and the presence of saddle dolomite suggests temperatures of formation in excess of about 80°C.

All burial (subsurface) models for dolomitization essentially are hydrological models. They differ mainly in the hydrological drives and direction(s) of fluid flow. Four main types of fluid flow take place in subsurface diagenetic settings: (1) compaction flow; (2) thermal convection; (3) topography driven flow; and (4) tectonically driven flow. Combinations of these flow regimes and associated fluid compositions are possible under certain circumstances.

The oldest burial model of dolomitization is the compaction model, according to which seawater and/or its subsurface derivative(s), that were buried along with the sediments, are pumped through the rocks at several tens to several hundreds of metres as a result of compaction dewatering.

The compaction model in its original form was never especially popular because burial compaction can only generate fairly limited amounts of dolostone due to the limited amounts of expelled water. However, despite this mass balance constraint, the compaction model remains a viable alternative for burial/subsurface dolomitization where funnelling of the compaction waters is/was possible.

Thermal convection is driven by the temperature gradient prevailing across sedimentary strata, which is vertical in most geological situations, except in cases of vigorous advection, igneous intrusions, or in the proximity to plate boundaries and/or orogenic fronts, all of which can 'distort' the normal subvertical temperature gradient. Where the temperature gradient and average rock permeability are high enough, convection cells may become established. In principle, there are two types of convection, i.e., open and closed, although mixed cases are possible. Open convection cells (also called half-cells) may form in carbonate platforms that are open to seawater recharge and discharge laterally and at the top, respectively. Numerical modelling has shown that the magnitude and distribution of permeability are the most important parameters governing flow and dolomitization, and that this type of convection can be active to a depth of about 2–3 km, provided that the sequence does not contain effective aquitards, such as (overpressured) shales or evaporites. The amounts of dolomite that can be formed are theoretically very large, i.e., dolomite can be formed as long as convection is sustained, because Mg is constantly (re-)supplied from the surrounding seawater. However, even at a moderate width of only 40 km, complete dolomitization in a 2 km thick sequence takes about 30–60 million years, which is much longer than the time during which most carbonate platforms remain laterally open to seawater recharge. Hence, most carbonate platforms, even if subjected to thermal convection by seawater, would at best become only partially dolomitized during the time that they were open to seawater recharge.

Closed convection can occur, in principle, in any sedimentary basin over tens to hundreds of metres of thickness, provided that the temperature gradient is high enough relative to the permeability of the strata. As a rule of thumb, however, such convection cells will only be established, and capable of dolomitizing a carbonate sequence of interest, if a sequence is highly permeable and not interbedded with aquitards. Such conditions are rarely fulfilled in typical sedimentary basins, most of which do contain effective aquitards. Furthermore, even if closed thermal convection cells are established, the amounts of dolomite that can be formed are limited by the pre-convection Mg content of the fluids, even more so than in the case of compaction flow, as no new Mg is supplied to the system and 'compaction funnelling' is not possible. Therefore, extensive, pervasive dolomitization by closed cell thermal convection is highly unlikely.

Convection cells invariably have rising limbs that penetrate the overlying and cooler strata, linking thermal convection to hydrothermal dolomitization. There are well-documented examples of hydrothermal dolomite on a local and regional scale. Most cases of hydrothermal dolomitization are rather small and restricted to the vicinity of faults and fractures and/or localized heat sources. One striking case of this type is the Pb–Zn mineralized Navan dolomite plume in Ireland, and another is a dolomitized plume in the Latemar in the Italian Alps. There are also some cases of larger scale, even regionally extensive hydrothermal dolomitization, such as the Middle Devonian Presqu'ile barrier, which forms an aquifer in northwestern Canada that contains abundant saddle dolomite as a replacement and as a cement, including MVT-type mineralization near the discharge area at Pine Point. Texturally, most true hydrothermal dolomite is saddle dolomite.

Topography driven flow takes place in all uplifted sedimentary basins that are exposed to meteoric recharge. With time, topography can drive enormous quantities of meteoric water through a basin, often concentrated by water–rock interaction (especially salt dissolution), and preferentially funnelled through aquifers. Volumetrically significant dolomitization can only take place, however, where the meteoric water dissolves enough Mg *en route* before encountering limestones. This does not appear to be common.

Another type of flow that has been suggested to result in pervasive dolomitization is tectonically driven squeegee-type flow. In this type of flow system, metamorphic fluids are expelled from crustal sections affected by tectonic loading so that basinal fluids are driven towards the basin margin. Metamorphic fluids could be injected into compaction and/or topography driven flow, with attendant fluid mixing. However, it is doubtful whether tectonically induced flow, or the related fluid mixing, can form massive dolostones. Diagenetic studies on this type of flow system suggest that the fluxes are low and short lived.

Secular Distribution of Dolostones

The relative abundance of dolostones that originated from the replacement of marine limestones appears to have varied cyclically through geological time, commonly referred to as secular variation. Early data suggested that dolomite was most abundant in rocks of the Early Palaeozoic systems and decreased in abundance with time. Relatively recent reassessments of the dolomite distribution throughout time revealed two discrete maxima of 'significant early' dolomite formation (massive early diagenetic replacement of marine limestones) during the Phanerozoic, i.e., the Early Ordovician/Middle Silurian and the Early Cretaceous.

Various explanations have been proposed for this phenomenon, i.e., that periods of enhanced early dolomite formation were related to or controlled by plate tectonics and related changes in the compositions of the atmosphere and seawater, such as an increased atmospheric CO_2 level, high eustatic sea-level, low saturation state of seawater with respect to calcite, changes in the marine Mg/Ca ratio, or low atmospheric O_2 levels that coincided with enhanced rates of bacterial sulphate reduction. It appears possible that a combination of two or more of these factors was involved. Perhaps the most elegant explanation is that the secular dolomite variations are the result of the lengthy induction period for dolomite formation that was observed in laboratory experiments. Marine carbonates in prolonged contact with seawater may be dolomitized because they remained in contact with the dolomitizing solution (seawater) long enough to exceed the induction period. On the other hand, undolomitized carbonates were not in contact with seawater for long enough, and metastable precursors to dolomite that may have formed were destroyed by freshwater diagenesis during intervening periods of exposure. The secular variations in marine dolomitization may thus reflect periods of seawater contact longer or shorter than the induction period.

Evaporites

A C Kendall, University of East Anglia, Norwich, UK

Deposits Produced by the Evaporation of Seawater

Seawater is considered to be the major or the only feedstock capable of generating large bodies of evaporite. All deposits of potash salts are associated with large basin-central evaporites and, consequently, are believed by most to have been formed by the evaporation of seawater. The problem with this marine origin is that the chemical and mineralogical characters of most potash deposits depart significantly from those that would be expected from simple seawater evaporation. If the marine origin is correct, then other processes must have been involved to cause the differences.

Seawater becomes progressively more concentrated as it evaporates until it is supersaturated with respect to a particular mineral phase, which then precipitates. Precipitation of a salt preferentially extracts chemical components from the seawater-derived brine, altering its overall composition. Initially, calcium combines with bicarbonate, but, after seawater has been concentrated approximately 3.5 times, gypsum ($CaSO_4 \cdot 2H_2O$) saturation is reached and calcium and sulphate are extracted from the brine. Seawater contains abundant sulphate, and, after the greater part of the calcium has been extracted (as carbonates and as gypsum), fully two-thirds of the original sulphate remains in the brine. At this stage, and in all subsequent stages of evaporation, a marine-derived brine will be impoverished in calcium and should contain abundant sulphate.

The next mineral to precipitate by continued seawater evaporation is halite (NaCl), and this extracts sodium and chloride from the brine. At about 60 times seawater concentration, the sulphate remaining in the brine should begin to be removed in the form of various magnesium sulphate minerals. Only after considerable amounts of sulphate have been eliminated from the brine will the next mineral – carnallite (hydrated magnesium and potassium chloride) – precipitate. Finally, at the last stages of concentration, the mineral bischoffite ($MgCl_2$) is precipitated.

Typical Composition of Evaporite Deposits

Only about 10% of all potash-bearing evaporites contain significant quantities of magnesium sulphate, which would be expected from simple seawater evaporation. Of these 10%, all differ from direct seawater precipitation sequences in having different magnesium sulphate minerals in different amounts from those expected. These differences can be explained in two ways. First, most magnesium sulphates precipitated during experimental seawater evaporation are highly unstable hydrous phases. These alter to less hydrous minerals upon burial. Second, during evaporation, the concentrated brines may react with previously precipitated calcium sulphate to form the mineral polyhalite. This reaction removes sulphate and potassium from the brine, so changing its composition. Further evaporation of this modified brine is capable of generating the mineral sequences found in 10% of potash salt deposits.

The majority of potash salts, however, differ substantially from those expected to result from seawater

evaporation. After halite has precipitated, the next mineral to appear is carnallite (hydrous magnesium and potassium chloride) or sylvite (potassium chloride); usually there are no magnesium sulphates. The uppermost parts of some deposits, especially from the Atlantic-marginal Cretaceous salt basins of Brazil and Gabon, also contain the mineral tachyhydrite (hydrous calcium chloride). This highly soluble salt (which dissolves in atmospheric moisture) must represent the final evaporative stages of a brine. However, if this brine were concentrated seawater, then all the available calcium should have been extracted at a much earlier evaporative stage, during gypsum and early-stage halite precipitation.

Sylvite should not precipitate during simple seawater evaporation. Some sylvite can be explained as a later alteration product of carnallite, but in other cases textural evidence indicates that sylvite is a primary mineral. The absence of magnesium sulphates cannot be explained by later diagenetic changes (for instance, converting them to carnallite) because textural evidence also suggests that much carnallite is primary.

The Missing Sulphate

The brines that precipitated potash deposits low in magnesium sulphate did not lack magnesium (carnallite and bischoffite contain this element), and so the problem is to explain why marine-derived evaporites are impoverished in sulphate in their later evaporative stages.

Explanations of this missing marine-derived sulphate are unsatisfactory. One hypothesis suggests that sulphate is removed from the brine by the addition of river water containing additional calcium. This calcium strips the brine of its remaining sulphate by the precipitation of additional gypsum. Simple calculations indicate that the amount of river water needed would be enormous and more than enough to dilute the brines so that no evaporites would form in the first place.

A commonly proposed explanation is that sulphate is removed by the activity of sulphate-reducing bacteria. The sulphate is reduced to hydrogen sulphide, which is then lost to the atmosphere. Hite convincingly argued, by analogy with Holocene environments, that sulphate reduction would be confined to the uppermost metre of sediment, and so the sulphate-reducing capabilities of evaporite basins would be limited. His calculations showed that bacteria would be unable to remove all the seawater sulphate and, furthermore, that the amount of organic carbon required to reduce the marine sulphate could not be supplied, even if evaporite basins were extraordinarily productive.

The problem of the missing sulphate exists only if seawater was the original feedstock. It is clear from the presence of tachyhydrite in some sequences that either the seawater was substantially modified or some other water was evaporated to generate the potash salts. In essence, no brine containing more sulphate than calcium (including all modern seawater-derived brines) can generate tachyhydrite and evaporites deficient in magnesium sulphate, whereas these sequences can be generated if waters are used where more calcium than sulphate is present. By definition, any concentrated water that has excess calcium (calcium $>$ sulphate $+$ bicarbonate) is a calcium chloride brine.

Hardie believed that evaporites that are impoverished in magnesium sulphate formed by the evaporation of calcium chloride brines that were generated in rift or transtensional basins – basins with high heat flows and active hydrothermal groundwater circulations. Calcium chloride brines are being expelled today in these types of basin. Groundwater circulates deep in the crust and reacts with hot host rocks. Hydration of host-rock minerals removes water, concentrating the groundwater into a brine. The hot brine reacts with calcium-bearing minerals, commonly feldspars (exchanging sodium for calcium), and some of the expelled calcium reacts with any groundwater sulphate to precipitate anhydrite, thus stripping the brine of its contained sulphate. The final product is a brine that is depleted in sulphate and enriched in calcium. When heated, these brines become buoyant and may be expelled to the surface, where they evaporate.

Evaporites as Hydrothermal Deposits in Rift Basins

Rift and transtensional basins are ideal locations for evaporites to form. Commonly they are isolated or have very restricted access to the ocean. Even if they are not located in arid climatic zones, they may develop evaporites by virtue of uplifted rift shoulders or transpression ridges causing orographic aridity. Calcium chloride waters entering such basins as hot springs can evaporate and generate evaporite sequences without magnesium sulphate minerals. Many evaporites deficient in magnesium sulphate are located in present-day and ancient rift basins.

When hydrothermal waters are the only feedstock, the resultant evaporites may be entirely deficient in calcium and other sulphates. Evaporite sequences should have little, if any, gypsum and anhydrite. It is also possible, however, that the main water in the basin is seawater but that this is substantially modified by the addition of relatively small volumes of

hydrothermal brines, which nevertheless carry large amounts of dissolved materials. Hardie calculated that modern seawater could be modified by the addition of only just over 3% Salton Sea brine into water that would not precipitate evaporites containing magnesium sulphate.

Evaporites in Non-Rift Basins

Hardie's hydrothermal brine explanation is not convincing for some evaporite sequences because they occur in non-rift basins. Kendall provided an alternative explanation for some of these evaporites. Desiccation of large evaporite basins produces large and deep depressions. This induces a hydrodynamic drive, which causes subsurface waters to migrate into the basins, where they evaporate. Dolomitization of limestones by migrating formation waters with seawater-like compositions would release calcium and generate calcium chloride waters. Basin desiccation thus provides both the drive that allows formation waters to enter the basin and a mechanism to generate waters with more calcium than sulphate. Middle Devonian evaporites in western Canada provide evidence to support this desiccation–drive model. Where calcium-rich formation waters entered the Devonian evaporite basin, spring-associated carbonates were precipitated, and there was mixing with seawater-derived brines that had already precipitated gypsum. The addition of spring-water calcium stripped the remaining sulphate from the basin brine, precipitated anomalous concentrations of calcium sulphate far into the evaporite basin, and led to the formation of a sulphate-depleted brine, which may have caused later potash salts deficient in magnesium sulphate to form in the basin.

Halite-saturated brines, refluxing beneath large evaporite basins, react with all types of sediments (not just limestones) by exchanging sodium for calcium, to generate calcium chloride brines. The main problem in understanding how these deep dense brines could form potash salts is to explain how the brines are transported to the surface. This could occur at times of basin inversion, by heating (creating buoyant hydrothermal brines) or by evaporative draw into a later evaporite basin.

Past Composition of Seawater

A more exciting alternative that explains the seemingly anomalous compositions of most ancient potash salts is that seawater compositions were substantially different in the past. Secular variations in the distributions of magnesium sulphate and evaporites deficient in magnesium sulphate are in phase with better-known variations in the mineralogy of ancient marine carbonates. These secular variations can be attributed to changes in the major-ion composition of seawater over time.

A model that explains how seawater can change over time was used to predict periods when aragonite and evaporites containing magnesium sulphate are dominant, and episodes when calcite and evaporites deficient in magnesium sulphate are favoured. Seawater chemistry is controlled by steady-state mixing of river water and mid-ocean ridge hydrothermal brines (coupled with calcium carbonate and silica precipitation). Relatively small changes in mid-ocean ridge fluxes cause significant changes in magnesium : calcium, sodium : potassium, and chloride : sulphate ratios in seawater. Such changes are believed to be responsible for variations in the primary mineralogies of marine evaporites and carbonates. Variations in mid-ocean ridge flux correspond to variations in the production rate of oceanic crust (seafloor spreading rate), and this can be estimated using various proxies, such as areas of ocean floor of different ages, the global sea-level curve, and granite-pluton emplacement rates.

Predictions of the variation in past seawater chemistry produced by variation in mid-ocean-ridge flux rates are in agreement with the known age distribution of primary marine carbonate and evaporite mineralogies. The coherence of the datasets strongly suggests that past variations in evaporite and carbonate mineralogy were largely caused by secular variations in seawater chemistry.

The idea that varying seawater chemistry can explain potash salt composition has been challenged. Holland *et al*. predict similar changes of seawater composition but of much smaller magnitude. They argue that an apparent near constancy of the level of potassium in seawater during the Phanerozoic (demonstrated by the compositions of brines trapped in ancient halites) supports this view: Hardie's model predicts significant changes in the sodium : potassium ratio. Instead, Holland *et al*. suggest that changes in past evaporite mineralogy are due to differences in the extent to which dolomitization of carbonate sediments occurred before or during seawater evaporation. During times of rapid seafloor spreading, sea-levels are higher and large carbonate platforms are more abundant. Changes in seawater chemistry (caused by increased mid-ocean ridge flux) coupled with increases in the extent of dolomitization of carbonate platforms are believed to be responsible for the formation of potash deposits that are impoverished in magnesium sulphate. This explanation resembles, in part, that suggested earlier by Kendall.

Variations in the chemistry of primary fluid inclusions from ancient halite deposits are significant. They also imply that seawater chemistry has changed significantly. Variations are in phase with inferred seafloor spreading rates, global changes in sea-level, and the primary mineralogies of ancient marine carbonates and evaporites. Of particular significance is the fact that inclusions in halites of the same age from different geological basins exhibit similar compositions. This suggests that the association with dolomitization (proposed by Holland *et al*.) is incorrect: more interbasin variation in the amount of dolomitization would be expected, resulting in a greater variation in the chemistry of fluid inclusions than that observed. It is surprising, however, that the question of whether or not variations in sodium : potassium ratios match model predictions was not addressed. More recent, unpublished, work suggests that Cretaceous and Permian seawaters were enriched in potassium and relatively depleted in sodium, as would be expected from the Hardie hypothesis.

Ironstones

W E G Taylor, University of Lancaster, Lancaster, UK

Introduction

Ironstones have been critical to industry and industrial revolutions. They have been essential raw materials since the dawn of the Iron Age (about 700 BC). Without iron-rich deposits many of the manmade structures and utensils that we take for granted today – tall urban buildings, power pylons, bridges, ships, cutlery, hammers, saws, and the seemingly indispensable motor car – could not exist.

The point at which an ironstone deposit is considered to be an ore has changed considerably over the years and depends upon the particular economic, technological, social, and political circumstances at the time. Nowadays deposits need to have an iron content in excess of 60% by weight to be worked, whilst in the mid-twentieth century ironstones with 28% iron by weight were regularly extracted as ores. The quality of the potential ore, and in particular the proportion of phosphatic material, is an important factor that has to be considered in the mining of iron.

Initially, the availability of water power and the proximity of coal were the factors controlling production. The middle of the nineteenth century saw a change from coal-fired furnaces producing cast iron to the Bessemer process, which produced steel. Later in the same century, the open-hearth process and various refinements were developed. Each of these new production processes demanded ores of a particular quality.

Records of global production are scarce before the latter half of the twentieth century, and certainly in Europe much of the exploitation predates that century. In Great Britain the maximum annual output was in the order of 18 Mt (Milliontonnes) and occurred during two main periods – 1870–1890 and 1940–1945. In the former period the main type of ore extracted was from the blackband and claystone ironstones (see below) of the Carboniferous rocks of various coalfields, whilst in the latter period the

Figure 1 Ordovician ironstones, Betws Garmon, North Wales, UK (inset showing the steeply inclined stoping method of under ground mining for the deposit and a residual pillar of magnetite rich material).

ooidal ironstones of Northamptonshire and Lincolnshire were the dominant ores. Although Ordovician ooidal ironstones from North Wales were extracted until early part of the twentieth century (Figure 1).

The terms used to describe both the processes of ironstone formation and the ironstones themselves have been many and varied. Attempts to simplify and standardize the terminology have recently met with some success, mainly through the International Geological Correlation Programme (IGCP). For example, the terms 'Clinton' (from the Silurian Clinton Group of New York State, USA) and 'Minette' (from the Jurassic Minette oolitic ironstones of northeastern France and adjacent areas) as descriptions of ironstone types have proved to be unsatisfactory and have now fallen into disuse.

Definition

Largely because iron may invade and impregnate a wide range of rocks, defining what constitutes an ironstone has proved difficult. Exhortations to merge the nomenclatures of the various iron-rich deposits, such as the banded iron formations and ironstones, have been resisted on the basis that the mineralogy, petrology, and genesis of these deposits are distinct and separate. A precise definition of 'ironstone' was agreed only in the last decade of the twentieth century and stems from the work of the IGCP 277 (Phanerozoic Ooidal Ironstones). Ironstones are sedimentary rocks consisting of at least 15% iron by weight, which may be quoted as 19% FeO or 21% Fe_2O_3 or an equivalent admixture in a chemical analysis. They occur almost exclusively in the Phanerozoic Era and are distinguished from the mainly Precambrian banded iron formations (*see* **Sedimentary Rocks:** Banded Iron Formations) by their lack of both regular banding and chert and by their age: banded iron formations were produced when there was a deficiency of oxygen in the Earth's atmosphere. The ferruginization (iron enrichment) may be the result of either direct deposition or subsequent chemical changes.

Ironstone Mineralogy

The iron-ore minerals may be oxides (including goethite, haematite, and magnetite), carbonates (usually siderite), or silicates (normally berthierine or chamosite). They may be associated with other carbonate minerals, sulphides and/or phosphatic minerals.

Goethite – FeO(OH) – is commonly formed by oxidation during weathering. Also, in many ooidal ironstones, it can result from the oxidation of berthierine; the two minerals may be found intermixed, often in alternate concentric layers, in ooids. Limonite was formerly thought to be a distinct mineral with the composition $2Fe_2O_3 \cdot 3H_2O$ but is now considered to have a variable composition (and properties) and to consist of several iron hydroxides (commonly goethite) or a mixture of iron minerals. Generally, it occurs as a secondary alteration product. Haematite – Fe_2O_3 – can be an important mineral in some ironstones, where it is usually formed as a late-stage

diagenetic product of the alteration of goethite. Experimental synthesis indicates that this transformation occurs at a temperature above 80°C and at a depth of about 2 km. Magnetite – Fe_3O_4 – normally forms during the low-grade metamorphism of ironstones, although the mineral has been reported from unmetamorphosed deposits in Libya.

Siderite – $(Fe,Mg,Ca,Mn)CO_3$ – is a very important mineral in ironstones. It is the only iron-bearing mineral in many claystone and blackband ironstones. Substitution of magnesium, calcium, or manganese for iron in the structure of siderite has been hypothesized to be related to the environment of formation. Substitution appears to have been greatest in marine sediments and in those ironstones formed during the later diagenetic stages of non-marine sediments.

Berthierine – $(Fe^{2+},Fe^{3+},Al,Mg,Mn)_2(Si,Al)_2O_5(OH)_4$ – is a 0.7 nm repeat serpentine. Reported variations in the chemical composition may reflect the analytical difficulties of dealing with very fine-grained samples. The formation of berthierine in ironstones is the subject of some debate and will be considered later. Chamosite – $(Fe_5^{2+},Al)(Si_3Al)O_{10}(OH)_8$ – is a 1.4 nm repeat chlorite with a very similar chemical composition to berthierine. Experimental work has shown that berthierine may be transformed into chamosite at a temperature of about 150°C and a depth of about 3 km. The phyllosilicate glauconite – $(K,Na)(Al,Fe^{3+},Mg)_2(Al,Si)_4O_{10}(OH)_2$ – is generally thought to be restricted to marine environments and occurs in some ironstones.

Other carbonate minerals, such as calcite, aragonite, dolomite, and ankerite – $Ca(Mg,Fe)(CO_3)_2$ – may be particularly common in ironstones both as a constituent of the cement and as discrete bioclasts. Phosphate minerals, such as francolite (carbonate fluorapatite) and vivianite – $Fe_3(PO_4)_2 \cdot 8H_2O$ – can be major components of ooidal ironstones. They can be a detrimental contributory factor to the viability of a deposit as an ore, particularly since, in most cases, the mineral grains are very small and difficult to separate.

Types of Ironstones

Extensive use of high-precision microscopy and analytical techniques has allowed detailed insights into the composition and formation of ironstones. A formal classification of ironstones has not yet been universally accepted, but three distinctive categories have been recognized (Figure 2).

Blackband Ironstones

Blackband ironstones are, typically, fossiliferous sapropel-rich (usually with an organic content in excess of 10%) finely laminated sideritic ironstones. Although non-laminated types are known, more frequently they are formed of alternating siderite- and organic-rich laminae. They are found almost exclusively above coal seams in a lacustrine parasequence

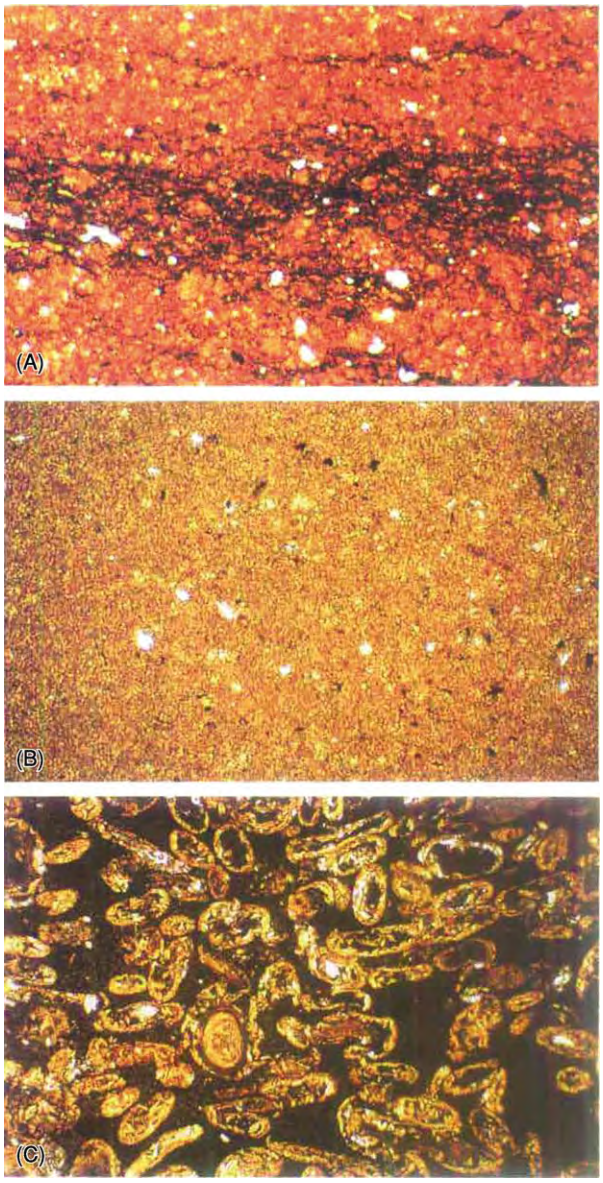

Figure 2 Typical photomicrographs of the three categories of ironstone. (A) Blackband ironstone. Note the dark organic rich lamination in a mainly sideritic matrix. Plane polarized light; horizontal dimension is 1.3 mm. (B) Claystone ironstone. Note the lack of organic material in the mainly sideritic matrix. Plane polarized light; horizontal dimension is 1.3 mm. (C) Ooidal ironstone. Ooids, showing selective replacement by siderite and phosphatic minerals, are set in a berthierine rich mudstone matrix. Plane polarized light; horizontal dimension is 5.2 mm (reproduced with kind permission of Kluwer Academic Publishers from Young TP (1993) Sedimentary iron ores. In: Pattrick RAD and Polya DA (eds.) *Mineralization in the British Isles*, pp. 446 489. London: Chapman & Hall, plates 14b, 14a and 14e).

with mudstone and seat earth deposits (Figure 3). Palaeontological and mineralogical evidence indicates that these ironstones were formed during freshwater inundation. Unlike non-marine clayband ironstones, there is an absence of early diagenetic pyrite, and the occurrence of coal balls (calcite–pyrite concretions) is an indication of marine incursion. The ironstones typically form thin (less than 10 cm) sheets of less than 10 km^2 extent and often change laterally into limestones with similar textural characteristics. Bog iron ores, which occur as lenses of ferruginous concretions within peat deposits, are thought to be the modern analogues of blackband ironstones.

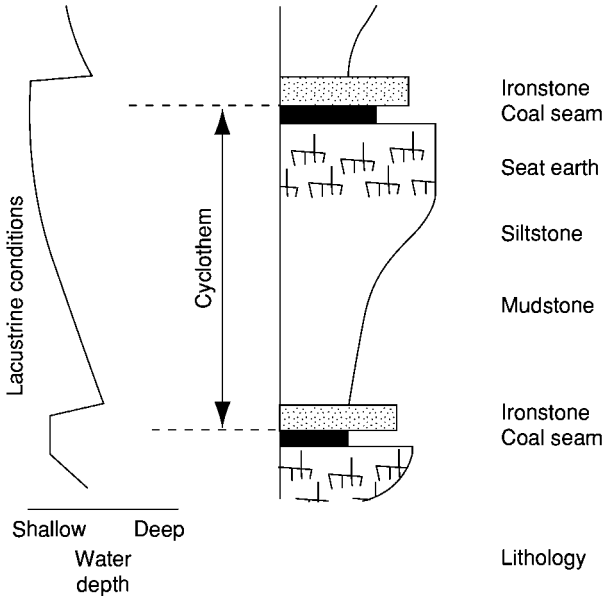

Figure 3 Idealized stratigraphical column for blackband iron stones showing relative water depths of sedimentation, not to scale.

Claystone Ironstones

Claystone or clayband ironstones have been the basis of the steel industry in many industrialized countries, largely because of their association with coalfields. Essentially, they are accumulations of iron carbonates (usually siderite) that have replaced the non-marine shales of coal-measure cyclothems (parasequences) and occur as either thin sheets or, more commonly, layers of concretions (Figure 4). Occasionally these sheets may extend over several hundred square kilometres. Normally, each concretion is unlaminated and does not contain high amounts of organic material, and the siderite grains are usually microscopic or sub-microscopic in size (less than 10 μm). Marine claystone ironstones are predominately rich in ankerite with pyrite, and production of siderite is suppressed. Irregularly shaped sphaerosiderites (ball ironstones), which usually occur at the base of palaeosols, are composed of siderite cement in the form of distributed spherulites (0.5–1 mm in diameter).

Ooidal Ironstones

Ooidal ironstones are characterized by the presence of ooids and/or pisoids and are very diverse, with a

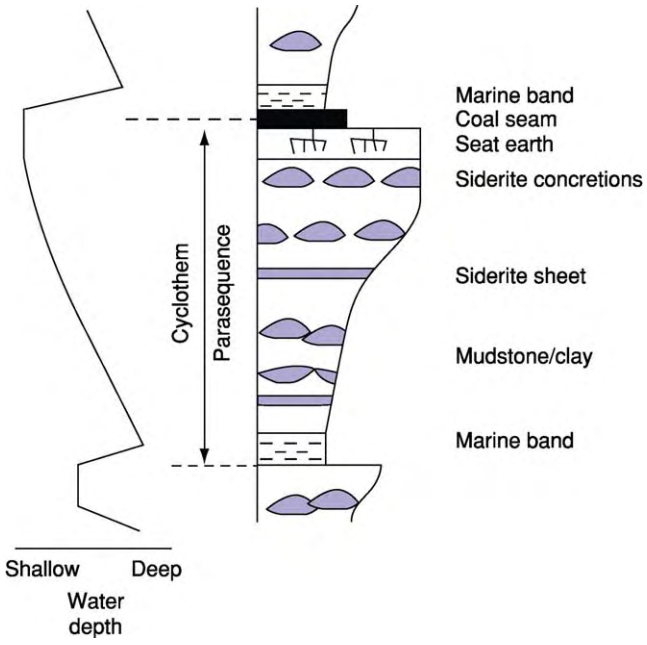

Figure 4 Idealized stratigraphical column for claystone ironstones showing relative water depths of sedimentation, not to scale.

wide range of mineralogy, textures, and chemical compositions. Because they possess oolites, shell fragments, and mud matrices in various admixtures similar to limestones (*see* **Sedimentary Rocks:** Limestones), most researchers in the field use the petrographic terminology advocated by Young to describe and classify ooidal ironstones. Most ooidal ironstones are less than a metre in thickness and are laterally persistent over approximately 100 km^2. A few deposits are in excess of 15 m thick (e.g. the Gara Djebilet Ironstone in Algeria). Although an idealized stratigraphical model for this type of ironstone consists of an upward shoaling sequence from black shales at the base, through progressively coarser deposits, to the ironstone at the top (Figure 5), in practice there are many deviations from this standard. Ironstones develop during periods of reduced sediment input (starvation), with abundant bioturbation, and often exhibit signs of storm reworking to form tempestites. The earliest-formed minerals are usually iron oxides and silicates. Iron-rich carbonates may be generated subsequently, often during early diagenesis.

Modern Examples of Ironstone Development

Bog iron ores are found associated with peat deposits in swampy conditions. Typically they contain hydrated ferric-oxide and manganese-oxide cements but, below the water table, they may be cemented by siderite. It has been suggested that microbial activity in tropical climates particularly promotes the direct precipitation of siderite.

A possible present-day analogue of ancient ooidal ironstones appears to be the verdine facies. In this facies, iron-rich aluminous green clay minerals replace bioclasts and pellets. Ferruginous peloids, in many cases altered faecal pellets, are known to be forming today in sediments deposited in front of equatorial deltas, such as those on the continental shelves off Senegal, Guinea, Nigeria, Gabon, Sarawak, and east Kalimantan. Present-day examples of ferruginous ooid accumulation are rare. In the interior of Africa, along the southernmost parts of Lake Malawi, amorphous ferric-oxide ooids have been found associated with geothermal springs, and, in the brackish open water of southern Lake Chad, goethitic brown ooids are being formed. In the shallow seas of northern Venezuela, berthierine-rich green-brown muddy ooidal sediments with peloids have been discovered.

Environment of Deposition and Subsequent Alteration during Lithification

Very few generalizations can be made about the sedimentary environment of ironstones. Ironstones may be deposited in shallow-marine, interdeltaic, nonmarine lacustrine, and alluvial environments and may interfinger or replace sandy and shelly marine deposits laterally. They are frequently associated with

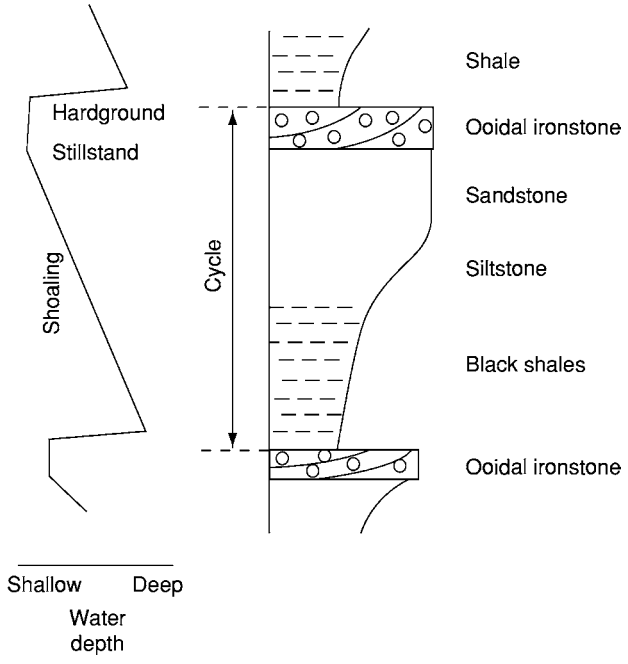

Figure 5 Idealized stratigraphical column for ooidal ironstones showing relative water depths of sedimentation, not to scale.

phosphates, coals, evaporites or laterites, and most have no direct relation to volcanism.

Blackband ironstones have many of the characteristics of bog iron ores, which are developed *in situ*, soon after deposition, by a reaction between organic material and underground colloidal iron-rich solutions under a thick vegetative cover. Progression of the process could yield siderite by reduction. Alternative evidence has been put forward suggesting that these deposits could form by direct sideritic precipitation from tropical swamp waters that are already rich in iron. Blackband ironstones are always developed in close proximity to coal seams, so either process could be feasible.

The diagenesis of the fine-grained claystone ironstones has been studied in great detail (Figure 6). Most became enriched in iron during very early diagenesis along or near the sediment–water interface. Based upon distinct chemical reactions involving the oxidation of organic matter buried within the sediment, diagenetic zones have been established. Although the zones can be considered as due to burial, their development is especially dependent upon the availability of oxidizing agents and organic matter, the sedimentary environment, the nature and amount of organic material, the composition of the inorganic sediment, the hydrological regime of the sedimentary pile, and the composition of the overlying water. The reactions below the oxic zone may be complicated by kinetic controls, which could explain the occasional appearance of residual ferric iron in an anoxic environment. Because some siderite concretions are developed early and are associated with many nonsequences, the sedimentation rate must have been relatively low (less than 40 m Ma ^{1}). Whilst claystone ironstones are formed during diagenesis by the growth of siderite in the pore spaces of argillaceous materials, sphaerosiderites form by the direct precipitation of siderite from pore fluids, and their size and shape probably reflect a higher growth rate. They can occur in a variety of environments, including the deep sea, but are usually products of a waterlogged zone below a leached soil profile.

The exact genesis of ooidal ironstones remains controversial. Particularly, the origin of the ooids is the subject of a long-lasting debate. The original constituents of ooids and how they vary from deposit to deposit are not known with any certainty. It is debatable whether the ooids grew from solutes, colloidal particles in solutions, or gels. The ferrous ion in bicarbonate form survives only in an anoxic or reducing environment, so this would place a severe constraint on its presence in solution. Ferruginous ooids are commonly built of alternating ferric oxide and berthierine sheaths of submicroscopic thickness. Whether the initial crystalline phase was berthierine

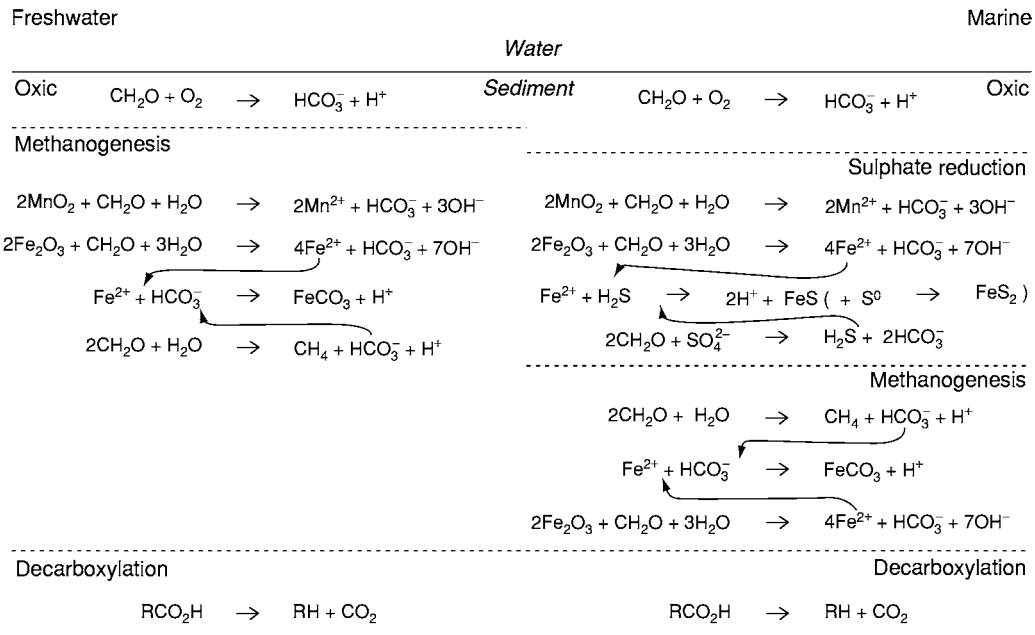

Figure 6 Summary of reactions and zonation that may occur during the diagenesis of sediments in marine and non marine conditions (after Curtis and Coleman 1986, Spears 1989 and reproduced with kind permission of Kluwer Academic Publishers from Young TP (1993) Sedimentary iron ores. In: Pattrick RAD and Polya DA (eds.) *Mineralization in the British Isles*, pp. 446 489. London: Chapman & Hall, Figure 9.5 after Curtis and Coleman 1986 and Spears 1989).

or a precursor ferric mineral (e.g. odinite) is uncertain. Some feel that it was crystallized at the earliest stage, probably from a gel; others have suggested that it formed during the early stages of burial diagenesis. Alternatively, it could be a product of the transformation of either a mixture of kaolinite and hydrous ferric oxide or a complex synthesis of silicic, ferric, and aluminous substances. The processes involving micro-organisms (such as bacteria) are not understood, particularly in terms of how they promote the growth of ooids. Reworking of ooidal sediments in shallow-water environments often separates, concentrates, and highly sorts the ooids, forming lenses, which probably accumulated in shallow depressions. Often zonation of ironstones may be observed when the body is less affected by redistribution.

The variable nature of the nuclei of ooids and the trapping of marine microflora during growth indicate that ooids are probably generated within the host sediment. Ferruginous ooids could have grown on the seafloor, at the water–sediment interface, by either concentric growth due to precipitation of mineral matter, frequently around heterogeneous nuclei, or mechanical accretion by rolling (like a snowball). Alternatively, they could have grown inside the sediment at shallow depths below the water–sediment interface either as early diagenetic microconcretions or by replacement or addition of iron to peloids. Fluviatile examples do exist (e.g. the Late Oligocene deposits of Aral Lake, Russia), in which ooids have been developed on land and then moved, but this has not been convincingly demonstrated to be of general application.

The IGCP 277 came to the conclusion that ferruginous deposition must have been due to the interplay of a number of different processes and hence that there is rarely a single genetic explanation. The salinity of seawater, the carbon dioxide and oxygen contents of the atmosphere, the action of organisms, the sources and availability of iron compounds, seasonal or long-lasting climatic conditions, specific physicochemical conditions, the marine water depth, diagenetic processes, and tectonism are all potential factors. However, the dominant influences seem to be the local hydrodynamic conditions and the topographical relief of the land and seafloor, which may help to protect the ooidal deposits from excessive dilution by clastics. Paradoxically, the rates of deposition of the stratigraphical equivalents of many ooidal ironstones do not always correspond to the periods of lowest detrital input. Changes during burial are numerous and complex and include the formation of phosphatic minerals, iron oxides, siderite, pyrite, and quartz. In most cases, these are followed by alterations due to the effects of meteoric waters.

The Ferruginization Process

Although ironstones are generally considered to be the products of ferruginization during diagenesis, the physical sedimentary environment is thought to control the style of diagenesis in ironstones. Blackband ironstones are geochemically and isotopically homogeneous, suggesting stability of conditions during growth. They were probably formed close to the sediment surface, with precipitation of siderite, and not during progressive burial (**Figure 7**). The high manganese content of siderite, the relatively low calcium and magnesium contents, and the high carbonate content support this. Studies of carbon isotopes show that calcareous shells from limestones and ironstones have similar $\delta^{13}C_{PDB}$ values (from +4‰ to −6‰), indicating that the siderites replaced original calcite or aragonite and precluding the domination of methanogenesis. As has been previously noted, very early siderite could be precipitated directly from swamp waters, but could precipitation have occurred from primitive freshwater too?

Claystone ironstones usually have lower manganese and ^{13}C enrichment than blackband ironstones, which can be related to slightly later ferruginization, which takes place below the oxic zone in non-marine waters by diagenetic distribution of iron within the sediment (**Figure 8**). The relationships leading to the precipitation of iron minerals are complex and are susceptible to slight shifts in the concentrations and availability of reactants especially S and organic C. The thermodynamics of the reactions predict the observation of manganese enrichment within the concretion cores. The iron and manganese would have been present in the silicate minerals of the sediment. Sulphate reduction would be inhibited, as the sediments were isolated from potential sources of sulphate (e.g. seawater), and changes in organic matter would be methanogenic, giving rise to bicarbonates rich in ^{13}C ($\delta^{13}C_{PDB}$ values in the order of +10‰). Also precipitation would be enhanced by an increase in alkalinity resulting from the combination of changes in organic matter and the reduction of Fe^{3+} and Mn^{4+}. Any growth at deeper levels of burial would be slow under decarboxylation conditions with bicarbonate depleted in ^{13}C. In marine claystone ironstones, sulphate and iron reduction would proceed broadly simultaneously, leading to the production of iron pyrites. Siderite is normally rare in marine sediments because iron can become incorporated in carbonates only below the zone of sulphate reduction.

Over the past two decades there have been significant developments in research into the environmental conditions under which ooidal ironstones are formed.

In: Pattrick RAD and Polya DA (eds.) *Mineralization in the British Isles*, pp. 446 489. London: Chapman & Hall, Figure 9.7).

Sea-level change may be the most significant genetic control since it can generate very low accumulation rates within basins with low overall sedimentation rates (Figure 9). Widespread sediment starvation could be produced by relative sea-level rise in shallow epeiric seas with a topographically low hinterland. There is a dispute as to whether these conditions appertain to the end of regression or to the beginning

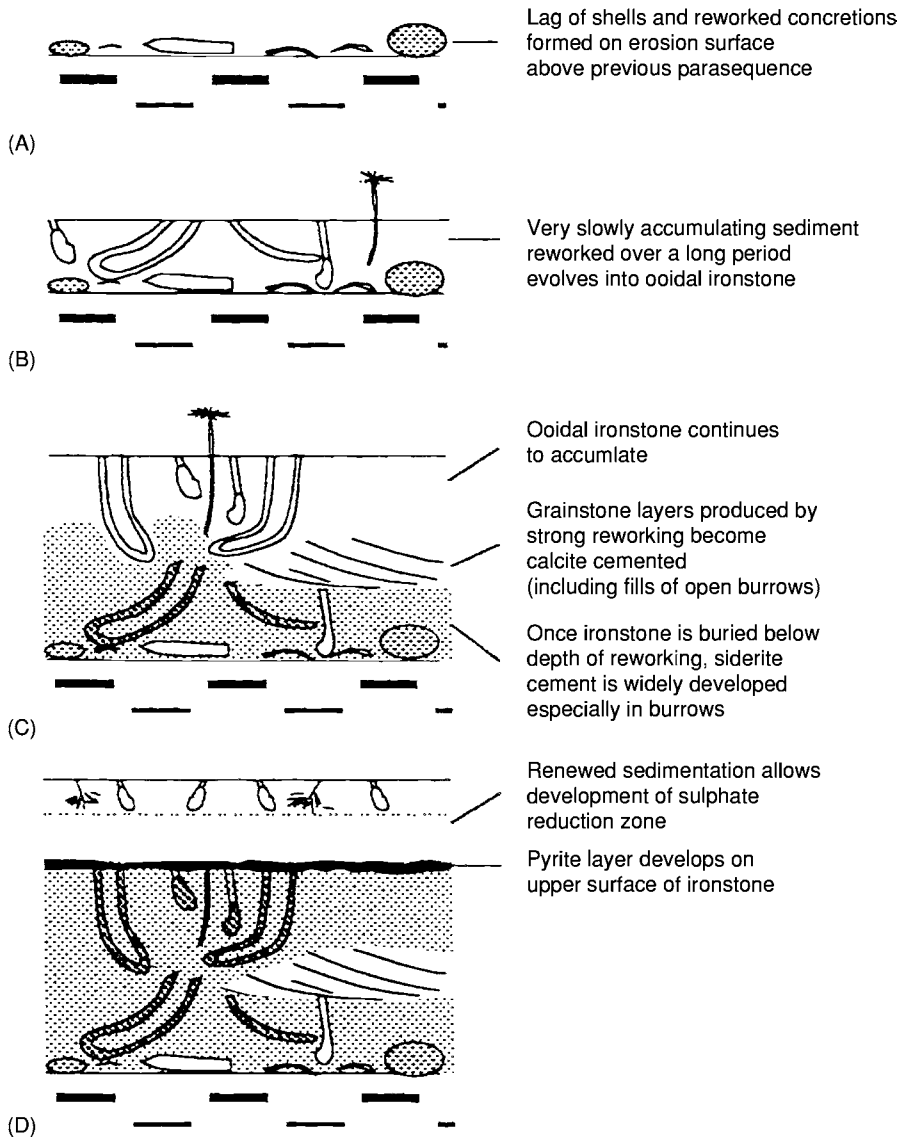

Figure 9 Model of mineralization for ooidal ironstones; (A), earliest phase; (B) and (C), middle phases; (D), latest phase (reproduced with kind permission of Kluwer Academic Publishers from Young TP (1993) Sedimentary iron ores. In: Pattrick RAD and Polya DA (eds.) *Mineralization in the British Isles*, pp. 446 489. London: Chapman & Hall, Figure 9.13).

of transgression. Similarly, the origin of early sideritic units can be related to a decrease in the role of sulphate reduction, a low sedimentation rate (less than 40 m Ma ^{1}), and oxygenated and carbon-poor sediments (values of $\delta^{13}C_{PDB}$ for various cements vary from -3 to $-22‰$).

The source and influx of iron is a subject of much controversy. In 1856, Sorby proposed that extensive ferruginization occurred during later diagenesis, but this idea is no longer accepted, since most ferruginous ooids were formed within the depositional environment. There are three proposals for the origin of iron enrichment:

1. iron-rich exhalative fluids, supplying the sediment–water interface (some examples do seem to be related to the episodic reactivation of faults involving exhalative hydrothermal or seep sources);
2. mechanical accretion of lateritic terrestrial weathering products (e.g. kaolinite and iron oxides) or lateritic soils to form ooids in a marine environment, with subsequent transformation to berthierine (this does not seem to be generally applicable since unaltered primary ooids with mixed iron oxide–kaolinite composition have not been found in marine ooidal ironstones); and

3. leaching from underlying sediments, especially organic-rich shales, during very early marine alteration of detrital material (the diagenetic redistribution of iron within sediments is difficult to demonstrate in ancient ooidal ironstones since the process would probably require considerable time).

The role of clay minerals in effecting ferruginization is unknown, particularly in respect of the transformation of non-iron-bearing phyllosilicates into iron-bearing ones and the role of iron-rich green trioctohedral clay minerals of warm seas as possible precursors of later ooidal minerals.

Stratigraphical Record (Temporal Occurrences) and Tectonic Settings

It has puzzled geologists that some geological periods have significant numbers of ironstones, whilst other periods are devoid of them. Ironstones are almost completely restricted to the Phanerozoic. Blackband and claystone ironstones are particularly prevalent in the Carboniferous, when the depositional basins occupied near-tropical locations. Ooidal ironstones are particularly common in the Ordovician, Devonian, Jurassic, and Cretaceous periods. Most ironstones were formed in warm climates, although some were deposited in cooler climates (e.g. the Late Ordovician and Late Permian ironstones). Palaeolatitude data has shown that the Ordovician and Devonian ironstones formed in a zone of the Gondwanan shelf seas ranging from 45°N to 65°S of the palaeoequator. In the Jurassic and Cretaceous, ironstones formed between 70°N and 10°S. For this reason climate cannot be the major contributory factor in their formation.

Ironstones are largely confined to three types of cratonic setting.

1. Many developed in anorogenic basins dominated by prolonged stability and sometimes with complex extensional faulting that involved the formation of marine basins and swells in areas of subdued relief.
2. Some developed along the margins of cratons during initial convergence or divergence of plates.
3. Other ironstones accumulated on the inner sides of mobile belts at times of diminished deformation.

Glossary

Condensed deposit A relatively thin but uninterrupted sedimentary sequence representing a significant period of time during which the deposits have accumulated very slowly. It is generally correlated with a thicker time-equivalent succession elsewhere.

Ferruginization A synonym of ferrification and the preferred term by IGCP 277 to describe the processes of iron-enrichment of various Earth materials.

Hardground A zone at the seafloor a few centimetres thick, where the sediment is lithified to form a hardened surface, which is often encrusted and bored.

IGCP The International Geological Correlation Programme.

Neoformation A synonym of neogenesis, the formation of new minerals.

Ooid A synonym of oolith and the preferred term to describe a spherical or ellipsoidal accretionary sand-sized (diameter of 0.25–2 mm) particle in a sedimentary rock (mainly limestones and ironstones). Ooids usually consist of successive concentric layers (often carbonates) around a central nucleus.

Pellet A small, usually ellipsoidal, aggregate of accretionary material (mainly micrite) that has, in most cases, formed from the faeces of molluscs and worms.

Peloid An allochem composed of micrite, irrespective of size or origin, without internal structure. Includes both pellets and intraclasts.

Pisoid A synonym of pisolith and the preferred term to describe small round or ellipsoidal particles (diameter of 2–10 mm) in a sedimentary rock (mainly limestones and ironstones). Pisoids are larger than ooids and usually consist of concentric layers around a central nucleus.

Stillstand A period of time when an area of land is stable relative to mean sea-level (or some other global measure), leading to a relatively unvarying base level of erosion.

Verdine facies Green marine clay characterized by the authigenesis (neoformation *in situ*) of iron-rich aluminous clay minerals, especially 0.7 nm repeat odinite, but not berthierine or glauconite.

Limestones

R C Selley, Imperial College London, London, UK

Introduction

Limestones are one of the most important of all the sedimentary rocks introduced in (*see* **Sedimentary Rocks:** Mineralogy and Classification). Limestones are composed largely of calcium carbonate ($CaCO_3$) in the mineral form calcite, but there are several other important carbonate minerals with which limestones are associated. This article opens by discussing important differences between limestones and sandstones, and continues by outlining the mineralogy, classification, and rock names of limestones. This is followed by a brief account of limestone depositional environments, and, logically, by their postdepositional diagenesis. The article concludes with a description of the economic importance of limestones, which is considerable, and a selected reading list.

Differences between Limestones and Sandstones

Limestones and sandstones are the two most important groups of sedimentary rocks. However, limestones pose a completely different set of problems to those of sandstones, the solutions of which require the application of different concepts and techniques.

First, limestones, unlike sandstones, are intrabasinal in origin. That is to say they form in the environment in which they are deposited. The source material of sandstones, by contrast, has been weathered, eroded, transported, and may finally be deposited hundreds of kilometres from its point of origin. Sandstones (or siliciclastic rocks) therefore often contain many different minerals. Limestones, by contrast, have a much simpler mineralogy, generally consisting of only calcite and two or three others (which will be mentioned shortly). Siliciclastic sand grains may hold clues to their source, but tell little of their depositional environment. Limestone grains, by contrast, although largely monomineralic, occur in a wide range of sizes and shapes, reflecting their multiple origins. These grains form in specific environments from which they are seldom transported. Limestone grains thus give important clues about their environment of deposition.

When studying sandstones, vertical profiles of grain size and analysis of sedimentary structures are the keys to environmental diagnosis. With limestones, however, it is the analysis of grain type and texture that aids environmental diagnosis.

The second large difference between sandstones and limestones lies in their chemistry. Sandstones are

composed largely of quartz (SiO_2) sand, whilst limestones are composed largely of the mineral calcite ($CaCO_3$). In the subsurface environment, silica is chemically relatively inert, whereas calcite is much more reactive. This means that diagenesis in sandstones is relatively less important. Primary intergranular porosity may be preserved as it was when the sand was first deposited. In limestones, however, primary intergranular porosity is often quickly infilled by cement, even before the sediment has been buried. In the subsurface though, limestones are more vulnerable to the effects of acid solutions which can selectively leach out the rock and generate secondary pores. These may just be where individual fossil shells have leached out (Biomouldic porosity). These pores may enlarge to cross-cut the fabric of the rock (vuggy porosity), or even form caves, described by geologists as cavernous porosity (cavernous pores are defined as those that are large enough to contain a crouched geologist, or for the drill string to drop by 1 m or more). Fenestral porosity is a less common but significant type of pore system found in intertidal lagoonal muds. It forms from the buckling of laminae or the trapping of gas bubbles in carbonate mud when exposed to hot sunshine. It is characterized by thin, horizontally elongated pores, thus giving good horizontal and poor vertical permeability. The replacement of limestone by dolomite (dolomitization) may create intercrystalline porosity.

Through the creation of pore systems of diverse shapes and sizes, diagenesis may completely destroy the original depositional fabric of the sediment, a feature unknown in sandstones whose diagenetic overprint has little impact on the primary features.

These differences between limestones and sandstones will become clearer as this article unfolds.

Limestone Mineralogy, Grains, and Rock Names

Limestone Mineralogy

Limestones are principally composed of calcium carbonate in the form of calcite ($CaCO_3$). They may also contain several other carbonate minerals, listed in Table 1, and several non-carbonate impurities. There are two varieties of calcium carbonate ($CaCO_3$): 'aragonite', which has an orthorhombic crystal system, and 'calcite', which has a hexagonal crystal system. Aragonite is an important component of carbonate mud and of many shells. It is, however, relatively unstable in the subsurface, and soon goes into solution, often generating mouldic porosity, either at the surface or during shallow burial. It is very rarely preserved in old and/or deeply buried limestones. Calcite also occurs in many shells and other carbonate grains. It is more stable than aragonite. 'Dolomite' ($CaMg(CO_3)_2$) is the third and most important mineral associated with limestones (described in detail in (*see* **Sedimentary Rocks:** Dolomites)). It rarely forms on the Earth's surface, but commonly does in the subsurface. With increasing abundance of dolomite, limestones grade, via dolomitic limestones, into limey dolomites, and finally dolomite rock. Geopedants restrict the name dolomite to the mineral, and dolostone to the rock. Not everyone is so particular. 'Magnesite', 'ankerite', and 'siderite' are rare constituents of limestones.

Limestone Grains and Matrix

Just like sandstones, limestones consist of framework grains, matrix (syndepositional), cement (postdepositional), and, sometimes, pores. There are many types of carbonate grain. They are briefly described here, and are illustrated in Figure 1. Probably the most common grain type in limestones is shell debris. Indeed, many limestones are made up of nothing but fossils, whole or fragmented. These are termed bioclastic or biogenic limestones. Because of their origin, palaeoecology is an important tool in the diagnosis of the depositional environment. Not only whole fossils but even fragmented bioclasts may be identifiable, and hence of diagnostic value. Some limestones are composed of rounded grains termed ooids, or ooliths, and the rock oolite (named from '*oos*', the Greek for egg, the rock having the appearance of the roe of a fish). Internally, ooids show a concentric growth ring structure around a nucleus of a quartz grain or shell

Table 1 Summary of the minerals commonly associated with limestones

Mineral	*Formula*	*Crystal system*	*Occurrence*
Aragonite	$CaCO_3$	Orthorhombic	Some shells and mud, unstable during burial
Calcite	$CaCO_3$	Hexagonal	Some shells and mud, relatively stable during burial
Magnesite	$MgCO_3$	Hexagonal	Rare surface mineral
Dolomite	$CaMg(CO_3)_2$	Hexagonal	Rarely at the surface, more common as a subsurface replacement
Ankerite	$Ca(MgFe)(CO_3)_2$	Hexagonal	A rare cement
Siderite	$FeCO_3$	Hexagonal	As ooliths and cement

fragment. Ooids form in shallow, high-energy marine environments with elevated temperatures and salinity, where carbonate precipitates episodically around an agitated nucleus. Larger sized concentric carbonate grains are known as pisoliths and oncolites; these are algally coated clasts. Some limestones are composed of structureless, bullet-shaped, sand-sized grains of lime mud and comminuted shell fragments. These grains are faecal pellets, the excreta of diverse burrowing aquatic creatures. Bizarre as it may seem, whole rock formations are composed of such material. Faecal pellets are the characteristic grain type of inner shelves, sheltered bays, and lagoons. Intraclasts are irregular, generally platy-shaped, carbonate grains

of various lengths and size. They are formed by the penecontemporaneous erosion of lithified carbonate sediment. Intraclasts are typically found in continental shelf and slope environments.

Between the framework grains briefly described above, there may be a finer grained syndepositional matrix. In sandstones, this is generally composed of clay minerals. In limestones, the matrix is more usually composed of lime mud, termed micrite. Micrite is sometimes aragonitic, sometimes calcitic. Micrite has several origins. It forms when calcareous algae decompose to liberate skeletal aragonite needles into the water. Waves and tidal currents, together with shell-munching predators, also play a part in disaggregating structured shells into comminuted lime mud. There is some evidence in modern warm shallow seas for the direct precipitation of aragonite mud in seawater. Limestone is commonly cemented by calcite, referred to as 'spar' or 'sparite' in this context. Several other carbonate and evaporite minerals precipitate out in limestone pore spaces as postdepositional cement.

Limestone Classification and Nomenclature

There are several different classifications of carbonate rocks. The one most widely used was proposed by Dunham in 1962 (Figure 1) and is briefly described below. 'Boundstone' is the term applied to limestone formed from organic skeletal material that grew bound together at the Earth's surface: in other words, reef rock. 'Mudstone' is composed of micrite with less than 10% grains; 'wackestone' is composed of micrite with over 10% grains. Both mudstone and wackestone are mud supported. That is to say the grains appear to 'float' within the micrite. In contrast, 'packstone' is grain supported, and the space between the grains is partly or completely filled with micrite matrix. 'Grainstone' is grain supported with negligible micrite matrix. The sequence mudstone–wackestone–packstone–grainstone reflects increasing depositional turbulence and energy, and is therefore useful in palaeoenvironmental reconstruction. Dunham's rock names can be qualified by grain type. For example, faecal wackestone, bioclastic packstone, ooidal grainstone, and so forth. The last rock name in Dunham's classification is 'crystalline carbonate', which would normally include dolomite and marble.

Limestone Depositional Environments

All carbonate sediment is precipitated by organic processes, either directly, as animals and plants secrete lime skeletons, or indirectly, as biochemical changes in water cause carbonate to precipitate as individual crystals. Except in a few deep marine environments, all ecosystems are based on plants, and all plants require sunlight to photosynthesize and grow. Plants provide the food for higher life forms to develop. Thus carbonate precipitation, caused or aided by plants, occurs in shallow water, and most of it takes place on the seafloor. Carbonate skeletal development decreases with increasing water depth, as darkness inhibits photosynthesis. Over time, therefore, a carbonate shelf will develop on a gently sloping seafloor (Figure 2). If sea-level remains constant, this shelf will gradually build out or prograde into deeper water. In certain situations, this gently sloping ramp may have an abrupt break in slope. This may occur in one of two ways. A fault may downthrow the seabed into deeper water. Rapid deepening may also occur if sea-level drops, erodes a sea cliff, and rises again, whereupon the rim will be oversteepened by rapid carbonate growth on the crest of the drowned sea cliff. These processes give rise to two types of carbonate setting: the gently sloping accretionary ramp, and the rimmed carbonate platform (Figure 3). This figure also shows the grain types and textures of the carbonate lithologies in these settings, and elegantly illustrates how carbonate rock type correlates with depositional environment. Considered in more detail, the following range of carbonate sediments may be found in sequence from the deep basin across the shelf towards the land. Basinal lime mud may form from the settling of organic detritus of plant and animal plankton that drifted near the surface. In this manner, many lime mudstones, including chalk, formed. These basinal muds may be interbedded with shallow-water carbonate sediment that was transported downslope as turbidity flows, submarine debris flows, and slides. Such transported carbonates, referred to sometimes as 're-deposited' or 'allodapic' limestones, are particularly common on the steep flanks of rimmed platforms and reefs. In warm, clear, shallow water, organic reefs may form by the *in situ* growth of corals,

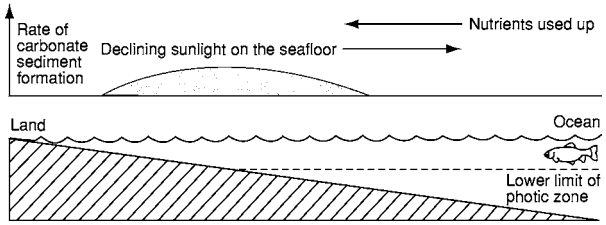

Figure 2 Diagram to show how carbonate sediment forms optimally in a zone between deep water, where the seafloor is too dark for photosynthesis to occur, and shallow water, where all the nutrients from the open sea have been used up. If sea level remains constant, the carbonate factory will gradually accrete seaward across the shelf into deeper water.

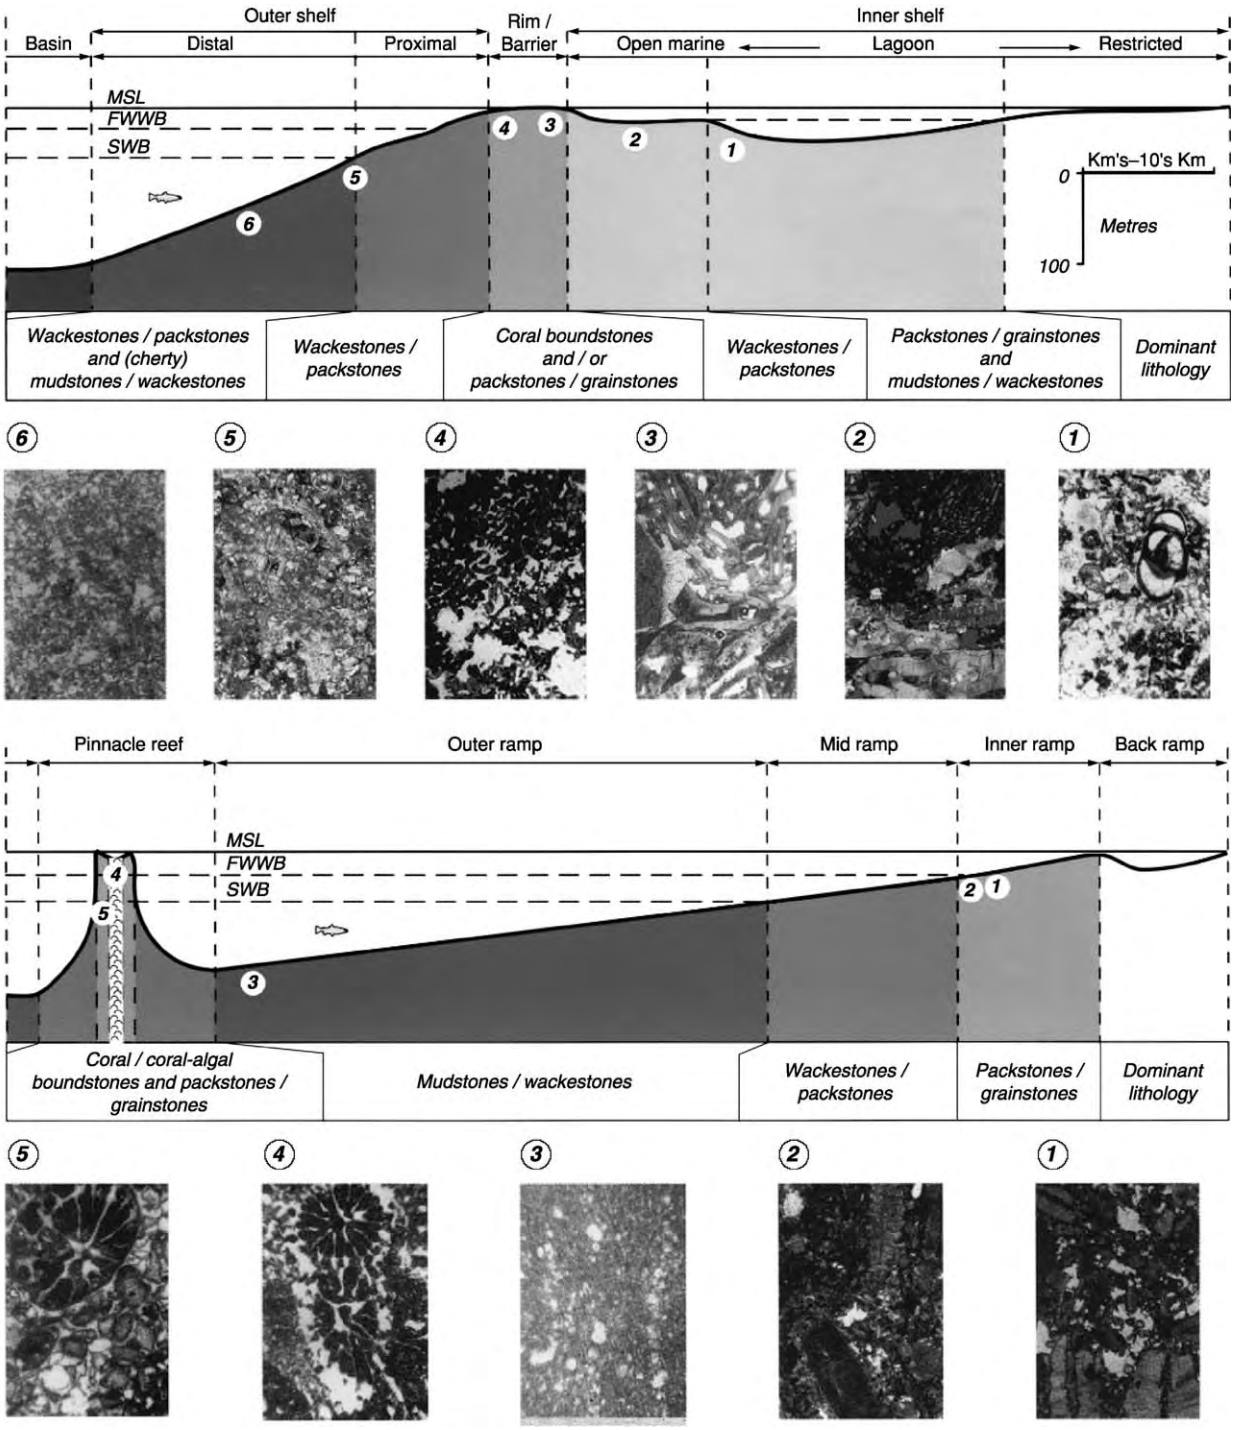

Figure 3 Cross sections to illustrate the correlation between depositional environments and carbonate rock types (grains and textures) for a rimmed carbonate platform (top) and a carbonate ramp (bottom). bryozoa, algae, and many other sedentary biota. In turbulent conditions, shoals of oolitic and skeletal grainstone may form, as seen in the modern carbonate banks of the Bahamas, as described in more detail in (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves). In sheltered lagoons behind the high-energy environments of reefs and shoals, burrowing marine animals may excrete faecal pellets

to deposit thick formations of peloidal packstones and wackestones. In arid climates, these sediments may, in turn, pass into 'sabkha' ('*sabkha*' is Arabic for salt marsh) where dolomite and evaporite minerals may form. In humid climates, where terrigenous sediment runs off from the land, the carbonate lagoons may interfinger with siliciclastic sand and mud.

The depositional environments of carbonate shorelines and shelves in general, and reefs in particular, are described in greater detail in (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves; Reefs ('Build-Ups')), respectively.

Limestone Diagenesis

As noted earlier, the minerals that form limestones are far less stable in the subsurface than are those that form sandstones. Recent carbonate sediment at the Earth's surface is composed of the two isomorphs of calcium carbonate: aragonite and calcite. Recent lime mud is largely aragonitic, but skeletal material is composed of both varieties, which vary in importance between different animal and plant groups.

The change of unconsolidated lime sediment into limestone happens very quickly, and with negligible burial. The 'fossilized' beer bottles and other anthropogenic detritus found in modern 'beach rock' prove this. These early cements are of both calcite and aragonite. In skeletal sands, one of the first diagenetic reactions is the dissolution of aragonite shells. This generates biomoldic porosity.

During burial, aragonitic muds undergo a reordering of the crystal lattice to form calcite. This change is concomitant with a volumetric increase of 8%, and a corresponding loss of porosity. This is why most ancient lime mudstones, certainly those of pre-Mesozoic age, are normally hard, tight, splintery rocks. By contrast, many Cretaceous and younger lime mudstones are light, porous, and chalky. Chalk consists mainly of the fossils of planktonic algae, termed the Coccolithophoridae, together with their disaggregated skeletal plates, termed coccoliths, coccolith-rich faecal pellets, calcispheres, and unicellular planktonic foraminifers. Coccoliths are not composed of unstable aragonite, but of the stabler calcite. Thus, during burial, these lime muds do not undergo expansive diagenesis like aragonitic muds. They maintain their chalky texture, being highly porous, but normally impermeable unless fractured. Chalks are described in greater detail in (*see* **Sedimentary Rocks:** Chalk).

Returning to the diagenesis of carbonate sands, during shallow burial, early cementation may destroy some porosity, but aragonite dissolution may enhance it. With continued burial, calcite cement may infill both biomolds and any remaining intergranular porosity. There are, however, several other diagenetic processes to which a cemented limestone may be subjected.

Limestones may undergo recrystallization, during which some or all of the primary fabric may be destroyed. Individual carbonate grains, generally bioclasts or ooids, may undergo pressure solution. This is a process whereby dissolution occurs at grain contacts due to overburden pressure. Concomitantly, the dissolved mineral matter may be precipitated as cement in adjacent pores. Additional evidence of dissolution is provided by stylolites. These are sutured surfaces, generally subparallel to bedding, where extensive dissolution has left an insoluble residue of clay, kerogen, and other matter along the suture. Stylolites occur in both pure limestones and quartzose sandstones.

Limestone diagenesis must not be thought of as a 'one-way street' that leads to the total loss of porosity and permeability. Limestones may be flushed through with acidic pore fluids, whose leaching properties may generate secondary porosity and permeability. The acidic fluids may come from adjacent compacting clay beds, conveniently generating secondary porosity ahead of petroleum invasion. More usually, however, secondary solution porosity is the result of uplift and erosion, and the flushing of limestone by acidic meteoric water (there is nothing new in acid rain). Solution may form moldic and vuggy pores. It may enlarge fractures and, in extreme cases, develop karstic caverns with concomitant collapse breccias (*see* **Sedimentary Processes:** Karst and Palaeokarst). Many of the best carbonate petroleum reservoirs occur where solution porosity has been developed and preserved beneath unconformities. The best way of preserving porosity in a limestone is for petroleum invasion to occur and expel cementing connate fluids. Renewed burial, without the benefit of petroleum invasion, may, of course, result in total recementation of the limestone as it makes its way to a completely cemented and recrystallized rock, termed marble.

The last important diagenetic process to which limestones are subjected is dolomitization, a process of such complexity and importance that it merits an article to itself (*see* **Sedimentary Rocks:** Dolomites).

Economic Importance of Limestones

Limestones are of great economic importance for many reasons. First, limestones contain lime, an essential ingredient for plant growth, and so limestone quarries are ubiquitous adjacent to farmland with lime-poor acid soil. Hard cemented limestones make excellent building stone and aggregate. Porous and permeable limestones, by contrast, serve as aquifers.

Limestone is used in the manufacture of cement and as a flux in the smelting of iron. Limestones are the host of several metallic minerals, including the eponymous Mississippi Valley telethermal Pb–Zn sulphide ores described in (*see* **Mineral Deposits and Their Genesis**). About 45% of the known petroleum reserves in the world occur in carbonate reservoirs (limestones and dolomites). Six main settings are recognized that preserve large volumes of porous and permeable limestone which have the potential to serve as petroleum reservoirs. These are: oolite grainstone shoals; reefs (often dolomitized); fore-reef talus; grainstone shoals sealed up-dip by evaporites; subunconformity traps, with extensive secondary porosity; and chalk, uplifted and fractured over salt diapirs. Small wonder, then, that limestones, their depositional environments, and diagenesis have been so intensively studied by geologists.

Oceanic Manganese Deposits

D S Cronan, Imperial College London, London, UK

Introduction

Manganese nodules and encrustations (crusts) together with micronodules are ferromanganese oxide deposits which contain variable amounts of other elements (Table 1). They occur throughout the oceans, although the economically interesting varieties have a much more restricted distribution. Manganese nodules are spherical to oblate in shape and range in size from less than 1 cm in diameter up to 10 cm or more. Most accrete around a nucleus of some sort, usually a volcanic fragment but sometimes biological remains. Crusts are usually tabular.

The deposits were first described in detail in the Challenger Reports. This work was co-authored by J. Murray and A. Renard, who between them initiated the first great ferromanganese oxide controversy. Murray believed the deposits to have been formed by submarine volcanic processes whereas Renard believed that they had precipitated from continental run-off products in seawater. This controversy remained unresolved until it was realized that they could obtain their metals from either or both sources. The evidence for this included the finding of abundant nodules in the Baltic Sea where there are no volcanic influences, and the finding of rapidly grown ferromanganese oxide crusts associated with submarine hydrothermal activity of volcanic origin on the Mid-Atlantic Ridge. Subsequently, a third source of metals to the deposits was discovered, diagenetic remobilization from underlying sediments. Thus, marine ferromanganese oxides can be represented on a triangular diagram (Figure 1), the corners being occupied by hydrothermal (volcanically derived), hydrogenous (seawater derived), and diagenetic (sediment interstitial water derived) constituents.

There appears to be a continuous compositional transition between hydrogenous and diagenetic deposits, all of which are formed relatively slowly at normal deep seafloor temperatures. By contrast,

although theoretically possible, no continuous compositional gradation has been reported between hydrogenous and hydrothermal deposits, although mixtures of the two do occur. This may be partly because: (i) the growth rates of hydrogenous and hydrothermal deposits are very different with the latter accumulating much more rapidly than the former, leading to the incorporation of only limited amounts of the more slowly accumulating hydrogenous material in them; and (ii) the temperatures of formation of the deposits are different, leading to mineralogical differences between them which can affect their chemical composition. Similarly, a continuous compositional gradation between hydrothermal and diagenetic ferromanganese oxide deposits has not been found, although again this is theoretically possible. However, the depositional conditions with which the respective deposits are associated i.e., high temperature hydrothermal activity in mainly sediment-free elevated volcanic areas on the one hand, and low-temperature accumulation of organic rich sediments in basin areas on the other, would preclude much mixing between the two. Possibly they may occur in sedimented active submarine volcanic areas.

Internal Structure

The main feature of the internal structure of nodules and crusts is concentric or tabular banding which is

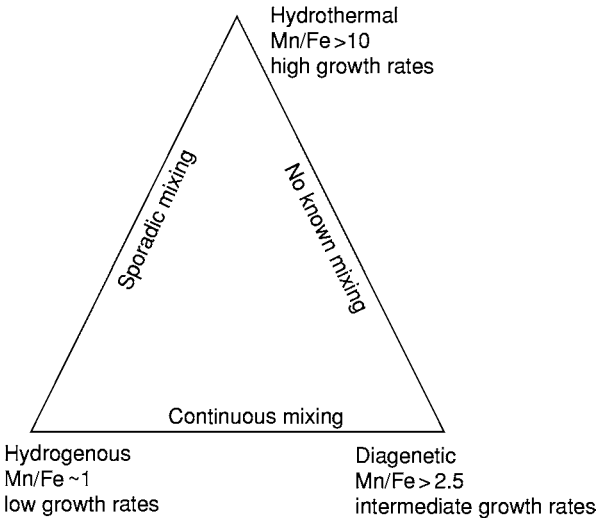

Figure 1 Triangular representation of marine ferromanganese oxide deposits.

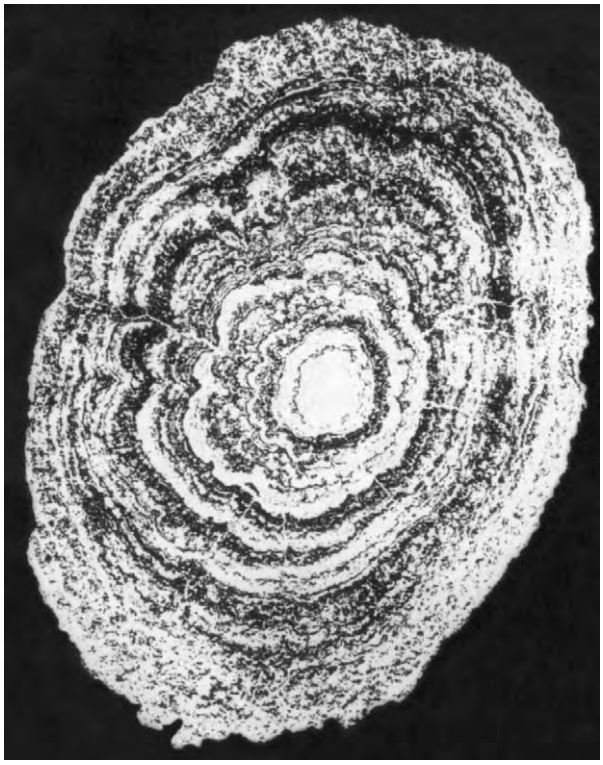

Figure 2 Concentric banding in a manganese nodule. (Reproduced by kind permission of CNEXO, France.)

developed to a greater or lesser extent in most of them (Figure 2). The bands represent thin layers of varying reflectivity in polished section, the more highly reflective layers being generally richer in manganese than the more poorly reflective ones. They are thought to possibly represent varying growth conditions.

On a microscopic scale, a great variety of structures and textures are apparent, some of them indicative of postdepositional alteration of nodule and crust interiors. One of the most commonly observed and most easily recognizable is that of collomorphic globular segregations of ferromanganese oxides on a scale of tenths of a millimetre or less, which often persist throughout much of the nodule or crust interior. Often the segregations become linked into polygons or cusps elongated radially in the direction of growth of the deposits. Several workers have also recognized organic structures within manganese nodules. Furthermore, cracks and fissures of various sorts are a common feature of nodule and crust interiors. Fracturing of nodules is a process which can lead to their breakup on the seafloor, in some cases as a result of the activity of benthic organisms, or of bottom currents. Fracturing is an important process in limiting the overall size of nodules growing under any particular set of conditions.

Growth Rates

It is possible to assess the rate of growth of nodules and crusts either by dating their nuclei, which gives a minimum rate of growth, or by measuring age differences between their different layers. Most radiometric dating techniques indicate a slow growth rate, from a few to a few tens of millimeters per million years. Existing radiometric and other techniques for dating include uranium series disequilibrium methods utilizing ^{230}Th ^{231}Pa, the ^{10}Be method, the K-Ar method, fission track dating of nodule nuclei, and hydration rind dating.

In spite of the overwhelming evidence for slow growth, data have been accumulating from a number of sources which indicate that the growth of nodules may be variable with periods of rapid accumulation being separated by periods of slower, or little or no growth. In general, the most important factor influencing growth rate is likely to be the rate at which elements are supplied to the deposits, diagenetic sources generally supplying elements at a faster rate than hydrogenous sources (Figure 1). Furthermore, the tops, bottoms, and sides of nodules do not necessarily accumulate elements at the same rate, leading to the formation of asymmetric nodules in certain circumstances (Figure 3). Differences in the surface morphology between the tops, bottoms, and sides of nodules *in situ* may also be partly related to growth rate differences. The tops receive slowly accumulating elements hydrogenously supplied from seawater and are smooth, whereas the bottoms receive more rapidly accumulating elements diagenetically supplied from the interstitial waters of the sediments

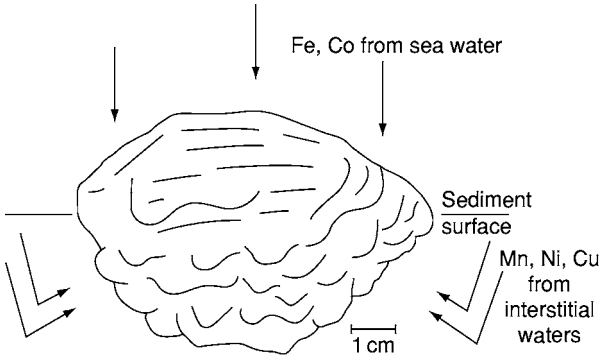

Figure 3 Morphological and compositional differences between the top and bottom of a Pacific nodule. (Reproduced with permission from Cronan, 1980.)

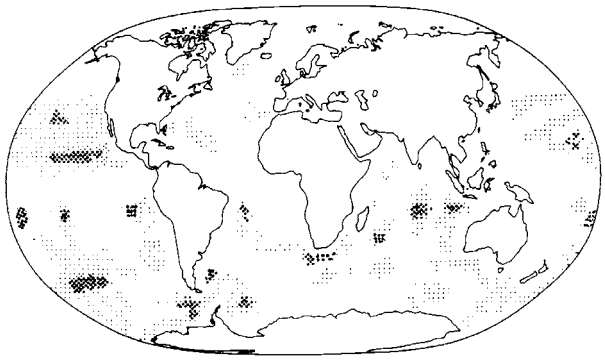

Figure 4 Distribution of manganese nodules in the oceans (updated from Cronan, 1980 after various sources.) ⋮⋮⋮, Areas of nodule coverage; ●●●, areas where nodules are locally abundant.

and are rough (Figure 3). The 'equatorial bulges' at the sediment-water interface on some nodules have a greater abundance of organisms on them than elsewhere on the nodule surface, suggesting that the bulges may be due to rapid growth promoted by the organisms.

It is evident, therefore, that growth cannot be regarded as being continuous or regular. Nodules and crusts may accrete material at different rates at different times and on different surfaces. They may also be completely buried for periods of time during which it is possible that they may grow from interstitial waters at rates different from those while on the surface, or possibly not grow at all for some periods. Some even undergo dissolution, as occurs in the Peru Basin where some nodules get buried in suboxic to reducing sediments.

Distribution of Manganese Nodules

The distribution and abundance of manganese nodules is very variable on an oceanwide basis, and can also be highly variable on a scale of a kilometre or less. Nevertheless, there are certain regional regularities in average nodule abundance that permit some broad areas of the oceans to be categorized as containing abundant nodules, and others containing few nodules (Figure 4), although it should always be borne in mind that within these regions local variations in nodule abundance do occur.

The distribution of nodules on the seafloor is a function of a variety of factors which include the presence of nucleating agents and/or the nature and age of the substrate, the proximity of sources of elements, sedimentation rates, and the influence of organisms. The presence of potential nuclei on the seafloor is of prime importance in determining nodule distribution. As most nodule nuclei are volcanic in origin, patterns of volcanic activity and the subsequent dispersal of volcanic materials have an important influence on where and in what amounts nodules occur. Other materials can also be important as nodule nuclei. Biogenic debris, such as sharks' teeth, can be locally abundant in areas of slow sedimentation and their distribution will in time influence the abundance of nodules in such areas.

As most nuclei are subject to replacement with time, old nodules have sometimes completely replaced their nuclei and have fractured, thus providing abundant nodule fragments to serve as fresh nuclei for ferromanganese oxide deposition. In this way, given sufficient time, areas which initially contained only limited nuclei may become covered with nodules.

One of the most important factors affecting nodule abundance on the seafloor is the rate of accumulation of their associated sediments, low sedimentation rates favouring high nodule abundances. Areas of the seafloor where sedimentation is rapid are generally only sparsely covered with nodules. For example, most continental margin areas have sedimentation rates that are too rapid for appreciable nodule development, as do turbidite-floored deep-sea abyssal plains. Low rates of sedimentation can result either from a minimal sediment supply to the seafloor or currents inhibiting its deposition. Large areas in the centres of ocean basins receive minimal sediment input. Under these conditions, substantial accumulation of nodules at the sediment surface is favoured.

Worldwide Nodule Distribution Patterns

Pacific Ocean As shown in Figure 4, nodules are abundant in the Pacific Ocean in a broad area, called the Clarion–Clipperton Zone, between about 6° N and 20° N, extending from approximately 120° W to 160° W. The limits of the area are largely determined by sedimentation rates. Nodules are also locally abundant further west in the Central Pacific Basin.

Sediments in the northern part of the areas of abundant nodules in the North Pacific are red clays with accumulation rates of around 1 mm per thousand years, whereas in the south they are siliceous oozes with accumulation rates of 3 mm per thousand years, or more.

Nodule distribution appears to be more irregular in the South Pacific than in the North Pacific, possibly as a result of the greater topographic and sedimentological diversity of the South Pacific. The nodules are most abundant in basin environments, such as those of the south-western Pacific Basin, Peru Basin, Tiki Basin, Penrhyn Basin, and the Circum-Antarctic area.

Indian Ocean In the Indian Ocean the most extensive areas of nodule coverage are to the south of the equator. Few nodules have been recorded in the Arabian Sea or the Bay of Bengal, most probably because of the high rates of terrigenous sediment input in these regions from the south Asian rivers. The equatorial zone is also largely devoid of nodules. High nodule concentrations have been recorded in parts of the Crozet Basin, in the Central Indian Ocean Basin, and in the Wharton Basin.

Atlantic Ocean Nodule abundance in the Atlantic Ocean appears to be more limited than in the Pacific or Indian Oceans, probably as a result of its relatively high sedimentation rates. Another feature which inhibits nodule abundance in the Atlantic is that much of the seafloor is above the calcium carbonate compensation depth (CCD). The areas of the Atlantic where nodules do occur in appreciable amounts are those where sedimentation is low. The deep water basins on either side of the Mid-Atlantic Ridge which are below the CCD and which accumulate only limited sediment, contain nodules in reasonable abundance, particularly in the western Atlantic. Similarly, there is a widespread occurrence of nodules and encrustations in the Drake Passage-Scotia Sea area, probably due to the strong bottom currents under the Circum-Antarctic Current inhibiting sediment deposition in this region. Abundant nodule deposits on the Blake Plateau can also be related to strong bottom currents.

Buried nodules Most workers on the subject agree that the preferential concentration of nodules at the sediment surface is due to the activity of benthic organisms which can slightly move the nodules. Buried nodules have, however, been found in all the oceans of the world. Their abundance is highly variable, but it is possible that it may not be entirely random. Buried nodules recovered in large diameter cores are sometimes concentrated in distinct layers. These layers may represent ancient erosion surfaces or surfaces of non-deposition on which manganese nodules were concentrated in the past. By contrast, in the Peru Basin, large asymmetrical nodules get buried when their bottoms get stuck in tenacious sediment just below the surface layer.

Compositional Variability of Manganese Nodules

Manganese nodules exhibit a continuous mixing from diagenetic end-members which contain the mineral 10Å manganite (todorokite) and are enriched in Mn, Ni, and Cu, to hydrogenous end-members which contain the mineral δMnO_2 (vernadite) and are enriched in Fe and Co. The diagenetic deposits derive their metals at least in part from the recycling through the sediment interstitial waters of elements originally contained in organic phases on their decay and dissolution in the sediments, whereas the hydrogenous deposits receive their metals from normal seawater or diagenetically unenriched interstitial waters. Potentially ore-grade manganese nodules of resource interest fall near the diagenetic end-member in composition. These are nodules that are variably enriched in Ni and Cu, up to a maximum of about 3.0% combined.

One of the most striking features shown by chemical data on nodules are enrichments of many elements over and above their normal crustal abundances (Table 1). Some elements such as Mn, Co, Mo, and Tl are concentrated about 100-fold or more: Ni, Ag, Ir, and Pb are concentrated from about 50- to 100-fold; B, Cu, Zn, Cd, Yb, W, and Bi from about 10- to 50-fold; and P, V, Fe, Sr, Y, Zr, Ba, La, and Hg up to about 10-fold, above crustal abundances.

Regional Compositional Variability

Pacific Ocean In the Pacific, potentially ore-grade nodules are generally confined to two zones running roughly east–west in the tropical regions, which are well separated in the eastern Pacific but which converge at about 170°–180° W (Figure 5). They follow the isolines of intermediate biological productivity, strongly suggestive of a biological control on their distribution. Within these zones, the nodules preferentially occupy basin areas near or below the CCD. Thus, they are found in the Peru Basin, Tiki Basin, Penrhyn Basin, Nova Canton Trough area, Central Pacific Basin, and Clarion–Clipperton Zone (Figure 5). Nodules in all these areas have features in common and are thought to have attained their distinctive composition by similar processes.

The potentially ore-grade manganese nodule field in the Peru Basin, centred at about 7°–8° S and 90° W

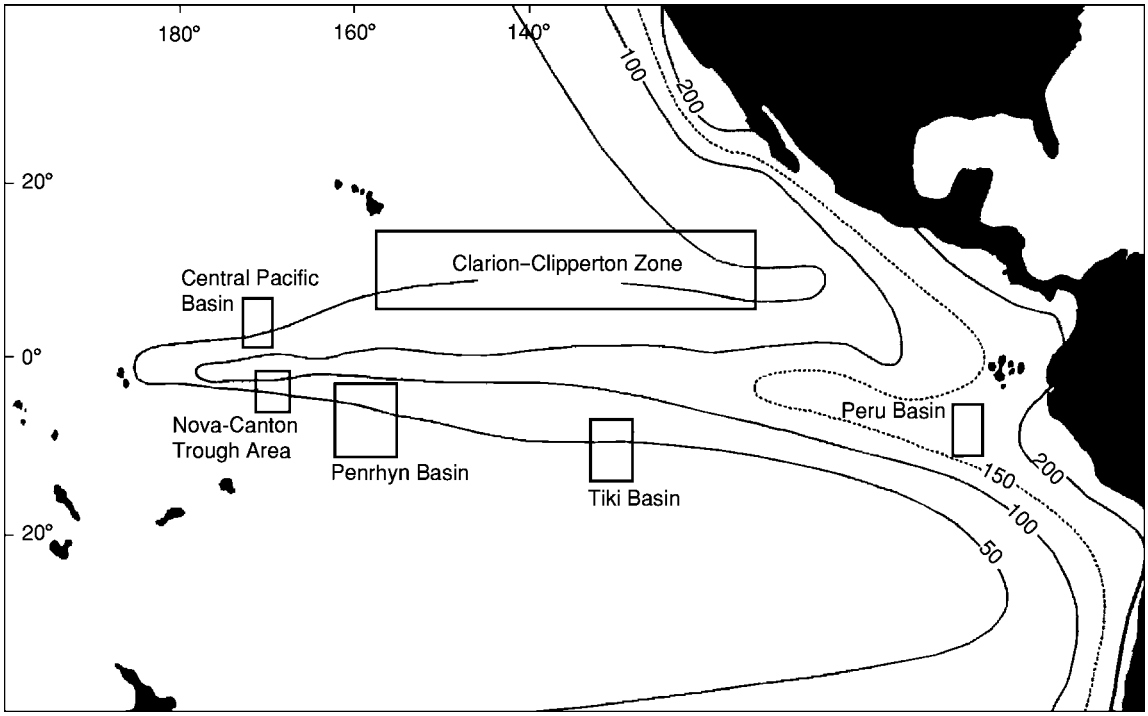

Figure 5 Approximate limits of areas of nickel and copper rich nodules in the subequatorial Pacific referred to in the text (productivity isolines in g Cm ^{2} y ^{1}).

(Figure 5), is situated under the southern flank of the equatorial zone of high biological productivity on a seafloor composed of pelagic brown mud with variable amounts of siliceous and calcareous remains. Nodules from near the CCD at around 4250 m are characterized by diagenetic growth and are enriched in Mn, Ni, and Cu, whereas those from shallower depth are characterized mainly by hydrogenous growth. The Mn/Fe ratio increases from south to north as productivity increases, whereas the Ni and Cu contents reach maximum values in the middle of the area where Mn/Fe ratios are about 5.

In the Tiki Basin there is also an increase in the Mn/Fe ratio of the nodules from south to north. All Ni + Cu values are above the lower limit expected in diagenetically supplied material.

The Penrhyn Basin nodules fall compositionally within the lower and middle parts of the Mn/Fe range for Pacific nodules as a whole. However, nodules from the northern part of the Basin have the highest Mn/Fe ratios and highest Mn, Ni, and Cu concentrations, reflecting diagenetic supply of metals to them, although Ni and Cu decrease slightly near the equator. Superimposed on this trend are variations in nodule composition with their distance above or below the CCD. In the Mn-, Ni-, and Cu-rich nodule area, maximum values of these metals in nodules occur within about 200 m above and below the CCD. The latititudinal variation in Mn, Ni, and Cu in Penrhyn Basin nodules may be due to there being a hydrogenous source of these metals throughout the Basin, superimposed on which is a diagenetic source of them between about 2° and 6° S at depths near the CCD, but less so in the very north of the Basin (0–2° S) where siliceous sedimentation prevails under highest productivity waters.

In the Nova Canton Trough area, manganese concentrations in the nodules are at a maximum between the equator and 2.5° S, where the Mn/Fe ratio is also highest. Manganese shows a tendency to decrease towards the south. Nickel and copper show similar trends to Mn, with maximum values of these elements being centred just south of the equator at depths of 5300–5500 m, just below the CCD.

In the central part of the Central Pacific Basin, between the Magellan Trough and the Nova Canton Trough, diagenetic nodules are found associated with siliceous ooze and clay sedimentation below the CCD. Their Ni and Cu contents increase south-eastwards, reaching a maximum at about 2.5°–3° N and then decrease again towards the equator where productivity is highest.

The Clarion–Clipperton Zone deposits rest largely on slowly accumulated siliceous ooze and pelagic clay below the CCD. The axis of highest average Mn/Fe ratio and Mn, Ni, and Cu concentrations runs roughly south-west–north-east, with values of these elements decreasing both to the north and south as productivity declines respectively to the north and increases towards the equatorial maximum in the south.

Indian Ocean In the Indian Ocean, Mn-, Ni-, and Cu-rich nodules are present in the Central Indian Ocean Basin between about 5° and 15° S. They are largely diagenetic in origin and rest on siliceous sediments below the CCD under high productivity waters. The deposits show north–south compositional variability with the highest grades occurring in the north.

Atlantic Ocean In the Atlantic Ocean, diagenetic Mn-, Ni-, and Cu-rich nodules occur most notably in the Angola Basin and to a lesser extent in the Cape/Agulhas Basin and the East Georgia Basin. These three areas have in common elevated biological productivity and elevated organic carbon contents in their sediments which, coupled with their depth near or below the CCD, would help to explain the composition of their nodules. However, Ni and Cu contents are lower in them than in areas of diagenetic nodules in the Pacific and Indian Oceans.

Distribution and Compositional Variability of Ferromanganese Oxide Crusts

Crusts generally accumulate on sediment free hard rock substrates, and thus their regional distribution is related to that of seamounts, plateaux, and other sediment free areas. In a major study on crusts by Hein *et al*. (2000) it is pointed out that the main substrata on which crusts form include basalt, phosphorite, and limestone. However, other than serving as nucleating surfaces for precipitation to occur, the substrata do not contribute to the formation or the composition of the crusts to any significant degree.

Ferromanganese oxide crusts (excluding hydrothermal ones) are generally less variable in composition than manganese nodules. In a large-scale study on crusts in the South Pacific, Verlaan *et al*. (in press) have shown that over the depth range from which the analysed crusts were sampled (650–5853 m), Co, Mn, and Ni increase as depth decreases, while Fe and Cu increase as depth increases. However, the relationship between crust composition and depth may be more complex than this, as analysis of crust composition versus depth in 500 m depth intervals, shows that in certain intervals the correlations between individual elements and depth differ from their overall correlations with depth. These differences are mainly found between three depth segments, above 1500 m (shallow), 1500–3000 m (middle), and below 3000 m (deep). Particularly noteable are the relationships (or lack of them) between elements in crusts and depth in the shallow segment in comparison with those in the deeper segments. There is an absence of any correlation with depth in the shallow segment for Co and Cu, and there is an opposite correlation with depth in the shallow segment for Mn compared with that in the middle and deep segments. Also noteable is the disappearance in the deep segment of any depth correlation for Ni and Fe, and the weakening of the correlation between Cu and depth.

Investigations on the regional variability in crust composition in the South Pacific by Verlaan *et al*. (in press), show that Co increases overall towards the equator. Manganese also increases from south to north and is generally low south of the 12th parallel. Nickel likewise increases northwards towards the equator, while Fe increases to the south-west, away from the equator. Copper shows little regional variation in crusts in the South Pacific. Regionally, Co, Mn, and Ni maintain an opposite behaviour to that of Fe throughout the South Pacific, over the full depth range of the samples collected. Furthermore, the overall equator-ward increase in Co, Mn, and Ni remains evident in each depth segment. The opposite trends in Co, Mn, and Ni enrichment, on the one hand, and Fe enrichment on the other, start from about the 10th parallel, which is the approximate latitude dividing the the high from the low biological productivity regions in the area studied, suggesting that the latitudinal compositional variations in crusts are at least partly productivity influenced. Longitudinally, Co, Mn, and Ni show a tendency to increase to the north-west and Fe towards the south-west, but these variations are much less pronounced than the latitudinal variations.

Economic Potential

Interest in manganese nodules commenced around the mid-1960s and developed during the 1970s, at the same time as the Third United Nations Law of the Sea Conference. However, the outcome of that Conference, in 1982, was widely regarded as unfavourable for the mining industry. This, coupled with a general downturn in metal prices, resulted in a lessening of mining company interest in nodules. About this time, however, several government-backed consortia became interested in them and this work expanded as evaluation of the deposits by mining companies declined. Part 11 of the 1982 Law of the Sea Convention, that part dealing with deep-sea mining, was substantially amended in an agreement on 28 July 1994, which ameliorated some of the provisions relating to deep-sea mining. The Convention entered into force in November 1994.

During the 1980s, interest in manganese nodules and crusts in exclusive economic zones (EEZs) started to increase. An important result of the Third Law of the Sea Conference, was the acceptance of a

200-nautical-mile EEZ in which the adjacent coastal state could claim any mineral deposits as their own. The nodules and crusts found in EEZs are similar to those found in adjacent parts of the International Seabed Area, and are of greatest economic potential in the EEZs of the South Pacific.

At the beginning of the twenty-first century, the outlook for deep sea mining remains rather unclear. It is likely to commence some time in this century, although it is not possible to give a precise estimate as to when. The year 2015 has been suggested as the earliest possible date for nodule mining outside of the EEZs. It is possible, however, that EEZ mining for nodules might commence earlier if conditions were favourable. It would depend upon many factors; economic, technological, and political.

Conclusions

Manganese nodules and crusts, although not being mined today, are a considerable resource for the future. They consist of ferromanganese oxides variably enriched in Ni, Cu, Co, and other metals. They generally accumulate on or around a nucleus and exhibit internal layering on both a macro- and microscale. Growth rates are generally slow. The most potentially economic varieties of the deposits occur in the subequatorial Pacific.

Phosphates

W D Birch, Museum Victoria, Melbourne, VIC, Australia

Introduction

Phosphorus is the tenth most abundant element on Earth and plays a key role in geological and biological processes. In the mineral kingdom, phosphates are amongst the most complex and diverse, with approximately 460 recognized species. Over the past five years about twenty new phosphate minerals have been recognized.

Phosphates are found in diverse geological environments and in many associations or assemblages. In igneous and metamorphic rocks, members of the apatite group, in particular fluorapatite, are the dominant phosphates. Because the solubility of phosphorus

is generally low in silicate minerals, fluorapatite and other ubiquitous phosphates such as monazite and xenotime usually occur as accessory minerals. An exception to this general rule is the wide diversity of late-crystallising phosphate minerals found in some granite pegmatites (*see* **Igneous Rocks:** Granite). Other important environments include sedimentary rocks, in which phosphates reach their maximum abundance in the form of phosphorite, and the oxidised zones of sulphide-bearing ore deposits. About ten phosphates, including four not found on Earth, have been recorded from meteorites.

Studies of phosphate minerals are important for scientific, environmental, agricultural, and health reasons. For mineralogists and crystallographers, the crystal chemistry of phosphate minerals embraces novel and diverse structures. To mineral collectors, the better crystallized and more colourful phosphates provide an unlimited source of intriguing and attractive specimens. The geochemistry of many phosphate minerals is important, as they commonly include trace amounts of uranium, thorium, and the rare earth elements. Apatite, monazite, and xenotime are significant for geochronology and thermochronology, utilising the trace amounts of radioactive elements uranium and thorium contained in their crystal structure. Phosphate enrichment of soils and discharge of phosphorus-bearing waste are human processes that have significant environmental impact requiring monitoring and control. As well, calcium phosphates are important constituents of human tissue.

There are thousands of references on phosphate minerals, which means that this review cannot be exhaustive. It deals mainly with the classification of phosphate minerals (*see* **Minerals:** Definition and Classification) and the major geological environments in which they occur.

Classification of Phosphate Minerals

The structures of phosphate minerals are almost exclusively built on the tetrahedral anionic unit $(PO_4)^3$, in which the P atom is central to the four O atoms. P–O bond lengths may vary, leading to distortions in the tetrahedra, but the average distance is 1.537 Å. From bond valence considerations, (PO_4) groups link easily with a range of non-tetrahedrally coordinated cations, such as Al^{3+}, Fe^{3+}, Mg^{2+}, Fe^{2+}, Mn^{2+}, Ca^{2+}, Sr^{2+}, Na^+, and K^+. Many phosphates are also hydrated and/or hydroxyl-bearing. Even though the anionic radius of P^{5+} (0.25 Å) is smaller than that of As^{5+} (0.42 Å) and V^{5+} (0.44 Å), a number of near-ideal solid solutions series are observed between phosphates and arsenates and to a more limited extent between phosphates and vanadates.

The crystal structures of most phosphate minerals have been well characterized, thereby facilitating classification. The simplest schemes divide the phosphates into classes based on whether they are anhydrous or hydrated, contain hydroxyl and/or halogen, or contain another anion such as $(SO_4)^2$, $(CO_3)^2$, $(CrO_4)^2$, $(AsO_4)^3$, and $(VO_4)^3$. The well-known Dana system adopts such an approach, as do James Ferraiolo and Hugo Strunz. Alexander Povarennykh combined this approach within divisions based on crystal chemical features. Perhaps because of the great diversity and complexity shown by phosphate structures, overall classification schemes based on crystal chemistry alone have been attempted by only a few researchers, notably Paul Moore, Frank Hawthorne, and Ivan Kostov. These schemes are generally based on the recognition that the PO_4 tetrahedra can polymerize in a number of ways, leading to a broad three-fold subdivision:

i. Polymerization of TO_4 tetrahedra, where T may be P, Be, Zn, B, Al, and Si
ii. Polymerization of PO_4 tetrahedra and MO_6 octahedra. This grouping covers a very large number of species and, within it phosphates can be further subdivided on the basis of whether polyhedra are unconnected, in finite clusters, or in infinite chains, sheets, or frameworks
iii. Polymerization of PO_4 tetrahedra and polyhedra that contain large cations coordinated by more than 6 oxygen atoms.

In many of these structures, OH and H_2O may provide one or more of the oxygen atoms in the PO_4 and MO_6 groups (for simplicity, this is not always indicated in the terminology used in the following review).

Structures with Polymerized TO_4 Tetrahedra

There are about 30 minerals in this category that have structures based mainly on polymerization of two or three PO_4 tetrahedra, or of PO_4 groups with BeO_4, ZnO_4, and AlO_4 tetrahedra. The structures can be based on finite clusters, such as in the rare isostructural zirconium-bearing species gainesite, $Na_2Zr_2[Be(PO_4)_4]$, mccrillisite, $NaCsZr_2[Be(PO_4)_4]$, and selwynite, $NaKZr_2[Be(PO_4)_4]$, or on infinite chains, sheets, and frameworks of tetrahedra. Examples of minerals with structures based on chains of PO_4–BeO_4 linkages included moraesite, $Be_2(PO_4)(OH)$ and roscherite, $CaMn_3[Be_2(PO_4)_3(OH)_3]$, while spencerite, $Zn_4(PO_4)_2(OH)_2$ involves chains of alternating $ZnO_2(OH)(H_2O)$ and PO_4 tetrahedra. Both PO_4–ZnO_4 and PO_4–BeO_4 linkages are present in the sheet-like structures, which include hopeite, $Zn_3(PO_4)_2 \cdot 4H_2O$, scholzite, $CaZn_2(PO_4)_2 \cdot 2H_2O$,

the isostructural herderite, $CaBe(PO_4)F$, (Figure 1) and hydroxylherderite, $CaBe(PO_4)OH$. In the infinite framework structures, all except berlinite, $AlPO_4$, which is isostructural with quartz, are based on PO_4–BeO_4 linkages, including beryllonite, $NaBePO_4$ and pahasapaite, $Li_8Ca_8Be_{24}(PO_4)_{24} \cdot 38H_2O$, which has a complex, zeolite-like framework structure.

Structures with Linked TO_4 Tetrahedra and MO_6 Groups

About 180 minerals are known to be represented in this structural grouping, with most being infinite frameworks. Only five minerals are known that have structures based on isolated or finite clusters of tetrahedra and octahedra, linked together by hydrogen bonding. They include struvite, $NH_4Mg(PO_4) \cdot 6H_2O$, anapaite, $Ca_2Fe^{2+}(PO_4)_2 \cdot 4H_2O$, and morinite, $NaCa_2Al_2(PO_4)_2(F,OH)_5 \cdot 2H_2O$. There are twenty-two minerals with structures based on infinite chains of tetrahedra and octahedra. These can be subdivided further into five topologically distinct types, depending on how the TO_4 and MO_6 groups are linked. A group of minerals that includes collinsite, $Ca_2(Mg,Fe)(PO_4)_2 \cdot 2H_2O$, and fairfieldite, $Ca_2(Mn,Fe)(PO_4)_2 \cdot 2H_2O$, consists of chains of alternating $(M^{2+}O_4\{H_2O\}_2)$ octahedra and pairs of (PO_4) tetrahedra, with the chains linked by 7-coordinated Ca atoms and by hydrogen bonding. In childrenite, $(Fe,Mn)Al(PO_4)(OH) \cdot H_2O$, and members of the jahnsite group, $CaMn(Fe,Mn,Mg)_2Fe_2(PO_4)_4(OH)_2 \cdot 8H_2O$, chains are based on corner-sharing octahedra with bridging (PO_4) groups, while in bearthite, $Ca_2Al(PO_4)_2(OH)$, adjacent octahedra share an edge to build chains linked by $(PO_4)_4$ groups and Ca cations.

Nearly 50 minerals are known to have structures consisting of infinite sheets of (PO_4) tetrahedra and (MO_6) octahedra. These structures can also be grouped, depending on how the octahedra and tetrahedra are linked. However, due to their complexity, it is not feasible to describe or summarise them here. Some of the more important phosphates with sheet-like structures include members of the crandallite group, based on $[Al_3(PO_4)(PO_3\{OH\})(OH)_6]$, and vivianite, $Fe_3^{2+}(PO_4)_2 \cdot 8H_2O$. About 110 phosphate minerals are known to have framework structures, by far the largest group. Important minerals in this category include wavellite, $Al_3(PO_4)_2(OH,F)_3 \cdot 5H_2O$ (Figure 2), variscite, $AlPO_4 \cdot 2H_2O$, pseudomalachite, libethenite, $Cu_2(PO_4)(OH)$ $Cu_5(PO_4)_2(OH)_4$, members of the turquoise $[CuAl_6(PO_4)_4(OH)_8 \cdot 4H_2O]$ group, the iron phosphates dufrenite, $Fe^{2+}Fe_4^{3+}(PO_4)_3(OH)_5 \cdot 2H_2O$, and rockbridgeite, $(Fe^{2+},Mn)Fe_4^{3+}(PO_4)_3(OH)_5$.

Structures with TO_4 Groups and Large Cations

In the phosphate minerals within this broad grouping, the main cations, which may be either monovalent, divalent, or trivalent, are coordinated to varying numbers of oxygen atoms to form polyhedra, which

are then linked in various ways, commonly through (PO_4) tetrahedra, to form chains. Chains are then linked to form sheets, which stack in various crystallographic directions. It is not possible here to describe or summarize individual structures, but some important minerals represented include xenotime, (Y,Yb)(PO_4), and members of the monazite (REE,Ce,Ca,Th)(PO_4) group, as well as a suite of hydroxyl-bearing and hydrated ammonium, sodium, and potassium-bearing species typically found in cave environments. However, the apatite group is the most significant in this structural category and is briefly outlined below. There is also an important and widespread suite of phosphate minerals whose structures are dominated by the uranyl $(U^{6+}O_2)^{2+}$ group (Figures 3 and 4).

Figure 3 Crystals of meta autunite, $Ca(UO_2)(PO_4)_2\ 6H_2O$ (up to 7 mm wide) from Autun, Burgundy, France. Museum Victoria specimen M27680, photograph by F Coffa. Reproduced with permission from Museum Victoria.

Figure 4 Crystals of saleeite, $Mg(UO_2)(PO_4)_2\ 8H_2O$ (up to 4 mm across) from the Ranger mine, Northern Territory, Australia. Museum Victoria specimen M45060, photograph by F Coffa. Reproduced with permission from Museum Victoria.

These include about thirty species in two main groups related to torbernite, $Cu(UO_2)(PO_4)_2 \cdot 10H_2O$, and phosphuranylite, $KCa(H_3O)_3(UO_2)_7(PO_4)_4O_4(UO_2)(PO_4)_2 \cdot 8H_2O$, respectively.

The Apatite structural group The apatite group contains ten species, including pyromorphite, $Pb_5(PO_4)_3Cl$, and belovite, $Sr_3Na(Ce,La)(PO_4)_3(OH)$. However, fluorapatite, $Ca_5(PO_4)_3F$, chlorapatite, $Ca_5(PO_4)_3Cl$, and hydroxylapatite, $Ca_5(PO_4)_3OH$, are the most widespread and influential in geological and biological processes. The essential atomic arrangement for these three species consists of (PO_4) tetrahedra and two Ca polyhedra (Figure 5). Ca1 is coordinated to nine oxygen atoms, and Ca_2 bonds to six oxygen atoms and one anion (F, Cl, or OH) situated in channels running parallel to the *c*-axis. The Ca1 polyhedron shows little response to the effect of different channel anions, whereas in the Ca_2 polyhedron there are significant shifts in the positions of the channel anions, arising from their markedly different sizes. The structure permits a very wide range of substitutions in all cation and anion sites in natural and synthetic apatites. For example, the monovalent ions in the *c*-axis channel sites can be replaced by divalent anions such as $(CO_3)^2$ (eg., in carbonite–fluorapatite) and O^2 . Vacancies may also occur in the *c*-axis channels. A large number of divalent cations (for example Pb^{2+}, Ba^{2+}, Mn^{2+}, and Sr^{2+}) can substitute for Ca. The (PO_4) group is commonly replaced by other tetrahedral anion groups, such as $(AsO_4)^3$, $(SO_4)^2$, $(SiO_4)^4$, and $(VO_4)^3$. Apatites may also take up rare earth elements but the mechanisms are complex and beyond the scope of this discussion.

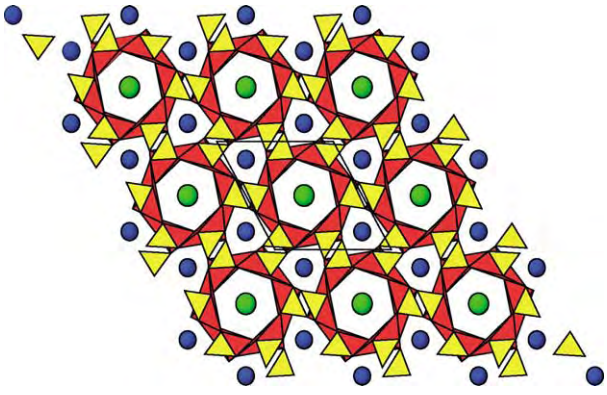

Figure 5 Apatite crystal structural diagram, viewed down the c axes and with the unit cell outlined in black. The PO_4 tetrahedra are yellow, the smaller Ca site is drawn as red polyhedra, the second Ca is shown as blue balls and the (F, Cl, OH) ion is green. Diagram prepared by A Pring.

Geological Environments for Phosphate Mineral Occurrences

Phosphate minerals are found in a wide range of igneous, metamorphic, and sedimentary rocks. In general however, only three minerals—apatite *per se*, monazite, and xenotime—are ubiquitous in typical igneous and metamorphic rocks. With a few exceptions, however, such as granitic pegmatites, alkaline intrusive rocks and some calc-silicate skarns and marbles (Figure 6), these minerals occur as primary accessory phases only. Their abundance is a general indication of the phosphorus content of the rock, as phosphorus has low solubility in most silicate minerals. Extreme phosphorus enrichment in magmas in represented by carbonatites, in which apatite is the most widespread economic mineral, notably in two deposits, Phalaborwa in South Africa and Khibiny on the Kola Peninsula in Russia.

In sedimentary rocks, phosphate minerals are represented throughout the geological time-scale to the present day, and occur in a wide range of host rocks. Many are hosted by metasediments, in which mobilization and recrystallization of original primary phosphate have yielded diverse assemblages of species.

Figure 6 Fluorapatite crystal (2 cm long) in marble from Wilberforce, Ontario, Canada. Museum Victoria specimen M39659, photograph by F Coffa. Reproduced with permission from Museum Victoria.

Granite Pegmatites

Apatite varieties dominate the phosphate suites found in many granite pegmatites and may crystallize at different stages. For example, primary apatite may occur intergrown with feldspar, quartz, and tourmaline, or it may crystallize later as a druse or miarolitic-cavity mineral during the hydrothermal stage (Figure 7). At lower temperatures, crusts of carbonate-bearing apatite may form.

Paul Moore has constructed a 'paragenetic tree' of pegmatite phosphates. Primary phosphates are found as giant crystals or lenticular masses which crystallized near the core of the pegmatite, usually embedded in massive quartz. As well as apatite, the triphylite–lithiophilite, triplite–zwieselite, and amblygonite–montebrasite series are significant at the primary stage, with the last series in places constituting an ore of lithium. Metasomatic alteration during the final stages of pegmatite formation may result in these primary phases being partially replaced by such species as alluadite, triploidite–wolfeite, and purpurite–heterosite, which may be nodular and fine-grained. Typical reactions during alteration involve Na, K, and

Figure 7 Fluorapatite crystal (12 mm across) showing colour zonation, in granite from Lake Boga, Victoria, Australia. Museum Victoria specimen M29944, photograph by F Coffa. Reproduced with permission from Museum Victoria.

Ca displacing Li, and the addition of OH. The largest diversity of phosphate species in granite pegmatites arises from the oxidation of these primary phases. This may take place under 'hydrothermal' conditions, at temperatures less than 250°C during the cooling history, or much later during atmospheric weathering. The great diversity of these secondary species reflects the mixed valence states of Fe and Mn; the different configurations in which oxygen atoms from H_2O molecules and OH and PO_4^2 groups may cluster around these metal cations in octahedral coordination; and the different ways the octahedra can combine (polymerise) to form clusters in solution. Such clusters may be represented in the crystal structures of secondary phosphates. Amongst these are barbosalite, rockbridgeite, beraunite, phosphosiderite, strengite, leucophosphite, bermanite, strunzite, laueite, cacoxenite, cyrilovite, eosphorite–childrenite, and ludlamite (Figure 8), which are derived from Fe- and Mn-bearing primary phosphates. Species such as hurlbutite, herderite, brazilianite, morinite, crandallite, and whitlockite are derived from primary phosphates with low Fe and Mn and/or high Li contents. Many of these secondary species crystallise as small crystals in open cavities, resulting from removal of much of the PO_4^2 and most of the alkalis.

Figure 8 Ludlamite crystal group (12 mm across) from the San Antonio mine, Chihuahua, Mexico. Museum Victoria specimen M37681, photograph by J Broomfield. Reproduced with permission from Museum Victoria.

The best known and most prolific localities for phosphate minerals include the famous pegmatites of the Black Hills, South Dakota; the Palermo mine, New Hampshire; Hagendorf Sud, Bavaria; Tsaobismund, Namibia; Buranga, Rwanda; Viitaniemi, Finland; Sapucaia, Brazil, and occurrences in southern California and Maine in the USA.

Sediment-Hosted Phosphate Deposits

Sedimentary phosphates—phosphorites—are the most important of the world's sources of phosphate rock (*see* **Sedimentary Rocks:** Mineralogy and Classification). They occur on every continent and range in age from Precambrian to Holocene, with nearly all having a marine origin. Modern phosphorites are mineralogically monotonous, consisting of grains of cryptocrystalline or amorphous carbonate-fluorapatite (variously referred to as collophane or francolite), occurring as beds ranging in thickness from a few centimetres up to tens of metres. Other forms of phosphorite include nodules and concretions. Phosphorites are commonly observed in shallow seas, along the edges of continental shelves, and on ocean plateaus. The phosphorus is believed to be derived from faecal matter, bone material, and decaying marine organisms that accumulate locally or are carried into shallow coastal regions by upwelling deep ocean currents. These nutrients encourage a diverse biota to flourish, ultimately producing organic-rich sediments. During early diagenesis, collophane precipitation occurs within the upper layers of these sediments from pore waters rich in phosphorus leached from the organic remains; precipitation is enhanced where phosphatic nuclei are already present. A changing depositional environment with periods of reduced deposition and reworking of sediments in shallow seas favours phosphogenesis. This model is generally applicable to old phosphorites that remain recognizable, such as those of the Cambrian–Ordovician Georgina Basin, in Queensland, Australia. However, settings and methods of deposition (including transport of phosphate grains) vary widely and are subject to debate. Study of the age and global distribution of phosphorites has led to the identification of major phosphogenic episodes as far back as the Proterozoic.

Older phosphorites are more likely to have undergone diagenesis, deformation, and metamorphism, to the extent that the original nature of the deposits may become obscured. Phosphorus may be mobilized in solution and distributed into surrounding rocks, where diverse suites of well-crystallized secondary phosphates may form. Perhaps the most notable such

occurrence is in the Cretaceous Rapid Creek Formation in the Canadian Yukon. Here, a marine sequence of ironstone and shale containing unusual Fe- and Mn-bearing phosphates instead of collophane has been deformed and uplifted. This resulted in sets of fractures in which a wealth of well-crystallized phosphate minerals have formed. Four major assemblages characterized by the predominance of specific elements and related to a specific host rock have been identified, with at least five new phosphate species recognized (baricite, garyansellite, gormanite, kulanite, and penikisite). As well, remarkable crystals of arrojadite, augelite, and lazulite, amongst others, occur in this fracture-filling paragenesis.

In south-eastern Australia, a variety of settings for sedimentary phosphate deposits has been recognized, with several producing a range of unusual, in some cases new species. Some deposits have been exploited for phosphate, but all are low grade. The oldest deposits are in South Australia, where there are two main phosphatic horizons, one Late Precambrian, the other Early Cambrian, associated with limestones. There has been local leaching and intermittent concentration of phosphate by replacement. The Moculta deposit has been affected by regional metamorphism, which has recrystallised and brecciated the phosphatic rock. A range of secondary phosphate minerals, such as wavellite, beraunite, cyrilovite, leucophosphite, variscite, crandallite, and aldermanite (for which Moculta is the type locality) has been recorded in veinlets and small cavities and probably formed during near-surface weathering. An intense and prolonged weathering origin can probably be ascribed to a suite of phosphate minerals found in metamorphosed Early Proterozoic iron-rich sediments at Iron Monarch, in the Middleback Ranges. Over thirty phosphate species, including bermanite, collinsite, cyrilovite, fairfieldite, kidwellite, montgomeryite, turquoise, and wavellite, have been identified. A number of vanadates also occur in the assemblage. In central Victoria, small, low-grade phosphate deposits within Ordovician black slate–chert host rocks exhibit a number of mineralization styles, such as phosphorite bands, intraformational breccias, and vein networks. Secondary minerals resulting from weathering of the primary phosphorites include wavellite, turquoise, variscite, cacoxenite, and fluellite.

Amongst the world's largest phosphate deposits are those of Morocco, where Late Cretaceous marine sediments occur on the plains fronting the Atlas Mountains (*see* **Africa:** North African Phanerozoic). These are nodular and sandy deposits riddled with fish teeth and fit well into the upwelling nutrient-rich current model outlined above. Other significant world producers of sedimentary phosphate are the USA, Brazil, and China.

Guano Deposits

Phosphate deposits derived from bird and bat guano represent only a small proportion of the total world reserves of phosphate rock. Insular deposits are common in warm-arid or semi-arid regions with large bird populations either at the present day or in the recent past. The most important deposits, now essentially worked out are on larger islands over 50 metres above sea-level, such as Nauru and Christmas Island, and are thought to be older than about one million years old. In these deposits, solutions derived from overlying bird droppings have percolated into the bedrock, where minerals such as apatite, whitlockite, crandallite, and millisite have crystallized. This phosphatized bedrock forms much of the resource.

Cave phosphate deposits derived from bat droppings are of more interest for the unusual minerals they may contain than for their economic value. Such deposits are mostly in limestone caves, with a minority in lava-tube caves. The chemical reactions involved in forming phosphate minerals are complex, but usually begin with leaching of very soluble nitrogen from the guano. This leaves phosphorus to combine with whatever cations are available from the surrounding rocks. The resulting sequence of minerals may be well stratified within the guano. Typical cave phosphates include brushite, carbonate-hydroxylapatite carbonate-fluorapatite, taranakite, and variscite, generally occurring as powdery nodules within the guano or as coatings on bedrock or cave walls. Distinct crystals of phosphate minerals, such as newberyite and struvite are rare, with a notable occurrence in lava caves at Skipton, Victoria.

Phosphates in Oxidized Metal Sulphide Deposits

Large numbers of phosphate minerals occur in the oxidized zones of base metal orebodies. Solubility phenomena play the most important role in determining which phosphates crystallize in these low-temperature environments, where generally acidic groundwaters dominate. Phosphates of Pb^{2+} are generally the least soluble, so these minerals, particularly pyromorphite (**Figure 9**), are prominent in oxidized zones above galena-bearing ores. As primary ores commonly contain a mix of lead, copper, and zinc sulphides, as well as arsenopyrite, a diverse suite of secondary phosphates and arsenates can form in oxidized zones. Whether phosphates will be prominent over arsenates depends on the availability of phosphorus, usually as apatite, in either the primary ore or the host rocks – it can vary widely. These differences are illustrated by the two most mineralogically diverse oxidized zones known. At Tsumeb, Namibia, arsenates generally dominate the secondary assemblage, whereas at Broken Hill,

Figure 9 Pyromorphite crystals (up to 5 mm long) from Yang Shao mine, Guangxi Province, China. Museum Victoria specimen M48184, photograph by J Broomfield. Reproduced with permission from Museum Victoria.

in New South Wales, Australia, both phosphates and arsenates occur. The phosphate assemblage libethenite–pseudomalachite is particularly widespread above copper-bearing sulphides in arid regions. Notable occurrences of zinc phosphates, including parahopeite, hopeite, tarbuttite, and scholzite, occur at Broken Hill, Zambia, and at Reaphook Hill, in South Australia. The great chemical diversity shown by secondary phosphates is reflected in their often-spectacular colours and crystal habits, making them much prized by mineral collectors.

Geochronological and Thermochronological Applications of Phosphate Minerals

Apatite, monazite, and xenotime commonly contain between a few tens and hundreds of ppm U and Th in their crystal structures. As a result, several different isotopic dating techniques can be applied to them. While the underlying principles, assumptions, and counting methods for each technique are complex and beyond the scope of this review, a brief summary of each is useful. Fission track dating (*see* **Analytical Methods:** Fission Track Analysis) uses damage tracks in apatite arising from the spontaneous fission of ^{238}U, which occurs at a known rate. Measuring the number of tracks that have accumulated since a crystal formed, along with estimating the amount of uranium it contains, means that a geological age can be calculated. Because fission tracks in apatite are 'healed' or annealed at temperatures over about 120°C, only rocks which have not undergone subsequent heating events can be dated this way. However, the annealing properties of apatite fission tracks have led to a growing number of opportunities to model significant thermal processes in the upper parts of the Earth's crust. These include reconstructing the thermal histories of sedimentary basins (*see* **Sedimentary Environments:** Depositional Systems and Facies) and evaluating their potential for oil and gas resources, and estimating the timing and magnitude of erosional and tectonic denudation of mountain ranges (*see* **Plate Tectonics**).

The U–Th–Pb and (U–Th)/He dating methods applied to apatite, monazite, and xenotime have as their basis the decay series of the long-lived isotopes of uranium, ^{238}U and ^{235}U, and of thorium, ^{232}Th. These decay at a known rate through a series of short-lived radionuclides ultimately to Pb isotopes. Determination of the ratios of ^{206}Pb/^{238}U and ^{207}Pb/^{235}U enables a concordia plot to be drawn, which provides an age for the crystals being analysed. However, there are many complicating factors involved in interpreting these plots and in measurement of the data. As well, different methods of determining isotopic compositions are available and need to be selected, depending on which mineral is involved, the precision required, and other factors. The assumption behind the (U–Th)/He method is that all three phosphates appear to retain He, which is produced during the alpha decay of ^{147}Sm. By measuring U, Th, and He contents, an apparent He age can be calculated on the assumption that the initial He content of the mineral was zero. Both the U–Th–Pb and (U–Th)/He methods are still being developed and refined but offer great scope for accurate dating of Earth processes.

Phosphate Biomineralization

The main inorganic constituent of bones and teeth in vertebrate animals, including human beings, is an apatite-like mineral similar to carbonate-fluorapatite. Small amounts of other elements such as sodium, potassium, magnesium, and zinc are present in the structure. The precipitation of apatite takes place after secretion of certain proteins by specialized cells. Other phosphate minerals such as whitlockite, struvite, and brushite, as well as a number of amorphous calcium and/or magnesium-bearing phosphates, have been found in pathological tissue calcifications, such as dental and urinary calculi. Formation of these and other biophosphates is sensitive to conditions such as temperature and pH, so that transformation by dissolution and recrystallization, especially of apatites, may take place. A range of synthetic apatites, in the form of cements and porous ceramics, is now being developed and trialled in order to repair defects and damaged tissue and to correct deformities. These have the capacity to considerably improve both the quality and span of human life.

Environmental Significance of Phosphate

Phosphorus is essential for all forms of life. Considerable cycling of phosphorus takes place within the biosphere and interchange occurs between ecosystems. While the overwhelming amount of phosphorus fluxing takes place between marine organisms and ocean water, human activities play a significant role at the ecosystem scale. The widespread use of phosphate-based fertilisers and insecticides, the disposal of sewerage sludge and industrial waste, including some derived from nuclear reactors, are examples of larger-scale processes that can have serious environmental impacts. Perhaps the best known involves the overload of phosphorus in streams and lakes, leading to an explosion of plant life, especially algae, which upon decay uses up most of the dissolved oxygen. This process, known as eutrophication, results in fish kills (*see* **Fossil Vertebrates:** Fish) and degradation of water quality. On a more restricted scale, there is some evidence for the formation of lead phosphates such as plumbogummite–crandallite and pyromorphite–apatite in soils verging on roads and highways used by vehicles burning leaded gasoline. Increasing awareness of all these problems has meant that control programmes are in place in many regions. Phasing out of lead-based fuels and phosphate-based detergents, together with possible use of crystalline phosphates and phosphate glasses for nuclear waste immobilization, are also helping to improve environmental outcomes.

Rudaceous Rocks

J McManus, University of St. Andrews, St. Andrews, UK

Introduction and Terminology

Sedimentary rocks in which coarse particles are dominant are termed 'rudites'. They consist of broken fragments, clasts, of pre-existing rocks, and have formed in a wide range of conditions, such as in scree, in landslides, as tills, on alluvial fans and in many sites along river courses, on beaches, in offshore reef-fringing areas and in deep-water environments. Characteristic inter-relationships between the rudites, and other environmentally significant features of these rocks and their associated sediments provide clues to their modes of origin. The clasts themselves provide additional evidence from their shapes and composition. The particle shapes evolve during transport, and textural sorting by size, shape or form may characterize certain depositional conditions. The composition of the particles often indicates the nature of the source from which they were derived. The rudaceous deposits, therefore, provide a stimulating variety of geological challenges at all levels.

The term conglomerate is applied to rudaceous rocks composed of rounded pebbles, and breccia to those composed of angular clasts. A distinction is made between rudaceous rocks where the clasts are in contact with one another, and those in which the clasts 'float' in a finer matrix of sand and clay. These are termed 'clast-supported' and 'matrix-supported' conglomerates respectively. Intraformational rudaceous rocks are composed of clasts of penecontemporaneously cemented sediment; limestone 'beach rock', for example, or intraformational shale pellet conglomerates. Most rudaceous rocks, however, are composed of 'extraformational' clasts derived from outside the formation in which they occur. A further distinction is made between rudaceous rocks composed of many or one rock type. These are termed 'polymictic' and 'ologomictic' conglomerates respectively.

Rudaceous Rock Textures and Fabrics

The size of the particles is of primary importance. Pebbles are defined as particles between 4 mm and 64 mm in diameter and cobbles up to 256 mm. Coarser materials are boulders or blocks. No natural deposits of clastic materials consist of clasts with a single size of particles and a range of diameters are always present. This is partly a function of the material supplied and partly due to variations in the dynamics of the transporting medium and in the conditions during deposition. As large quantities of sediment (often tens of kg) need to be analyzed to obtain statistically meaningful information on coarse grain size populations, such information is relatively rare. In many cases the coarseness quoted is related to the diameter of the largest clast observed, or the average of the largest clasts.

When clasts are released from their source rocks their shapes are defined initially by the distribution of weaknesses in the parental rocks. Fractures such as bedding planes, joints, or cleavages exert a major influence in both the size and shape of the materials produced. Likewise the composition of the bedrock determines the ease with which the large fragments become broken and rounded in transport. Soft, poorly cemented sandstones and limestones break apart more readily and form better rounded clasts than schists, quartzites or granites.

Three aspects of particle shape need to be considered characterizing pebbly materials, namely roundness, sphericity, and form. The three measures may appear related but they address totally different aspects of the clasts. In a numerical sense the roundness is the relationship between the radius of curvature of the sharpest edge and the length of the longest or intermediate axes or a combination of the two. It is conventionally expressed:

$$\text{Roundness} = \frac{\text{average radius of corners and edges}}{\text{radius of maximum inscribed circle}}$$

For speed of processing, most workers assess roundness with the aid of visual comparator charts, as shown in Figure 1.

The sphericity of a clast is the ratio of the diameter, D, of a sphere having the same volume as the clast to that of a circumscribing sphere (i.e., the longest axis, A). It may also be defined as a triaxial ellipsoid based on the product of the lengths of the three diameters of the particle to the volume of the circumscribed sphere, i.e., BC/A^2, where B and C are the intermediate and short axes respectively. Sphericity is also expressed as:

$$\text{Sphericity} = \frac{\text{surface area of the particle}}{\text{surface area of a sphere of equal volume}}$$

Since particles settle through any transporting medium with their maximum projection area

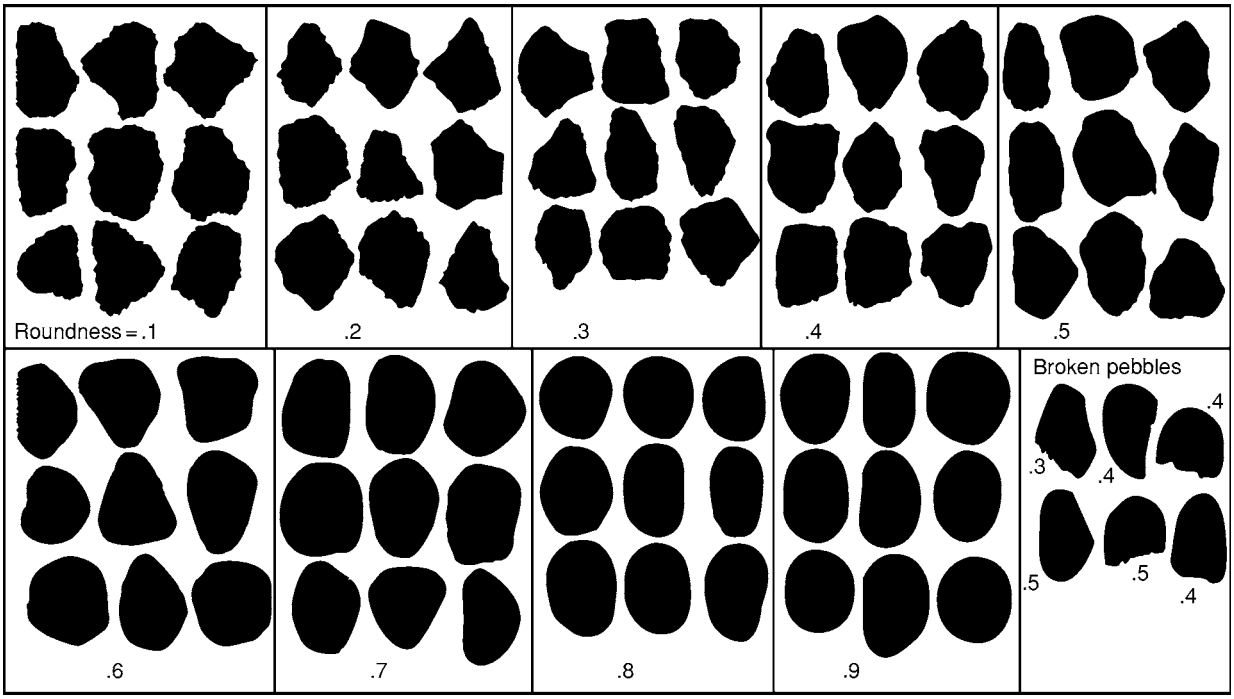

Figure 1 Roundness chart for particles 16 32 mm diameter (Reproduced from Source; Krumbein WC (1941) Measurement and geological significance of shape and roundness of sedimentary particles. *Journal of Sedimentary Petrology* 11: 64 72).

perpendicular to the direction of settling a more dynamically related measure may be obtained by comparing that value with the projection area of the maximum circumscribing sphere as (C^2/AB) 1/3. The reciprocal of this value is of importance, relating to the ease of transport.

Clast form notation (Figure 2) is based on two ratios (2/3) of the particle axes, B/A and C/B to define four form fields: spheres (equant), discs, blades and rods. Using the same three axial lengths it is possible to create a triangular, ten-field form diagram (Figure 3). Although various other combinations of axial ratios have been suggested none has achieved the lasting impact of the above methods of characterizing pebble form. In any attempt to relate the particle form to particular environments of deposition it is necessary to measure a significant number of pebbles (over 200), so that a definitive spread of values may be obtained.

Plotting the values of A against A/B enabled Moss (1962) to identify three particle populations, which he termed framework, interstitial and contact, in a range of gravel deposits. The framework consists of a pebble population graded in size from small and equant particles to relatively large and elongated clasts over a small size range. The interstitial population is subsidiary to and always associated with the framework. Its coarsest pebbles are the same size as, but more elongated than the finest framework material. The contact population, which may be very minor in proportion or may dominate the deposit, is normally coarser than the coarsest part of the framework and characteristically is more equant in form. The contact population is of materials that are unable to fit into the stable gravel bed and commonly move more rapidly along the river than the bulk of the bed material. The value of 1.5 for A/B provides a separation of blades and rods from the discs and spheres, but as indicated above, in natural systems the rods and spheres generally behave similarly. In order to provide a dynamically meaningful plot, while retaining the use of ratios of the A and B axes, the use of D, the volumetrically determined nominal diameter of the clasts, again enables the four particle forms to be recognized (Figure 4).

Since each of the three properties roundness, sphericity, and form are at least partly defined from the particle diameter they are not entirely independent. Along a sediment transport path, such as a river, the mean clast diameter decreases with distance traveled, an exponential relationship, in which the most rapid changes occur near the source and progressively lesser changes in more distal locations (Figure 5).

Both sphericity and roundness increase as the particles decrease in size, and again the changes are most

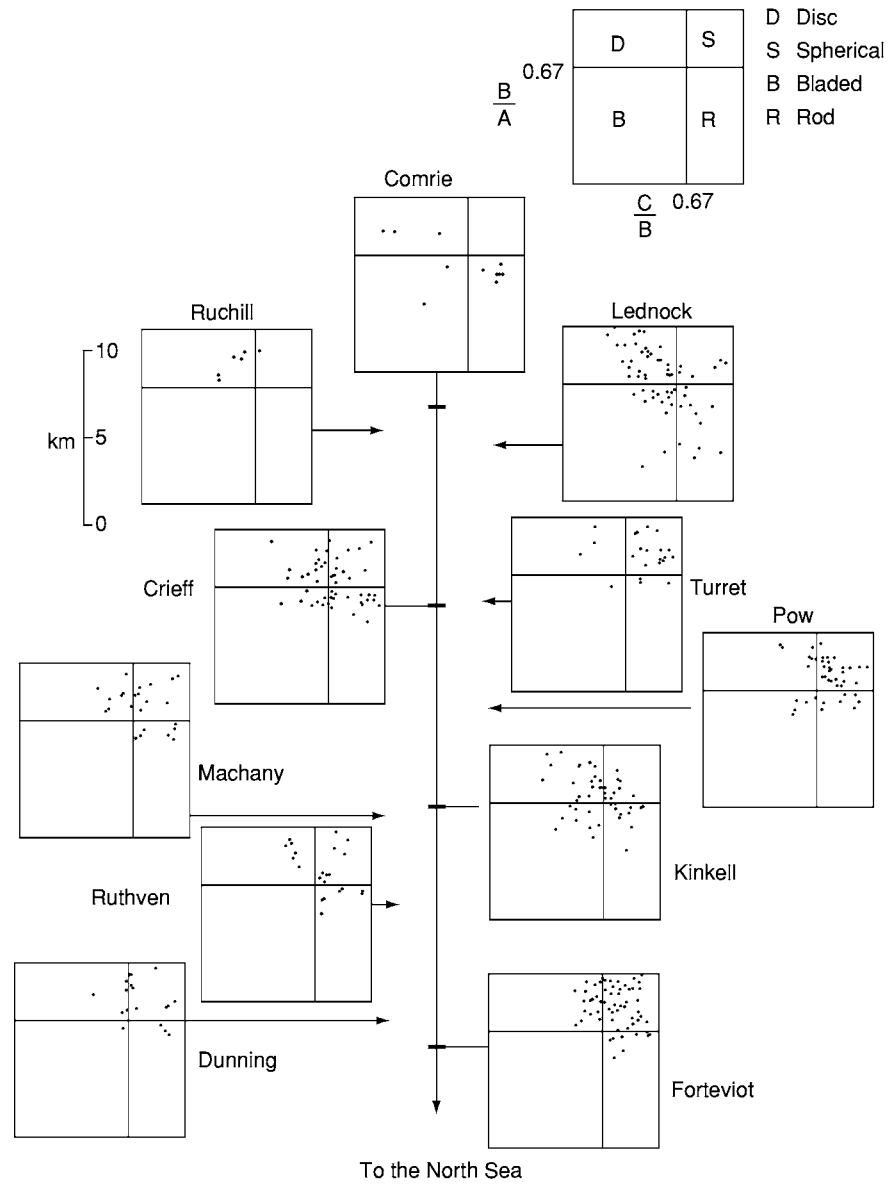

Figure 2 Variation of form of quartz pebbles along the River Earn, Scotland, using the Zingg (1935) plot (after Al Jabbari, Al Ansari and McManus (1982) *Journal of Water Resources* 1, 81 110).

rapid near the source. The main controls of roundness are a) distance traveled; b) composition of the pebble; c) clast size; d) initial clast form; e) nature of the bed material, and f) the dynamics of the transporting medium. Whilst these controls are readily isolated in the laboratory they are not so readily assessed in the field, where most gravel-transporting streams receive detritus derived from tributary catchments that includes pebbles having different transport histories that are added along the length of the stream. Furthermore, erosion of stream bank terraces or tills may lead to the addition of clasts at any point along the stream.

Clasts in Natural Environments

When the coarse particles are released from the exposed rock surfaces to form scree move down slopes debris flows or landslides, or enter streams to be carried into lakes or the sea, where they may form beaches, gravity is the prime motive force. Gravity is all-important in the initial stage, whether the clasts are released from the rock face by frost wedging or by a combination of physical and chemical weathering processes. Within scree, debris flow or landslide particle motion is enhanced by the lubricating and hydraulic effects of water, or ice, working in

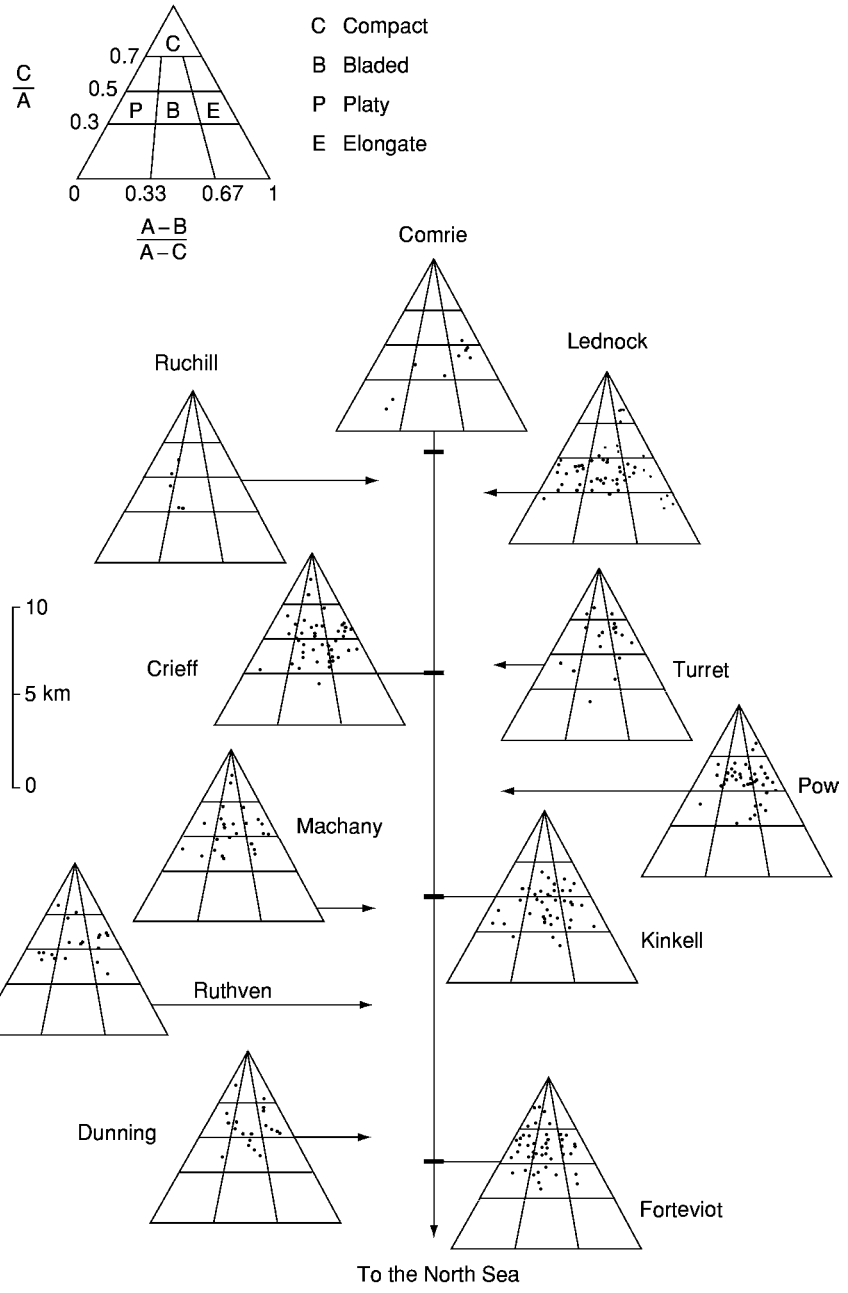

Figure 3 Variation of form of quartz pebbles along the River Earn, Scotland, using the Sneed and Folk (1958) plot. (After Al Jabbari, Al Ansari and McManus (1982) *Journal of Water Resources* 1, 81 110).

combination with gravitational downhill pull, although frictional forces generated by neighbouring materials impede free movement.

Measurement of clasts from screes of different rock types in Scotland revealed that very few of the original clasts fall into the form field for rods or spheres. Virtually all were either discs or blades when released into the environment. Both the composition and structure of the materials, as well as physical weathering by frost action, are believed to exert major controls on form.

Clasts in Streams

When a mixed population of particles occurs on a stream bed the finest, silt-sized particles are carried away in suspension, and the sands saltate downstream, bouncing along with the flow. The pebbles normally remain on the bed, often with their upper parts extending through the boundary layer of the flow. Once flow strength exceeds some critical value the smaller pebbles begin to slide or roll along the bed, and as flow strength increases so increasing quantities

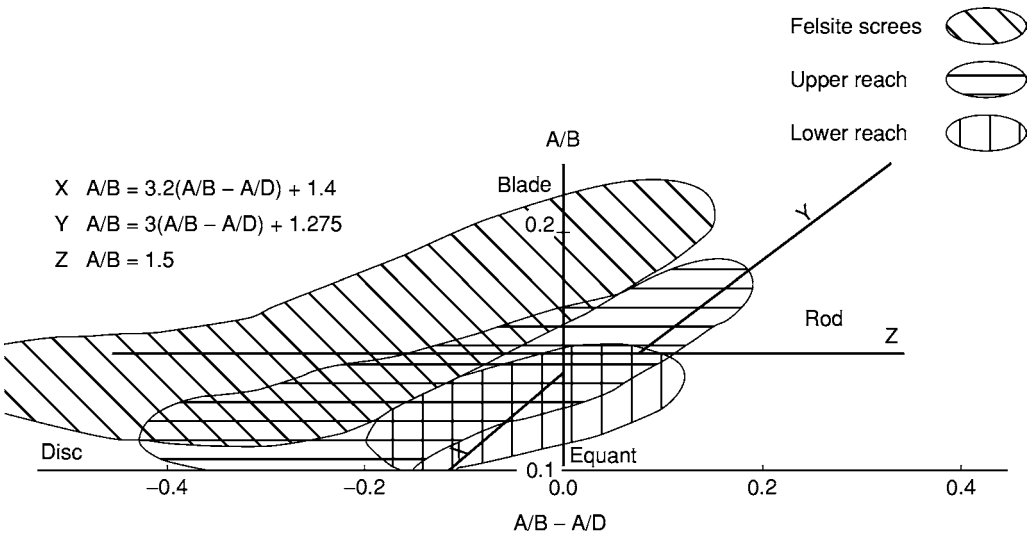

Figure 4 Variation of pebbles form from scree, and the upper and lower reaches of the Shee Water, Scotland, using the A, B and D diameters (after Dhiab IH 1979, unpublished M.Sc. Thesis, University of Dundee).

migrate until, in extreme floods, most of the bed is in motion. As the power of the flow decreases so particles become deposited and the bed aggrades, as material accumulates. During floods the entire bed down to bedrock may become removed from a reach of the river, to be replaced by new material as the peak of flooding passes. There are records of over 8 m of bed removal and replacement during individual storms in the western USA. The various interrelationships between water flow, sediment size, sediment load, and stream slope are summarized in Figure 6.

Under normal conditions the 'vibration' of the turbulent flow induces minor movement within the bed, leading to the upward migration of the coarser particles, while finer materials move downwards into the deposit. In this way the stream bed develops a residual lag of coarse pebbles, and there is a progressive downward fining of the gravels. Frequent inter-pebble contacts induce progressive rounding of edges through abrasion in the bed and surfaces exposed on the streambed become scoured through collisions with the saltating sand grains.

Within the stream bed the clasts may become arranged such that an internal texture, related to both size and form of the particles is developed. The texture results from burial of blades or discs whose intermediate axes slope upstream (up current). This is termed imbrication. During motion the more equant particles roll along the bed once they have been disturbed, whereas the flatter clasts are more likely to slide across the other pebbles, turning over as they encounter immobile clasts. The ability of the clast to find a place into which it can fit in the bed often determines the distance that it travels during any single displacement from the bed. The more nearly spherical the particle the greater the difficulty it experiences and the further it is likely to move once displaced from its resting place.

Attrition of the sliding and turning particles increases the probability of their splitting to form smaller more equant or rod-shaped pebbles. There is commonly a size gradation along the length of a gravel bar within a braided stream reach, with the coarsest clasts at the upstream end and progressively smaller ones downstream. As breaking of the pebbles occurs along the river so there is a downstream increase in the proportion of spherical clasts within the bed load.

Clasts on Beaches

Once the pebbles reach the sea, either from a river, or cliff collapse, they become subject to the motion of waves, which carry them along the coast by longshore drift, and deposit them on beaches. Beaches formed entirely of gravel occur on dynamic coasts. The presence of sand is an indication of quieter conditions. The latter used the 10-fold form diagram to differentiate between beach and river gravels with some success.

The gravel beaches of South Wales develop a fourfold structure, recognized on the basis of pebble size, form and the texture of the deposit. Between an upper zone of coarse discs and a lower zone principally of spheres lies a zone with imbricate discs, which passes down slope into a infill zone comprising particles of many shapes, and often incorporating sand (Figure 7).

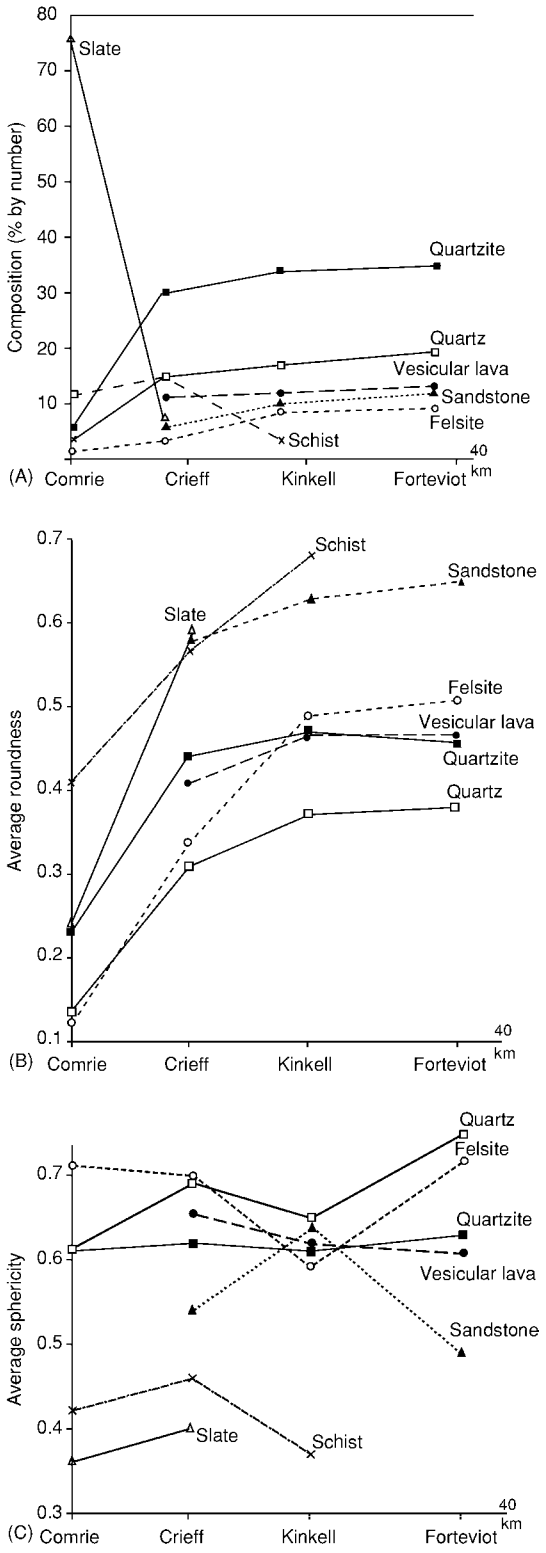

Figure 5 Variation of A) the pebble composition, B) roundness, and C) sphericity along the River Earn, Scotland (after Al Jabbari, Al Ansari and McManus (1982) *Journal of Water Resources* 1, 81 110).

As clasts are brought to a beach they are carried by waves that wash over the surface many times during transport of the particles. The mobile clasts interact with the underlying gravels. If they are larger than the pore spaces between the settled clasts the pebbles bridge the gap and continue to migrate along or up and down the beach. If the clasts are too small they enter the open spaces, but wash through to continue migrating. A clast of similar size will fully occupy the space provided. In this way clasts of similar size and form characteristics gather together usually on the lower parts of beaches and provide 'selection pavements', effectively providing a gauntlet through which clasts must pass if they are to move up or down the beach face. Noting the internal structure of many beaches in western Scotland, Bluck examined gravel beaches forming and migrating through time, drawing attention to the prevalence of imbricate structural zones in almost all beaches examined (Figure 8).

Particle tracing techniques using dyes, paint or creating artificial electronically tagged pebbles have enabled the motion of individual pebbles to be tracked sometimes for periods exceeding ten tides. Disturbance of the sediment often penetrates to 10–20 cm below the beach surface under moderate sea conditions. Large clasts migrate along the beach face more rapidly than do their smaller counterparts, and under identical conditions (on the same days) clasts of ironstone migrate more slowly than similar clasts of sandstone, and they in turn are more sluggish than matched coal fragments. The density of the particles provides the control in this case. On many British beaches rates have been measured of longshore movement of 5–8 cm diameter clasts of flint, chert, sandstone and ironstone of up to 10 m per tide under moderate wave conditions. This suggests that many of the features illustrated by Bluck may be essentially short lived, although regularly regenerated in the same locations.

Where steep rocky cliffs lie behind the coast, direct cliff fall contributes boulders and cobbles to the beach. The large clasts become rounded through attrition but remain on the beach.

Ancient or 'fossilized' cliffed coasts are rarely preserved, but at Enard Bay, north-west Scotland, a Precambrian coastline has been exhumed showing cliffs cut into Lewisian Gneiss, and cut into Lewisian gneisses with Torridon Group marginal fanglomerate and beach deposits banked against it (Figure 9).

Isostatic uplift following deglaciation has allowed many former coasts to rise above current sea level, and the raised beach features preserved around many northern European and north American coasts display most of the internal textures explored by Bluck.

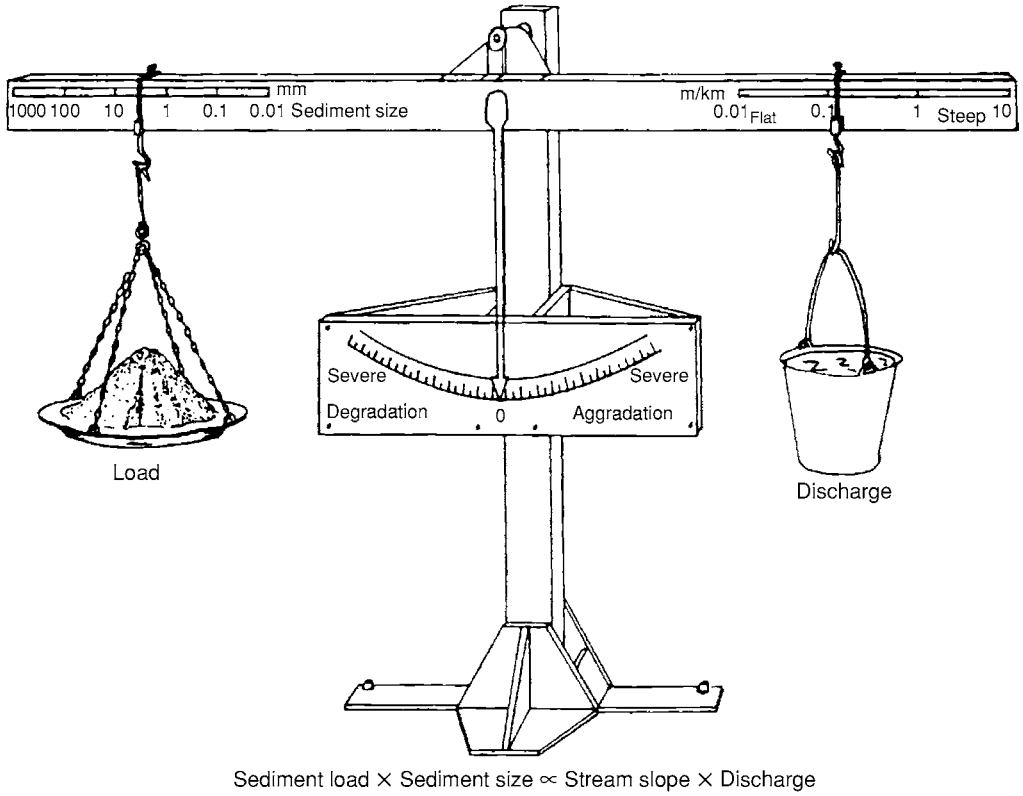

Figure 6 Interrelationships between factors controlling a stable channel bed in a river (after Lane 1955).

Lakeshore gravel beaches are common, but the low power in the waves generated on small lakes ensures that the beaches rarely achieve a fully mature condition. The large clasts are commonly essentially static, show limited size and shape sorting, and are often poorly rounded. Rods and spheres are generally more common in the coarser particles than in the smaller clasts.

In shallow tropical or subtropical seas carbonate sediment dominates. These include in situ reef rock, and carbonate sands and muds. All of these may become quickly cemented, and subsequently eroded during heavy storms generating large amounts of rudaceous detritus. An apron of limestone breccia may extend into deep waters at the foot of reefs and other abrupt carbonate shelf margins. Such reef apron breccias have been recognized in the Permian Capitan Reef of Texas and New Mexico, around many Carboniferous structures in Britain and Belgium, and round Cretaceous reefs in the French Juras.

Clasts on Alluvial Fans

Adjacent to newly emergent mountains, or uplifting fault blocks rapid changes of stream bed gradient ensure that deposition of sediment occurs adjacent to the source, creating alluvial fans of coarse detritus. These sediments are particularly well preserved in arid or semi-arid areas providing important sites in which rudaceous materials accumulate. In the geological past, before evolution of extensive land-living plants in the Devonian, fans were widely developed and thick accumulations of pebbly sandstones mark the margins of areas of active uplift.

The evolving alluvial fans, or the coalescent adjacent fans forming a bajada, produce wedges of sediment, commonly but against a fault. Repeated uplift generates successions of wedges of coarse materials stacked above each other, with thicker beds of coarse sediments near the source, grading to thinner beds of finer materials in more distal areas. The uppermost parts of the fans are characterized by the presence of debris- and mud-flow deposits, each of which contain large clasts, but the latter also contain much fine sediment. In essence the water drains from the moving sediment-enriched flow to induce deposition. The fan head is dominated by ribbons of the mass flow deposits, through which the streams erode as they flow towards the lower, outer parts of the fan, where slopes decrease from 5° to less than 1° and the waters become divided into many distributaries. The sediments of the outer part of the fan are dominated by sheets of sand or gravel from the often ephemeral, braided streams. Characteristically, the fan sediments

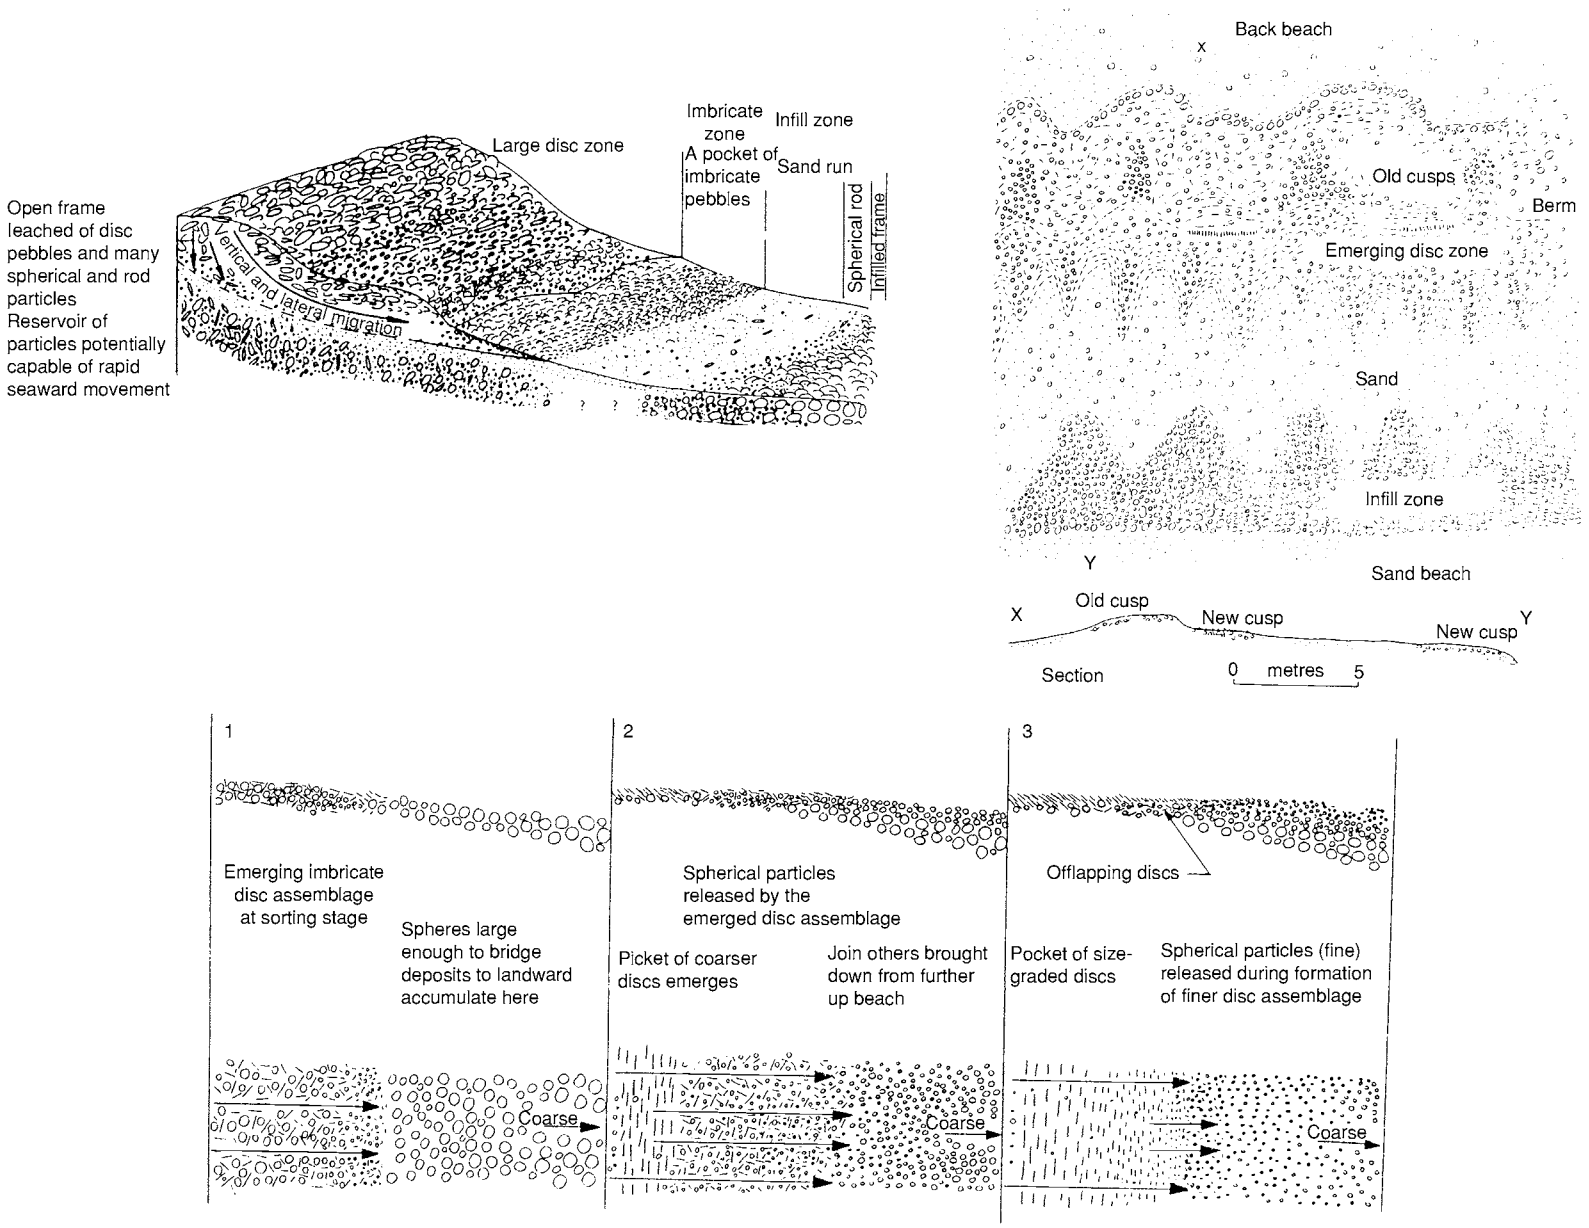

Figure 7 Arrangement of clasts on gravel beaches (after Bluck BJ (1999) *Transactions of the Royal Society of Edinburgh* 89, 291 323).

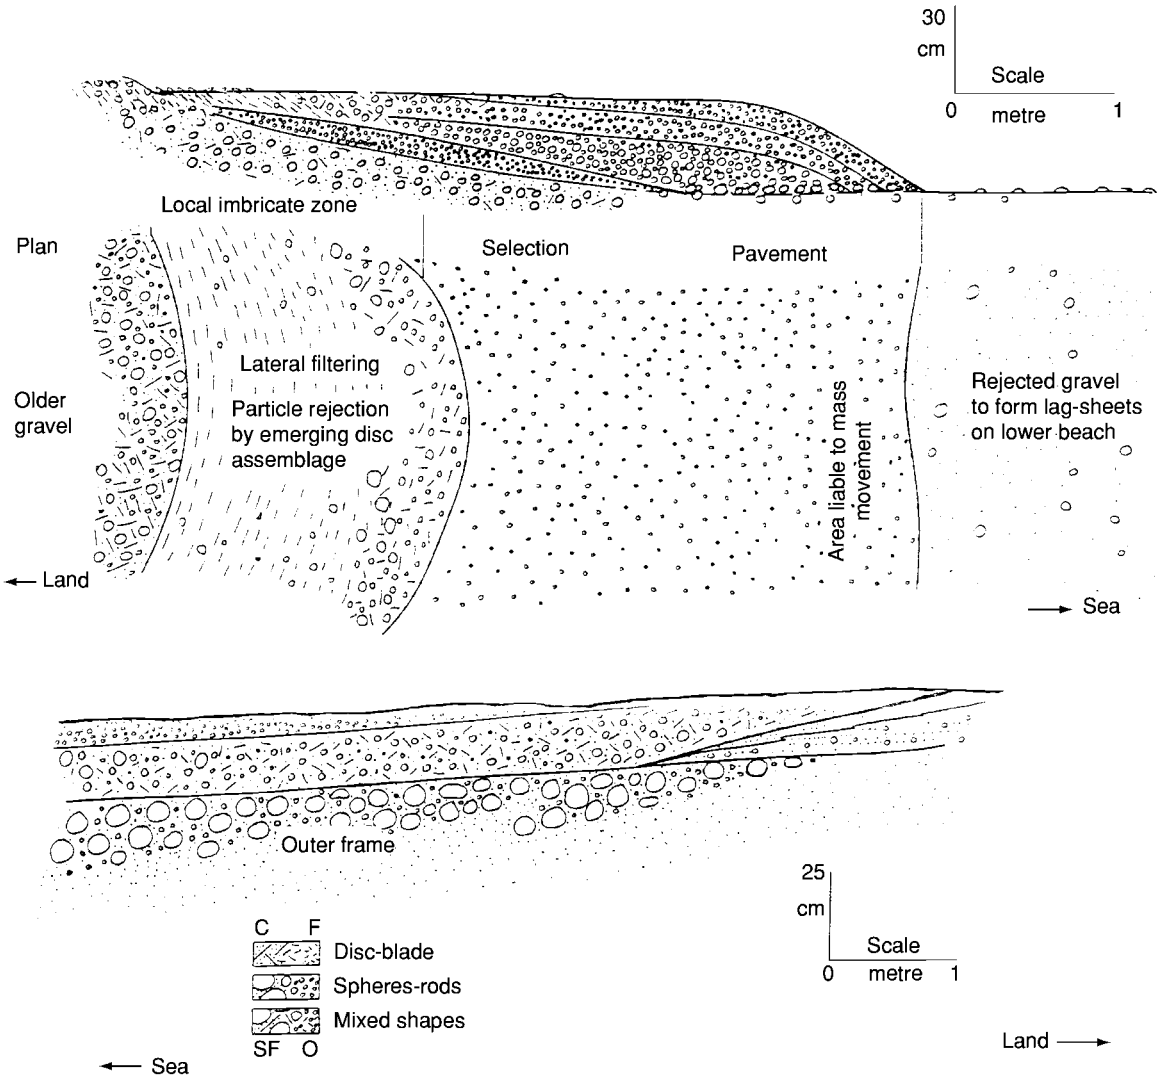

Figure 8 Schematic cross sections of beaches from south west Scotland (after Bluck BJ (1999) *Transactions of the Royal Society of Edinburgh* 89, 291 323).

are coarse, and dominated by gravels in the upper reaches, becoming more fine grained in the lower areas.

Sheet-like conglomerates with pebbles of similar sizes result from the formation of temporary selection pavements during sheet flows of flood discharge. Other deposits fill shallow channels scoured into pre-existing sediments. Sometimes their steeply inclined imbricate clasts serving to identify channel margins, while more gently inclined clast axes occur in the central parts of the channels. The maximum clast size decreases exponentially down fan, as does the thickness of the individual conglomeratic beds.

The alluvial fan-bajada systems may extend for 25–30 km from the fan head on to alluvial plains, for tens of kilometres along active mountain fronts, and, where long-lived geologically the deposits may reach several kilometres in thickness. Such dimensions are recorded from modern systems in Nevada, ancient fans in Texas, and from Neogene deposits of Italy and Switzerland, related to the rising Apennines and Alps respectively. In Britain large ancient fans have been identified from the Applecross Formation of the Torridonian (Late Precambrian) of northwest Scotland, with smaller fans in the Devonian successions of the Midland Valley and Orcadian basins of Scotland, and of Permian age in south-west England.

Clasts in Braided Rivers

The outermost parts of some fans are dominated by braided streams, whose normally shallow channels of low sinuosity, become subdivided by mid-channel

Figure 9 Exhumed cliffline and beach sediments of Early Torridonian age, Enard Bay, north west Scotland.

bars. The braided rivers beyond the fans typically develop in areas with greatly varying water discharge histories. The wadi-floor streams of desert and semi-desert areas, for example, receive little water for many months before floods sweep through the area carrying sediment-charged waters capable of transporting material up to the size of large boulders. Thus more people drown in deserts than die of thirst. As the waters subside the sediments are rapidly deposited to give a layer of coarse, matrix-supported gravel.

Another important site for the formation of braided systems is in the periglacial sandurs and plains associated with glacial retreat, such as those of Iceland. The rivers carry little water during the winter months, but in summer may carry large quantities of glacial melt water, accompanied by the transport of high sediment loads, which become deposited as the bed gradient and flow velocities fall. These streams drain areas in which sediments of all size are available and movement is minimally restricted by vegetation. In rift valleys rudaceous marginal fault-bounded fanglomerates may pass out into braided river sands and gravels on the floor the central parts of basin (Figure 10).

The deposits of braided rivers, explored by Miall and Bluck, typically show successions of fillings of stacked channels, some of the major stream, and others of second or third-order channels (Figure 11). Typically upward fining sheets of sand and gravel result from the migration of mid-channel and overbank bars that are the principal sites of deposition. Miall showed that in the upper reaches of some

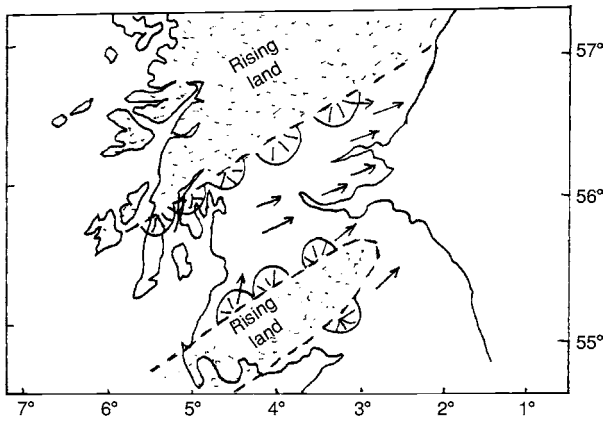

Figure 10 Suggested distribution of Upper Old Red Sandstone alluvial fans in central Scotland (after Trewin NH and Thirlwall MF (2003) Old Red Sandstone. In: Trewin NH (Ed.) *The Geology of Scotland*, 4th edn, pp. 213 251. London: The Geological Society of London).

braided systems debris flows occur within the more normal upward fining cycles of the flood deposits. He identified three pebble-rich assemblage types, dominated by channel gravels with intervening debris flows, by superposed channel bars or by channel floor gravels passing upwards into current bedded sands. Pebbles also occurred less frequently in other sand-rich braid deposits. In the British geological column the braided systems have been recognized from the Precambrian Torridonian, in both the upper and lower Old Red Sandstone (Figure 12) of the Devonian and in the New Red Sandstones of the Permo-Trias.

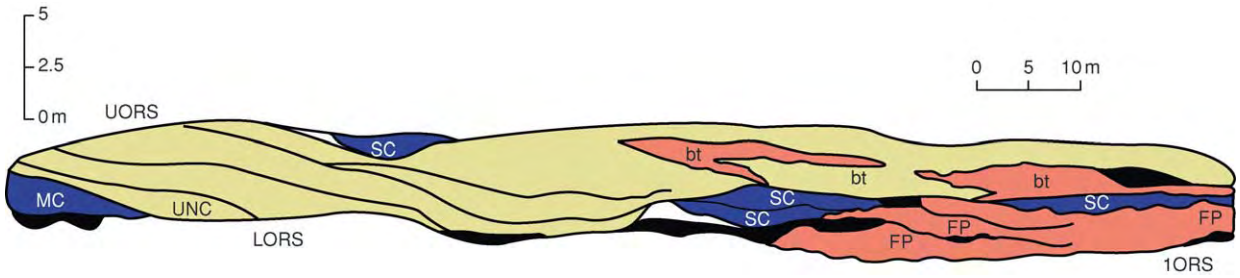

Figure 12 Coarse Lower Old Red Sandstone conglomerates at Stonehaven, Scotland. The larger clasts are over 1 m in diameter.

Clasts in Tills

Rudaceous sediment is found in glacial tills (*see* **Sedimentary Processes:** Glaciers). Tills may be composed of any mix of coarse and fine materials. Whereas in the mountains large boulders are common in clast-supported tills, in more distal areas the more readily transported fine materials dominate. Two forms of till are recognized. Lodgment tills are in direct contact with the underlying rocks, and have usually been deposited beneath the moving glacier, and been partly compressed by the weight of overlying ice. Particles in this deposit may be striated. The overlying ablation till is structurally weaker, having been deposited from down-melting ice. Imbrication, indicating the direction of ice flow, may form in clast-supported or matrix-supported tills. Often in areas away from the mountain sources the large Pleistocene ice sheets became enriched with locally derived materials in addition to those derived from upper catchment areas. Tills containing glacial erratic clasts have been recorded from the Precambrian and Permo-Carboniferous and Cretaceous glaciations in many parts of the world.

Deep Water Rudaceous Deposits

Rudaceous deposits, both terrigenous and carbonate, occur in deep-water environments, ranging from turbidites to mega-boulder complexes. Gravels in turbidites are restricted to the basal part of the graded bed, and increase in size and abundance towards the source. Isolated clasts occur in debris and grain flows. At the other extreme is the 'Wild-Flysch' of Alpine geologists, termed 'olostostroma' by Italians. These are irregularly shaped formations that contain clasts the size of skyscrapers and jumbo-jets. Such deposits usually occur at the foot of submarine fault scarps, and are associated with tectonic disturbances of violent intensity.

Conclusions

The clasts of rudaceous sediments hold important information about not only the rock types of the hinterland from which they were derived, but also about its geological history. As a terrain is unroofed it will shed progressively older and more lithified clasts into the depositional system. With continuous or discontinuous uplift erosion unmantles progressively older or more changed, often more highly metamorphosed materials, which are transported and deposited in the resultant conglomerates and breccias. Structurally or compositionally weak rocks do not preserve as well as stronger materials and allowance must be made in attempting to reconstruct unroofing histories. Furthermore, it is generally the more chemically stable silica-rich rocks that contribute to rudaceous deposits. Thus, of all of the sediments it is sandstones and cherts that are preserved at the expense of shales and limestones, of metamorphic rocks quartzites are preserved at the expense of slate and schist. Of all of the igneous rocks, pebbles of rhyolite are more usually preserved than those of basalt or gabbro.

Now that our understanding of the processes leading to the formation of rudaceous deposits is fairly advanced, much present research is moving into the field of exploring the geological characteristics of ancient catchments, even to the level of distinguishing separate phases of advance of thrust sheets into an area during orogeny.

The rudaceous rocks have much to offer the sedimentologist and the geological historian. The ability to recognize particular depositional environments in the ancient record and to recreate the conditions at the land surface during mountain-building enables the geologist to postulate the locations of potential metalliferous and hydrocarbon economic resources. Gold and uranium occur in Precambrian rudaceous rocks in Canada, the USA, Brazil and South Africa, wherein those of the Witwatersrand basin are probably the best known. Rudaceous rocks host placer ores in many parts of the world. Because they are composed of clasts, which of their very nature are tough, and therefore of low porosity, Rudaceous rocks are seldom good petroleum reservoirs. But it is as aggregates for road building and construction that unconsolidated rudaceous sediments are economically most important.

Sandstones, Diagenesis and Porosity Evolution

J Gluyas, Acorn Oil and Gas Ltd., Staines, UK

Introduction

Sand comprises particles of rock and mineral with a mean grain size between 0.0625 and 2 mm and deposited by sedimentary processes on the Earth's surface (*see* **Sedimentary Rocks:** Mineralogy and Classification).

The composition of sand is highly variable, depending on the source of the sediment and the extent to which weathering and erosion during transport have removed unstable minerals (*see* **Weathering**). As a general rule, sands derived, first cycle, from igneous and metamorphic terrains tend to contain more mineral phases that are unstable under surface and shallow burial conditions than do sands that have been involved in many cycles of erosion, transport, and deposition.

Following deposition, sand may become buried. It may also be lithified (indurated) into sandstone. The process whereby sand becomes sandstone is known as diagenesis (*see* **Diagenesis, Overview**). It includes three distinct components: one mechanical (compaction) and two chemical (cementation and dissolution).

When sands are deposited, they are commonly highly porous and highly permeable. Any given volume of newly deposited sand will contain between 40% and 50% pore space (Figure 1). The permeability of loose sand is enormous, measured in tens to hundreds of darcy. Sandstones are less porous and less permeable, there being a continuous range from the values for sand shown above to sandstones that are non-porous and impermeable.

Grain Size and Sorting

Sand having grain sizes between 0.0625 and 2 mm is further divided into a series of subcategories, from very fine sand at the lower end of the size range to very coarse sand at the upper end of the range. Smaller grains (silt and clay grade) and larger grains (granules to boulders) are defined in **Sedimentary Rocks:** Mineralogy and Classification. Grain size is governed by the grain or crystal size in the provenance area and the degree of abrasion suffered by the sediment *en route* from the source area to deposition. Sorting is a measure of the range of grain sizes in a given sand sample. Well-sorted sand has a narrower range of grain sizes than poorly sorted sand. Sorting within sand is controlled by both provenance and sedimentary process. Surface processes which constantly rework sediment, such as in shallow marine settings (wave

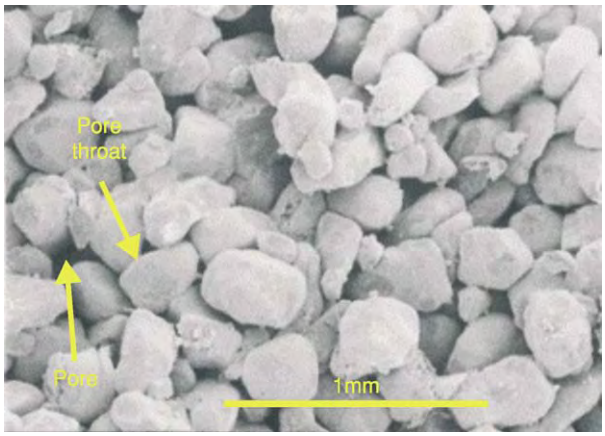

Figure 1 Well sorted, medium grained, aeolian, uncemented sandstone from the Cleeton Field, UK southern North Sea, showing well developed pores and pore throats; scanning electron photomicrograph. From Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

and tidal action), are likely to produce better sorted sand than, for example, gravity-driven processes such as debris flow. However, if the sediment provenance area comprises well-sorted sand, so too will the deposition area, irrespective of the specific sedimentary process responsible for deposition.

The grain size and sorting of sand control its initial permeability and the sorting of sand controls its initial porosity. Moreover, as compaction and diagenesis proceed, the 'memory' of the depositional characteristics can be retained, such that the sands that were the most permeable at deposition become the most permeable sandstones after compaction and cementation.

Compaction

Loose sand compacts easily. During initial burial, much of the compaction is taken up by the rearrangement of grains. Simple burial combined with seismic shock will turn loose sand into consolidated sand. The amount of porosity lost will depend largely on how well sorted the sand is. In poorly sorted sand, more porosity will be lost than in well-sorted sand – small grains fill in between larger ones. As burial continues, rough edges tend to be knocked off grains, so aiding greater compaction. At deeper levels (about 1–4 km), the sand begins to behave like a linearly deformable solid. Deeper still, plastic deformation is probably more common. The boundaries between the occurrence of these processes will vary from sand to sand and basin to basin and, in some instances, may be gradational.

The net outcome of all the above processes is that sands compact when stressed, but decompact very little when the stress is released. This means that, for compacted but uncemented sandstone at the Earth's surface, it is possible to calculate the maximum stress suffered in any previous burial phase. Such a stress calculation can be used to provide an estimate of the maximum burial depth.

In the geological literature, there are a large number of so-called compaction curves for sandstones. Alas, most of these curves are porosity/depth plots, rather than porosity/stress plots. As such, the great swathes of data on these plots include, but do not differentiate, the effects of fluid overpressure and sandstone cementation. However, experimental data are available on the way in which sands compact and, for clean quartzose or arkosic sandstones, these data have been used to formulate a compaction equation

$$\Phi = 0.5 \exp\left(\frac{-10^{\ 3}z}{2.4 + 10^{\ 4}z}\right)$$

where z is in metres.

In this equation, porosity is expressed as a fraction (i.e., <1) and the equation is calibrated to a normal hydrostatic pressure gradient. If the system is overpressured, the pressure borne by the grains is less than in a hydrostatic system and an effective depth must be calculated. As a simple rule of thumb for typical burial depths of 2–4 km, 1 MPa of overpressure is equivalent to about 80 m less burial. The equation is well tested, predicting porosity to within $\pm 3\%$ at 95% confidence limits.

Sands that contain easily squashed grains, such as glauconite or mica, and those rich in matrix clay lose porosity much more readily at a given applied stress. Empirical curves linking porosity to applied stress have also been constructed for sands with various quantities of easily deformed grains.

Detrital Mineralogy

Quartz is the most common mineral found in sands and sandstones (*see* **Minerals:** Quartz). Feldspar and lithic (rock) fragments are also common in most sandstones and, as a consequence, these three components are often used to classify sandstones. The QFL plot sums the three components (quartz, feldspar, lithics) to 100% on a triangular diagram (Figure 2). The triangle is divided into fields: quartz arenite, sublithic arenite, arkosic arenite, etc. There is no strict convention as to whether polycrystalline quartz is included with (monocrystalline) quartz or with lithic fragments, although it is common to label the diagram so as to show where the polycrystalline quartz has been included. The feldspar component includes both alkali and plagioclase, whilst the lithic component can include sedimentary, igneous, and metamorphic

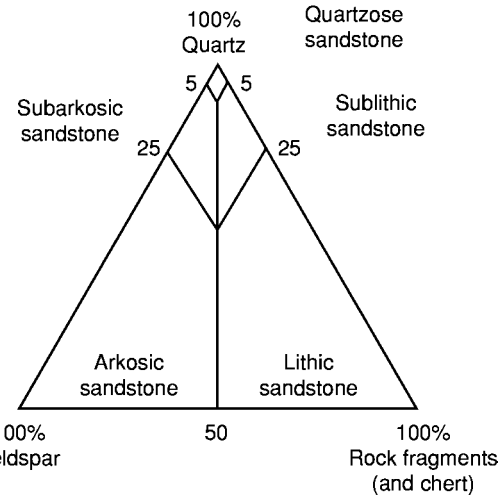

Figure 2 Sandstone classification using the QFL (quartz, feld spar, lithic fragments) system.

Table 1 Summarized mineralogy of the Upper Jurassic Brae Formation (Miller Field) and Middle Jurassic Etive Formation (Columbia Field), UK North Sea

	Brae formation	*Etive formation*
Quartz + polycrystalline quartz	86.3	74.1
Total feldspar	2.0	3.3
Mica	1.0	1.9
Other detrital minerals	1.6	1.1
Matrix clay	0.9	1.2
Organic matter	1.1	0.4
Calcite cement	0.2	1.8
Siderite cement	0.0	0.0
Quartz cement	5.3	3.9
Pyrite cement	0.2	0.4
Kaolinite cement	0.1	6.1
Illite cement	1.3	5.8
Number of samples	56	18

rock fragments. Although the QFL diagram is widely used, it may not be adequate for some sandstones, in which case alternative classifications and descriptions may be employed, e.g., micaceous sandstone, glauconitic sandstone, shelly sandstone, and tuffaceous sandstone. Most sandstones contain between about 10 and 20 distinct mineralogical and rock components (Table 1).

Diagenetic Mineralogy

Minerals that precipitate during diagenesis are commonly referred to as cements. A wide variety of cements have been identified in sandstones. Some are common, others are rare. The most common cements, in decreasing order of abundance, are quartz (Figure 3), carbonates, zeolites, clays, and evaporite minerals (Figure 4). Less common cements include barite, celestite, opal, amorphous silica, albite, haematite, pyrite and other sulphides, apatite, and many more. A systematic study of more than 100 case histories of diagenesis from a range of sandstones worldwide has revealed several recurring patterns, in addition to demonstrating the relative abundance of the five mineral groups (quartz to evaporites) listed above (Figure 5). There appear to be five common styles of diagenesis that can be seen in sandstones of different ages from across the globe. The mineral associations that form these styles are as follows.

- Quartz-dominated diagenesis with lesser quantities of clay minerals and carbonate minerals that precipitated after the quartz.
- Clay mineral-dominated diagenesis with lesser quantities of carbonate minerals and quartz or zeolite that precipitated after the quartz.

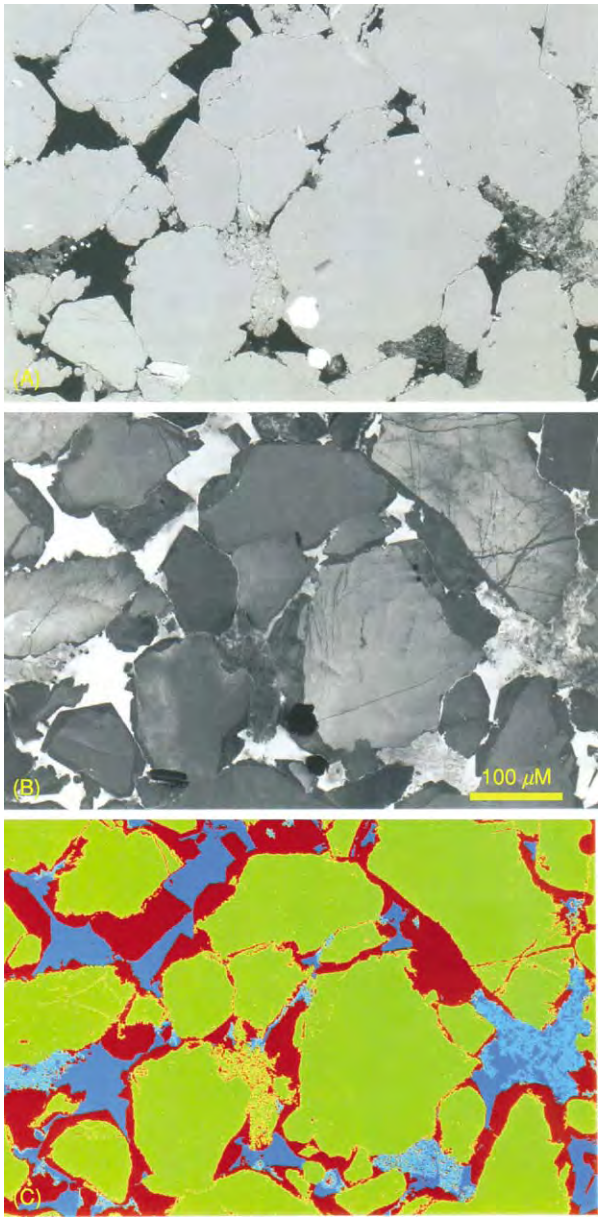

Figure 3 Quartz cemented quartzose sandstone, Miller Field, North Sea. (A) Backscattered scanning electron microscopy (BSEM) photomicrograph. Minerals with highest mean atomic number appear white and those with lowest mean atomic number appear black. Pore space is filled with a low mean atomic num ber resin, so appearing black. (B) Scanning electron microscopy (SEM) cathodoluminescence (CL) image of the same field of view as in (A). There are a few impurities and lattice defects in the syntaxial quartz cement and fracture fills, and so these areas appear darker than the detrital grains. (C) Combined BSEM and CL images with false colour added. Green, quartz grains; red, quartz cement; blue, pore space. The areas of pale blue are resin impregnated kaolinite plates and partially dissolved feld spar grains. From Gluyas JG, Garland CR, Oxtoby NH, and Hogg AJC (2000) Quartz cement; the Miller's tale. Figure 5 Styles of diagenesis summarized from a worldwide survey. From Kupecz JA, Gluyas JG, and Bloch S (1997) *Reservoir Quality Prediction in Sandstones and Carbonates, American Association of Petroleum Geologists' Memoir 69*. Tulsa: American Association of Petroleum Geologists.

- Grain coating clay precipitated soon after deposition and wholly or partially inhibiting subsequent precipitation of quartz and carbonates.
- Carbonate cements precipitated soon after deposition.
- Zeolites precipitated with clays, followed by carbonates and opal or quartz.

The reasons why such associations are common are investigated in the following sections.

Diagenetic Sequence

From the associations listed above, it is clear that diagenesis has a chronology. Observations made under the microscope (optical microscopy, scanning electron microscopy (SEM), transmission electron microscopy (TEM), backscattered scanning electron microscopy (BSEM), cathodoluminescence (CL), **Analytical Methods:** Geochemical Analysis (Including X-Ray)) allow mineral precipitation (and dissolution) events to be arranged in a temporal sequence. It is also possible to include the relative timing of compaction within such sequences. An example of the mineral precipitation sequence for the Middle Jurassic Brent Sandstone from the North Sea is shown in Figure 6. The sequence of diagenetic events was deduced from observations made using thin sections and SEM. Although such diagrams are useful in conveying the sequence of events, they often accidentally convey two other impressions, neither of which is likely to be true. In the absence of quantitative data on when and where cements precipitated, it is common to display the high-abundance cements as having taken the longest to precipitate. This is probably an error. It is also common for the sequence of events to fill up all the available time from the deposition of the sand to the present day. This is certainly an error. A similar diagenetic sequence diagram is

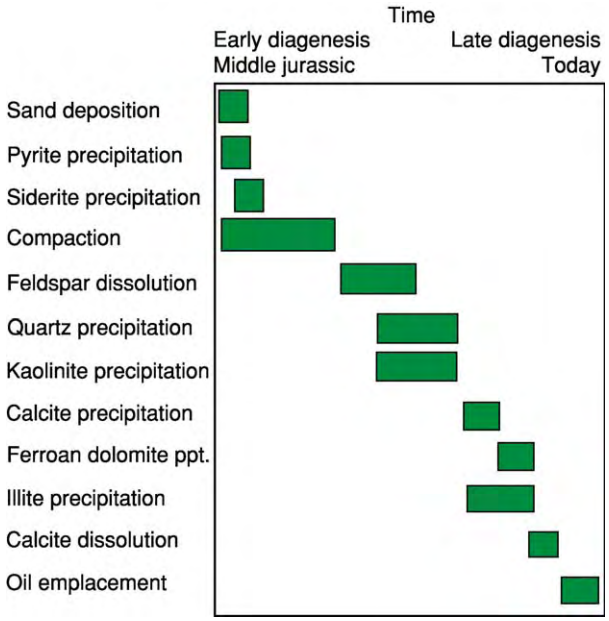

Figure 6 Diagenetic sequence deduced from thin section and scanning electron microscopy (SEM) analysis, Brent Group, North Sea. Adapted from Eglington G, Curtis CD, McKenzie DP, and Murchison DG (1985) Geochemistry of buried sediments. *Philosophical Transactions of the Royal Society of London, Series A: Mathematical and Physical Sciences* 315.

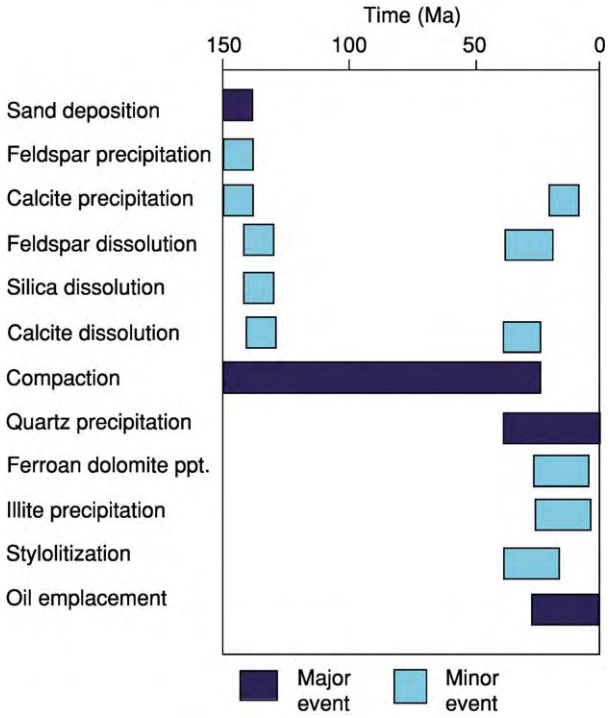

Figure 7 Diagenetic sequence calibrated to absolute time using geochemical and isotopic analysis in addition to conventional petrographical observations, Ula Formation, North Sea. Tulsa: American Association of Petroleum Geologists.

shown in Figure 7, although here the duration of events has been constrained using additional data from geochemical, isotopic, and petrographical analyses.

There are many descriptive terms used to refine the qualitative description of diagenesis. Thus, it is possible to read of 'early carbonate', 'mesogenic quartz', 'burial cements', 'late ferroan dolomite', and so on. It is all too easy to be confused by the plethora of terms, particularly when some are contractions of long, although better, descriptive terms. For example, 'early carbonate' is often used to describe calcite or dolomite that precipitated soon after the deposition of a sand, before significant compaction, and whilst the sand was still in contact with surface or near-surface formation water.

Mineral Dissolution

Dissolution of either grains or cements in a sandstone leads to the development of secondary porosity. In the 1970s and 1980s, many publications suggested that mineral dissolution was a key process whereby significant porosity could be created at depth. Such porosity could then be occupied by petroleum. A range of dissolution mechanisms were proposed to explain this. More recently, new work has indicated that none of these mechanisms is likely to be capable of generating significant secondary porosity in the deep subsurface. That is to say, secondary porosity is rarely so extensive as to significantly improve reservoir quality.

Many minerals will dissolve during deposition and subsequent diagenesis. The only requirement is that the connate (formation) water that surrounds the grains is undersaturated with respect to the mineral in question. However, proof that a particular mineral has dissolved during diagenesis is often more difficult to come by. Grains that have partially dissolved are positive proof that secondary porosity has been created, as is mouldic porosity within otherwise tight rock (Figure 8). However, so-called oversized pores are commonly cited as evidence for the complete dissolution of grains and, although such claims are sensible, proof of secondary porosity creation is lacking.

Advocates of secondary porosity often claimed the wholesale dissolution of mineral cements (particularly calcite) during deep burial, rendering once cemented, low-porosity sandstones highly porous and permeable. Popular amongst the various processes invoked for such widespread dissolution was appeal to

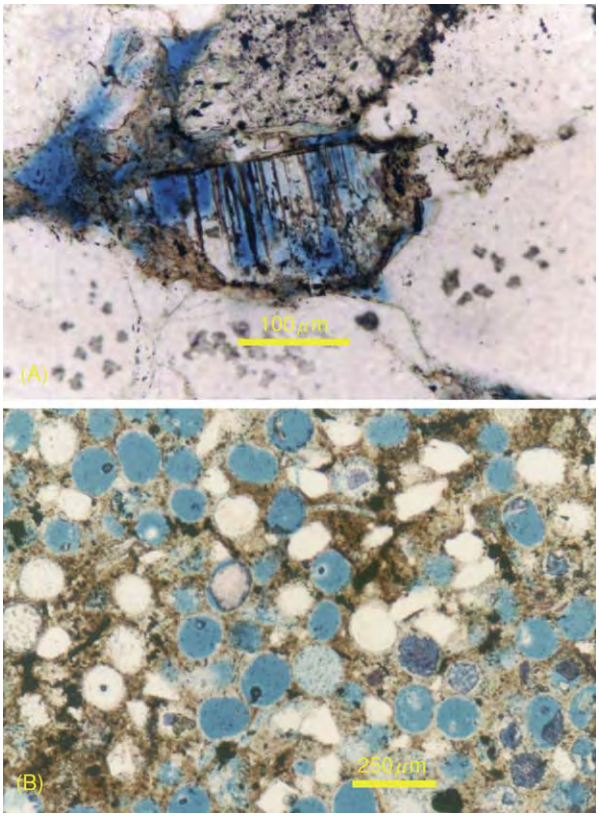

Figure 8 (A) Skeletal feldspar grain (blue, porosity), Upper Jurassic Fulmar Sandstone, North Sea; plane polarized light photomicrograph. (B) Sponge spiculite sandstone in which many of the spicules have dissolved (blue pore space) and microcrystalline quartz has precipitated in the original pore space (stained brown by oil), Jurassic Alness Spiculite, North Sea; plane polarized light photomicrograph.

organic acids created during the initial phases of oil source rock maturation. The hypothesis invoked such acids racing ahead of the migrating oil, leaching carbonates as they went. Oil then followed in the newly created porosity. In an anthropomorphic twist, this became known as the 'John the Baptist Hypothesis' – porosity created ahead of the oil coming. Although appealing and superficially elegant, there is scant evidence to support such a hypothesis. Quite apart from the difficulties of creating sufficient acid and getting it to the reservoir where secondary porosity is required, it remains difficult to find convincing evidence of large-scale, large-volume mineral dissolution in the deep subsurface. A partial exception to this rule occurs in association with unconformities. There is commonly ample evidence of porosity creation due to reaction between rock and meteoric water beneath unconformity surfaces. The improved porosity is then commonly (partially) retained during reburial of the sequence (Figure 9).

Diagenesis Quantified

The foregoing text describes diagenesis in terms of minerals that can precipitate and others which dissolve. It also investigates the relative timing of diagenetic events. However, in order to understand how diagenetic processes operate, it is important to determine when and where minerals precipitate and dissolve and the quantities of matter involved in such reactions.

Before about 1990, there were few published examples in which the absolute date of precipitation, temperature of precipitation, and isotopic composition of the host fluid were known. A wide range of analytical techniques are now available which enable quantitative or semi-quantitative data to be gathered on the 'when' and 'where' of diagenesis. The most commonly used techniques for obtaining quantitative data are listed below. A description of the methods is given in **Analytical Methods:** Geochemical Analysis (Including X-Ray).

- Fluid inclusion analysis: homogenization temperature data obtained from aqueous inclusions within diagenetic minerals can be used to estimate trapping temperatures and hence the precipitation temperature of the minerals (Figure 10) (*see* **Fluid Inclusions**).
- Radiogenic dating: potassium–argon, argon–argon, and several other methods can be used to give absolute precipitation dates for a few diagenetic minerals, such as illite (clay) and feldspar (Figure 11).
- Stable isotope analysis: $\delta^{13}C$, $\delta^{18}O$, $\delta^{24}S$, and δD (deuterium) are in common usage for helping to identify the source of elements, together with the temperature and composition of formation water during the precipitation of carbonates, sulphates, clay minerals, quartz, and sulphides (Figures 12 and 13).

The techniques outlined above allow some attempt to be made at quantifying when, at what temperature (and depth), and from what formation water a particular mineral precipitated. None of the methods addresses directly how much material moved and over what scale such movement took place during diagenetic processes. There have been many papers questioning whether sandstone diagenesis occurs in open or closed systems. There is no consensus. It is, however, important to try to answer the question because it has a direct bearing on the prediction of porosity (and permeability) ahead of drilling petroleum exploration wells.

One method which has been used to address the movement of matter during diagenesis is whole rock geochemistry. The basic premise of the method is to compare portions of the sandstone that have and have

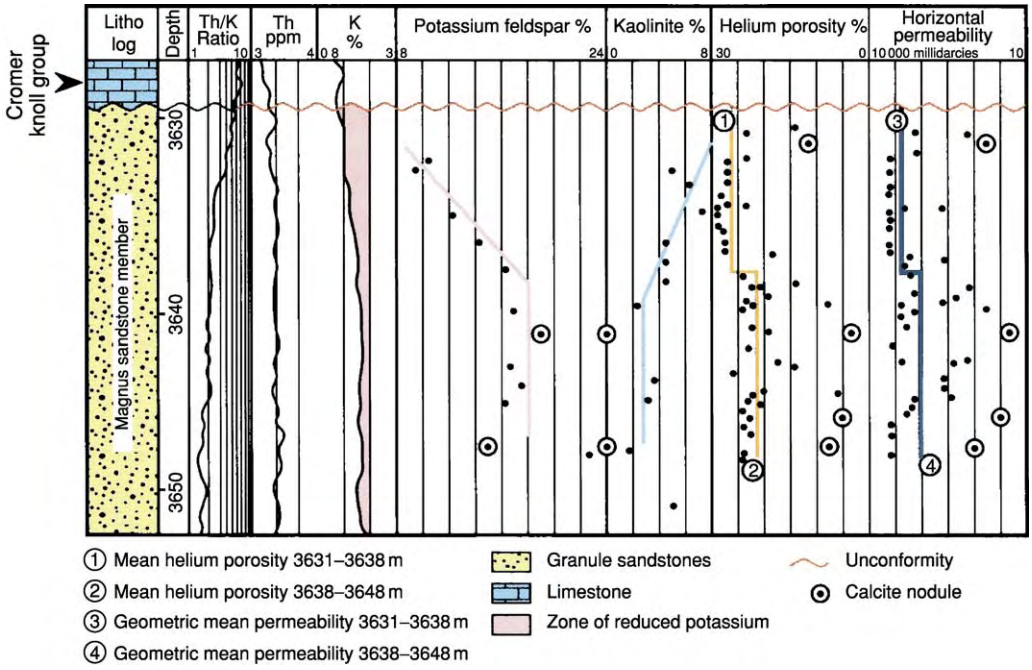

Figure 9 Secondary porosity creation beneath an unconformity during exposure and weathering, Upper Jurassic Magnus Member Sandstone, North Sea. Reproduced courtesy of BP.

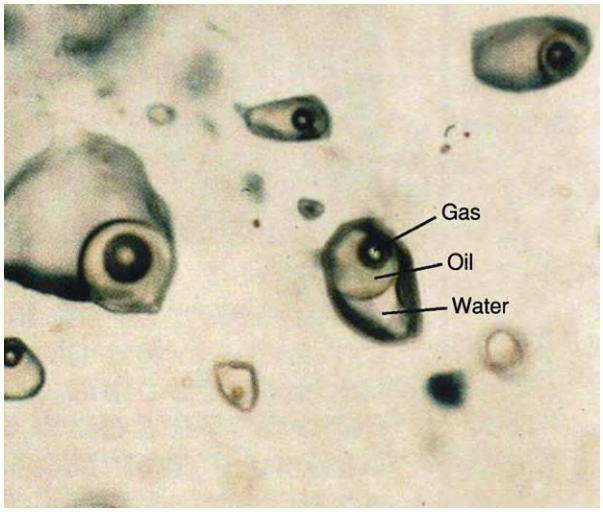

Figure 10 Fluid inclusion within mineral cement. On heating, the fluid phases within the inclusion homogenize. For aqueous inclusions, the homogenization temperature commonly equates to the minimum trapping temperature. Freezing the same inclu sions yields a measure of the salinity of the trapped fluid. For those inclusions containing petroleum, ultraviolet fluorescence analysis can give a measure of the maturity of the oil. Moreover, if abundant, oil can be extracted from the inclusions and analysed. Reproduced courtesy of BP.

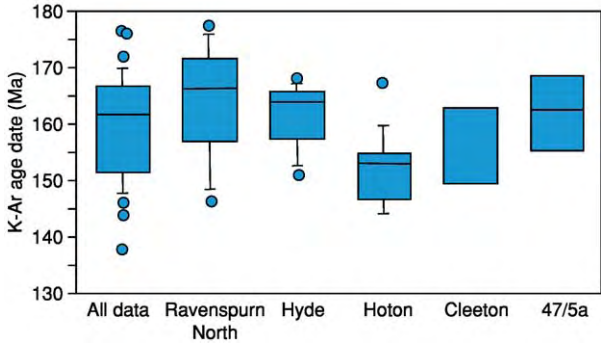

Figure 11 Potassium argon (K Ar) age distributions for illite extracted from the Permian Rotliegend Sandstone within the North Sea Gas Fields. not undergone diagenesis. There are several possibilities for sand which has been unaffected by deep diagenesis. Part of the formation may never have been significantly buried or, alternatively, part of the formation may have been preserved from the effects of diagenesis. The Garn Formation from the Middle Jurassic of the Norwegian Sea area provides a good example, where little buried sandstone from the Draugen Field at 1.6 km can be compared with deeply buried sandstone in the Smørbukk Field at >4 km. The deep samples are relatively enriched in silica and depleted in potash compared with the shallow samples when normalized to TiO_2 content which is essentially immobile. The same results have been obtained when comparing sand trapped within calcite

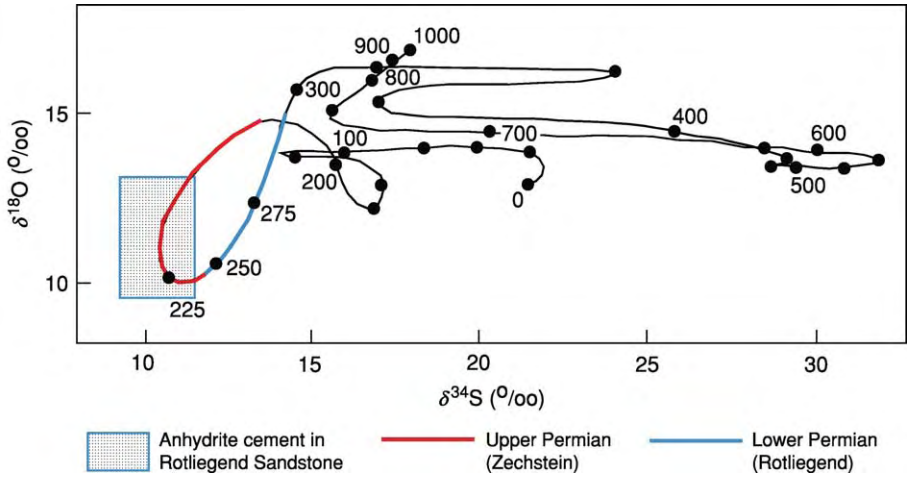

Figure 12 Global secular curve for sulphur and oxygen isotope covariance in marine derived sulphate minerals. The Permian interval is highlighted, as is the distribution of data obtained from anhydrite and barite cements in the Rotliegend Sandstones of the Amethyst Field (North Sea). The sulphur isotope data clearly indicate derivation from the overlying Zechstein. Modified from Gluyas JG, Jolley EJ, and Primmer TP (1997) Element mobility during diagenesis: sulphate cementation of Rotliegend sandstones, Southern North Sea. *Marine and Petroleum Geology* 14: 1001 1012.

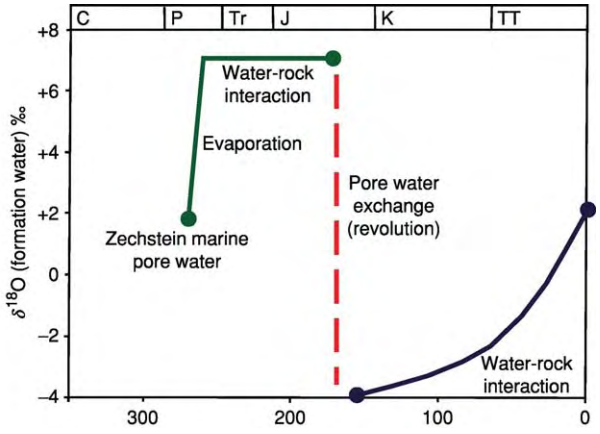

Figure 13 Pore water evolution for the Permian Rotliegend Sandstone of the Village Fields Area (North Sea) deduced from analysis of stable isotope ratios, fluid inclusion homogenization temperatures, and radiometric dating in and of mineral cements.

concretions, which precipitated soon after deposition, with surrounding sandstones. It is tempting to deduce from such studies that (some) sandstones import silica and export potash during diagenesis. Critics of such studies point to the data obtained from formation water isotopic analysis, which have been used to suggest that the water budget is severely limited in the deep subsurface and there is insufficient water to transport the observed cement volumes to the site of precipitation. Others researchers invoke local sources of silica from pressure dissolution along stylolite seams, although this too is not a panacea, as many sandstones are without such pressure dissolution phenomena.

Diagenesis and Petroleum Emplacement

A possible relationship between diagenesis and petroleum emplacement has already been touched upon in the section on 'Mineral Dissolution'. Here, the likelihood of significant porosity creation by organic acids was questioned. Much more controversial is the effect on diagenesis caused by oil emplacement. There are two extreme viewpoints: oil emplacement halts diagenesis by displacing the formation water, and diagenesis continues unaffected by oil emplacement. It is probable that the truth lies somewhere between these two extremes.

Ample evidence exists of continued diagenesis in the presence of (possibly) low oil saturations. Oil-filled fluid inclusions occur in many mineral cements (Figure 10). However, quantitative analysis of these same inclusion distributions often indicates that the presence of petroleum inhibits mineral precipitation. Studies on several sandstones, including those from the Upper Jurassic of the North Sea, have shown that cementation and petroleum migration commonly occur at the same time. In some papers, this has been referred to by the acronym SMAC (synchronous migration and cementation) and in others as the 'Race for Space'. Oilfields so affected have highly porous sandstone at their crest and low-porosity sandstone at the oil–water contact. The rate of porosity decline as a function of depth is perhaps twice that of the regional porosity gradient determined from water-bearing sandstones. In the instance of the North Sea sandstones mentioned above, the regional gradient is

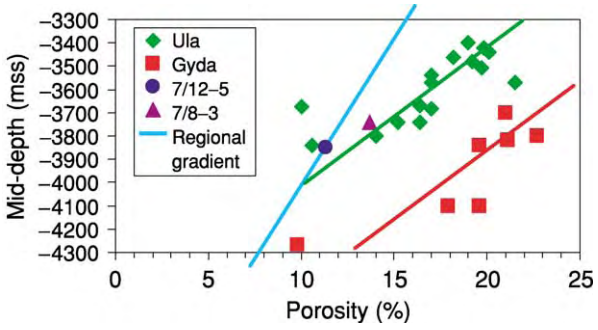

Figure 14 Porosity/depth relationships for fields within the Ula Trend (Norwegian Central Graben). Intrafield porosity gradients are about twice those observed for water bearing sandstones (regional gradient) in the same area. It is possible that oil em placement limited cementation within oil bearing reservoir inter vals. From Kupecz JA, Gluyas JG, and Bloch S (1997) *Reservoir Quality Prediction in Sandstones and Carbonates, American Association of Petroleum Geologists' Memoir 69*. Tulsa: American Association of Petroleum Geologists.

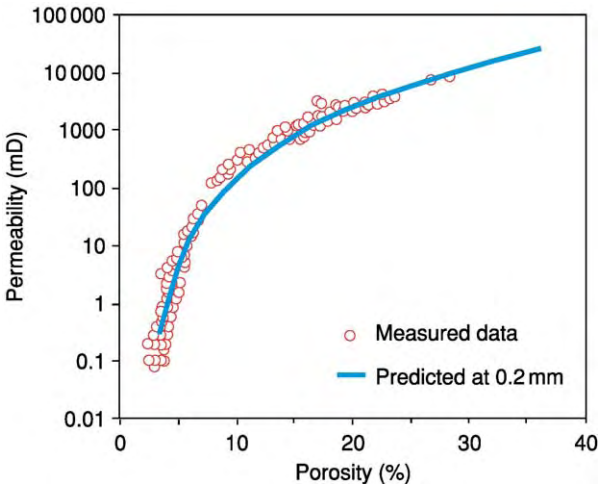

Figure 15 Measured relationship between porosity and per meability for the Fontainbleau Sandstone, and modelled relation ship for a monodisperse sphere pack with a grain size of 0.2 mm. Reproduced from Cade CA, Evans IJ, and Bryant SL (1994) Analysis of permeability controls: a new approach. *Clay Minerals* 29: 491 501.

8% porosity loss per extra kilometre of burial depth, whilst that seen in the Ula and Gyda Fields is 16% km ^{1} (Figure 14). This same pattern of porosity loss also occurs within individual coarsening-up sequences within the reservoir interval, particularly in the direction of known mature oil source. Detailed observations on the distribution of petroleum-filled fluid inclusions indicate an exponential decline in such inclusions from field crests to field flanks, with the same sort of distribution occurring in the individual retrogradational cycles. The sympathetic patterns of porosity and fluid inclusion distribution are most easily explained by considering that diagenesis was progressively retarded as the fields filled with oil. The coarse, permeable tops of the retrogradational cycles formed the natural migration pathways of oil into the structures and these, too, had retarded diagenesis.

Impact of Diagenesis on Porosity and Permeability

From a physical perspective, sands and sandstones comprise two basic components: solid and void. In the preceding sections, the intrinsic properties of the solid component, its grain size and sorting, and its mineralogy have been examined. The void space is now examined. The void in a sand or sandstone is porosity, an intricate network of pores connected by pore throats (Figure 1). At the Earth's surface, the void space is commonly filled by a combination of water and air (depending on the elevation of the sandstone relative to the local water table). In the subsurface, the void space can, in addition to water, contain petroleum (oil and/or hydrocarbon gas) and possibly non-petroleum gas (CO_2, H_2S, N_2, and He_2).

Porosity is measured as a percentage (or fraction) of the rock plus void. For sands, porosity commonly lies in the range 35–50%. Well-sorted sands are more porous than poorly sorted sands, and loosely packed sands are more porous than tightly packed sands.

Sandstones commonly have a lower porosity than sands. This is because compaction and mineral precipitation (diagenesis) reduce the pore space between grains. In extreme instances, the porosity of sandstone can be close to 0%.

The permeability is a measure of the rate at which fluid can be transmitted through a porous medium. It's unit is the Darcy (D), such that a rock has a permeability of 1 D if a potential gradient of $1\text{atm} \times 10^{-2}\text{m}$ induces a flow rate of $10^{-6}\text{m}^3\text{s}^{-1}10^{-4}\text{m}^{-2}$ and a liquid viscosity of 1cP. For loose sands, the unit of permeability is the darcy, whereas, for sandstones, a more convenient unit is the millidarcy. There is no particular reason why porosity and permeability should be related, other than that, for a rock to have non-zero permeability, it must also have non-zero porosity. However, for individual sands and sandstones, porosity and permeability are commonly positively correlated (more porous sandstones tend to be more permeable than less porous sandstones). Where it does exist in granular porous media, the correlation between porosity and permeability commonly reflects the variation in one or possibly more of the components. For example, the Fontainbleau Sandstone of the Paris Basin is essentially monodisperse (perfectly sorted) and uncompacted. However, the quantity of cement varies between 0% and about 40%. For this

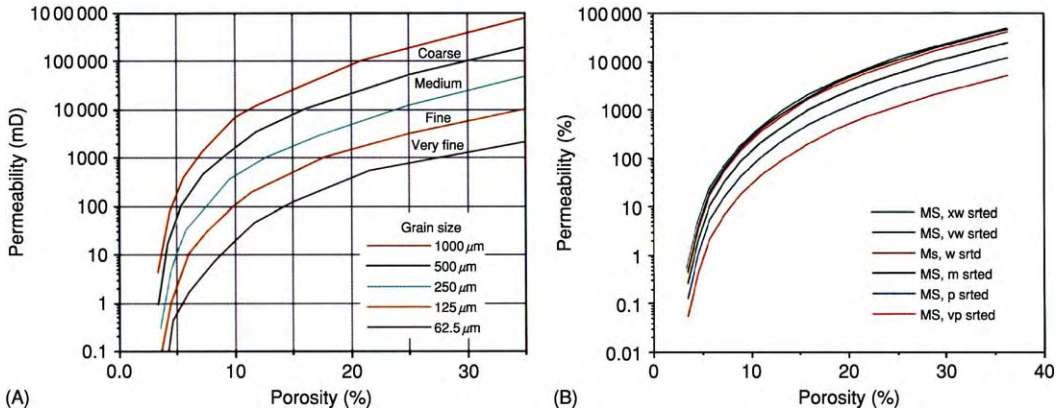

Figure 16 (A) Modelled relationship between porosity and permeability for monodisperse (perfectly sorted) sands of different grain size. (B) Modelled relationship between porosity and permeability for a medium grained sand with different sorting characteristics (xw, vw, w, m, p, and vp srted denote extra well, very well, well, medium, poorly, and very poorly sorted, respectively). Reproduced from Cade CA, Evans IJ, and Bryant SL (1994) Analysis of permeability controls: a new approach. *Clay Minerals* 29: 491 501.

sandstone, there is a non-linear correlation between porosity and permeability on a semi-logarithmic plot (Figure 15). The increasing rate of decline in permeability at low porosity is due to progressive closure of the pore throats between pores.

The relatively simple relationship between porosity and permeability for the Fontainbleau Sandstone has been used as the foundation for a comprehensive predictive model for permeability based on a real physical model of a porous medium. The model combines data derived from the perfectly sorted porous medium with empirical curves linking porosity and permeability for less well-sorted sands (Figure 16). Cements are then modelled as grain rimming or pore filling, and solid (such as quartz or carbonate) or microporous (clays).

Controls on Diagenetic Processes

In broad terms, near-surface diagenetic processes are much better understood than those occurring at depth. Geochemical and isotopic studies have revealed the importance of bacterial reactions in modifying pore water and inducing the precipitation of carbonates, oxides of iron and manganese, and sulphides.

For the deep subsurface, we know less about what triggers diagenesis, although we can, as shown above, determine when and under what conditions diagenetic reactions occurred. A recurrent observation is that major diagenetic events commonly accompany or follow immediately after significant geological events. This is almost self-evident in the case of mineral dissolution beneath unconformities, but in other situations it is a little more subtle. For example, most of the clay and carbonate minerals in the Permian Rotliegend Sandstone of the southern North Sea precipitated towards the end of the Jurassic, a time of major rifting in the area. At the same time, there was a fundamental change in the connate water from Zechstein (evaporated seawater) derived to meteoric, yet saline, water. There was also a dramatic loss of overpressure from the reservoir system (the reservoirs are normally pressured today). It is tempting to conclude that the rifting led to failure of the salt seals above the Rotliegend, and massive pore water revolution, so causing cementation. In contrast, the Middle Jurassic Brent Sandstone over much of the northern North Sea was cemented at around the Paleocene to Eocene boundary. This, too, may have been associated with the ingress of meteoric water as the rift shoulder became elevated. Although it is possible that such external factors were the cause of cementation in these two sequences, it seems probable that the degree and style of cementation was controlled by the conditions within any particular sandstone (temperature, pressure, mineralogical composition).

SEISMIC SURVEYS

M Bacon, Petro-Canada, London, UK

Introduction

Seismic methods study the subsurface by generating seismic waves and observing the way that they propagate through the Earth. Various methods of field acquisition and data processing are used, mainly with the objective of producing cross-sections through the subsurface that can be interpreted in geologically meaningful ways. The methods are particularly widely used in the oil and gas industries.

The type of wave most often used for seismic investigation is a low-frequency sound wave. This is usually called a P wave; during its passage, individual particles oscillate backwards and forwards in the direction that the wave is travelling, so that the wave consists of alternating compressions and rarefactions. The velocity at which the wave travels depends on the rock through which it is passing, and is related to the mineral constituents, the amount and geometry of the porosity, and the type of fluid contained in the pore space. Another type of wave sometimes used is the shear (or S) wave, where the particles vibrate at right angles to the direction in which the wave travels. This type of wave cannot travel through fluids. In rocks, its velocity is affected by similar factors to those that influence P-wave velocity, except that it is relatively insensitive to the type of fluid in the pore space.

Seismic reflection is the method most commonly used. The basic idea is shown in Figure 1. Seismic P waves are generated by a source (such as a small explosive charge) at the ground surface. They travel down through the Earth, are reflected at boundaries between rock layers, and travel back to the surface, where they are detected by a receiver (similar to a microphone, but sensitive to low frequencies down to 5 Hz) and recorded. The time taken for the wave to travel from source to receiver tells us the depth of the reflecting boundary, and, by repeating the measurement at a series of points, it is possible to map the reflecting surface. The principle is similar to the way a

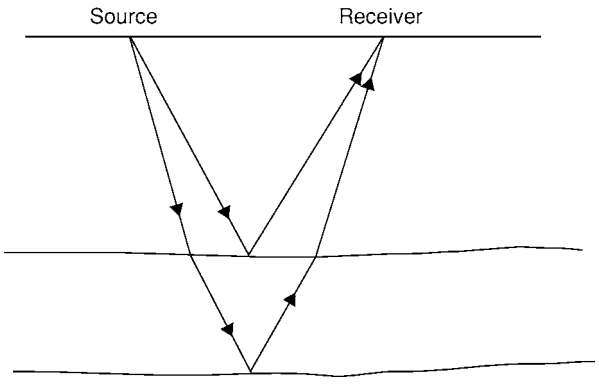

Figure 1 Principle of seismic reflection: seismic waves are generated by a surface source, are reflected at boundaries between rock layers, and are detected and recorded by a receiver at the surface.

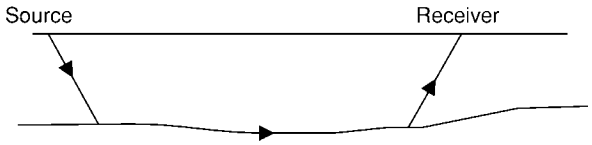

Figure 2 Principle of seismic refraction: a seismic wave travels between a surface source and a receiver along a subsurface boundary across which there is an increase in seismic velocity.

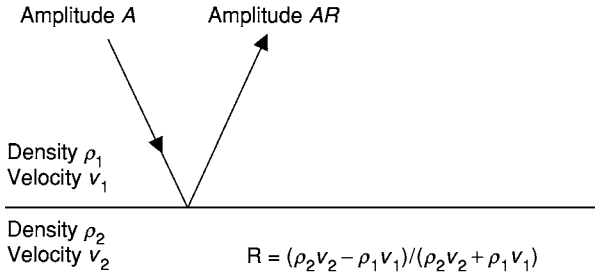

Figure 3 The amplitude of the reflection from an interface depends on the contrasts in density and seismic velocity across it.

ship's echo sounder is used to measure the distance to the seabed.

Other types of seismic wave can travel along boundaries between layers where there is an increase in wave velocity, and this is the basis of the seismic refraction method (Figure 2). A distance much larger than the depth of investigation separates the source and receiver. The travel time of the seismic signal is used to map the deep interface. This method is usually able to detect only a few such surfaces, across each of which there is a large velocity increase. It is used both for large-scale crustal studies and for shallow engineering investigations. The seismic reflection method is able to detect much more detail, typically allowing us to see many tens or even hundreds of reflecting surfaces. For this reason, it has become the method of choice for the subsurface investigation of sedimentary basins, particularly for petroleum exploration.

Most seismic reflection work uses sources and receivers at or near the surface, and this is what I shall proceed to discuss in detail. It is also possible to acquire data using a surface source and receivers in a borehole. The advantage of such a vertical seismic profile (VSP) is that a particularly detailed image of the subsurface is obtained, which can be closely tied to the drilled succession.

Reflecting Interfaces

What determines how well an interface between two layers will reflect seismic waves? There is a characteristic of a material called its acoustic impedance; this is the product of the seismic velocity and the density of the material. The amplitude of the reflected signal is proportional to the contrast in acoustic impedance across the interface. The formula shown in Figure 3 applies to P waves at an incident angle of 0°, when the seismic wave travels perpendicularly to the reflecting interface; at larger angles of incidence the formula is more complicated and involves a combination of S-wave and P-wave velocities. The acoustic impedance of a rock type depends on many factors. In a sandstone, for example, it will depend on porosity, cementation, and clay content; in a shale it will depend on the degree of compaction. In practice, many interfaces between different lithologies will have enough acoustic impedance contrast to cause appreciable seismic reflection. The interface needs to be sharp rather than gradational. This requirement is not onerous, however; the transition has to take place over a distance very much less than the seismic wavelength. Since the seismic signal typically has a frequency of 30 Hz and the seismic velocity in a sand or shale is typically $3\,\mathrm{km\,s^{-1}}$, a typical seismic wavelength is about 100 m. A lithological transition over a vertical distance of a few metres will therefore be seen as sharp by the seismic wave. A further requirement is that the reflecting interface should be laterally continuous over distances similar to the seismic wavelength. In sedimentary basins, there are often many interfaces that meet these criteria and are therefore a suitable target for the seismic reflection method. It is sometimes possible to use the method to investigate the internal structures of metamorphic or igneous rocks, but results are often poor owing to a lack of suitable reflecting surfaces or to scattering of seismic energy by internal complexity.

Data Acquisition and Processing

The simple geometry shown in Figure 1 is not usually an adequate approach to acquiring seismic data. The reflections are weak and easily swamped by noise. Increasing the power of the source will help. Modern seismic sources include airguns (which are used at sea and work by releasing a bubble of compressed air into the water) and vibrator trucks (which are used on land and vibrate a metal pad held in contact with the ground). Cost, practicality, and concern about possible environmental damage place limits on the energy that can be put into the ground. The solution is to use an array of receivers to make the best use of the available energy. Figure 4 shows how, in the marine case, a long array of receivers is towed behind a ship, which fires the source at regular intervals along a line. After acquisition is complete, the

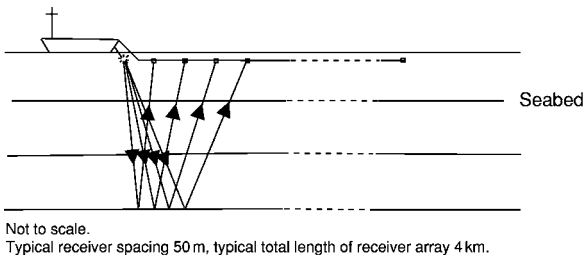

Figure 4 Schematic geometry for acquiring marine seismic reflection data.

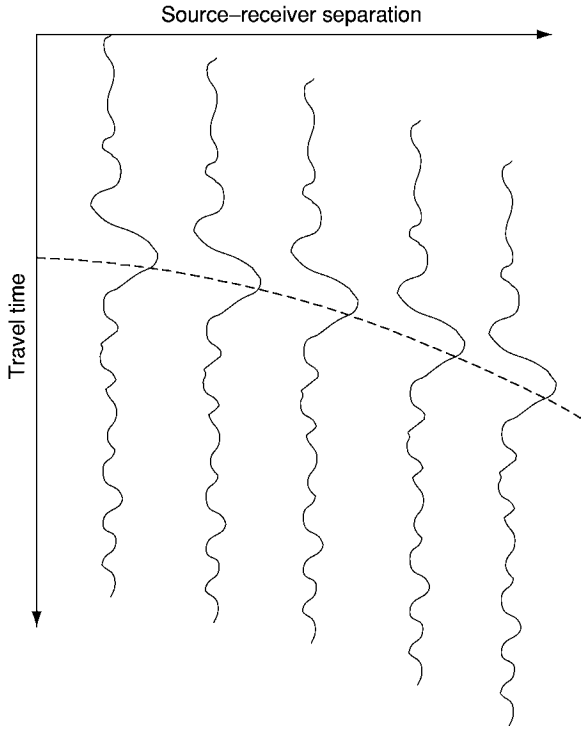

Figure 6 Schematic plot of traces acquired with the geometry shown in Figure 5.

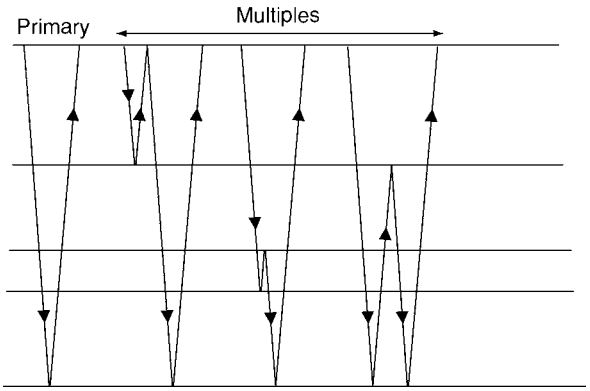

Figure 7 Travel paths for primaries and multiples.

recorded data from different shots can be reordered to bring together traces corresponding to a single reflection point in the subsurface (Figure 5). Of course, the travel time increases as the source–receiver separation becomes larger (Figure 6), but this can be corrected so as to line up all the signal peaks at the same travel time. They can then be added together (stacked) to create a signal with a much higher amplitude. The correction required to align all the traces contains information about the average velocity of the seismic waves, which is useful in later processing.

However, the medium above a target reflector is usually strongly layered. This means that signals can bounce back and forth between these shallow layers, and may perhaps arrive at the receiver at much the same time as a genuine reflection from a deeper layer (Figure 7). There are several ways to remove these 'multiples'. Many of these methods depend on the difference in average velocity along the travel path between the primary and the multiples, caused by the general increase of velocity with depth due to compaction. The multiples have spent more time at shallow depths, so their average velocity is lower than that of the deeper-penetrating primaries. Correction for variable source–receiver distances will thus line up the primaries but not the multiples, which will be attenuated in the stacked result. Various algorithms exploit this velocity difference to improve the discrimination against multiples further. The same process of multiple bounces, on a smaller layer-thickness scale, acts to blur the crisp initial seismic signal on its passage through the Earth. This combines with the effect of the absorption of seismic energy (which is more pronounced over a given distance for the higher frequencies) to reduce the content of high-frequency energy in deep reflections. Commonly, reflections from a depth of 3000 m will have peak energy at a frequency of 25–30 Hz. As we shall see, this reduces the resolution that can be achieved.

Seismic data are often acquired along a straight line, with the objective of producing a cross-section showing the subsurface reflectors along the line (2D seismic). At first sight, this just requires each stacked trace to be plotted in the correct place along the line; the wiggles corresponding to each reflector will then line up to produce a cross-section through the Earth, though the vertical axis will be travel time rather than depth. There is, however, a complication, which is illustrated in Figure 8. This shows the travel paths of the seismic signals for various source and receiver positions along a line over a schematic buried syncline. Since the data have been corrected for variable source–receiver distances and stacked, we can assume that they are equivalent to the data that would have been recorded with zero source–receiver separation at each point along the line. In that case, the seismic travel paths must hit the reflector at right angles, so that the reflected path is the same as the incoming path. We see from Figure 8A that at some surface locations it is possible to receive reflections from both sides and from the bottom of the syncline, so that the stacked section will present a 'bow-tie' appearance (Figure 8B). For other reflector geometries, the distortion would be less dramatic, but would still be present; it arises wherever the travel paths are not vertical, but we ignore this and plot the reflection traces vertically below the relevant surface point. To correct for the distortion, the reflector segment seen on each trace needs to be moved laterally by the correct amount. This process is known as migration. It requires knowledge of the seismic velocities in the subsurface, which have already been obtained for use in the variable source–receiver distances correction prior to stacking. The effect of migration in transforming the image into a recognizable picture of subsurface structure can be dramatic.

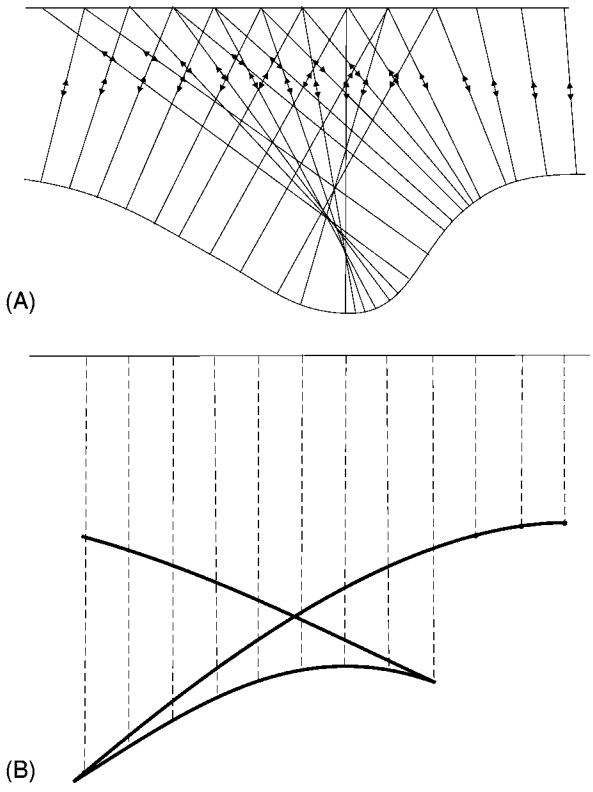

Figure 8 A (B) travel time section can be more complicated than (A) the real depth section. In (B) time is plotted vertically below the surface point concerned.

3D Seismic

Migration of seismic data along a 2D line does not perfectly position the reflectors in the right place, however. The problem is that, if the line is not exactly along the dip direction, reflection points may be laterally offset from the line (Figure 9). Standard processing has no way of detecting that this is so, and the final migrated section will be plotted vertically below the surface line. To minimize this effect, 2D lines are acquired along the dip direction where possible; however, the dip direction may change with stratigraphic level. A big improvement in subsurface imaging can be gained by the use of 3D seismic. Suppose we acquire a large number of parallel 2D lines, at close spacing (perhaps 50 m). Then information about the structure off to the side of each line is available from other lines in the dataset (except for the lines at the edge of the survey). We can reposition (migrate) the data in 3D, so that, when we plot a vertical section along one of the 2D lines, it contains only information about reflectors that are vertically below it.

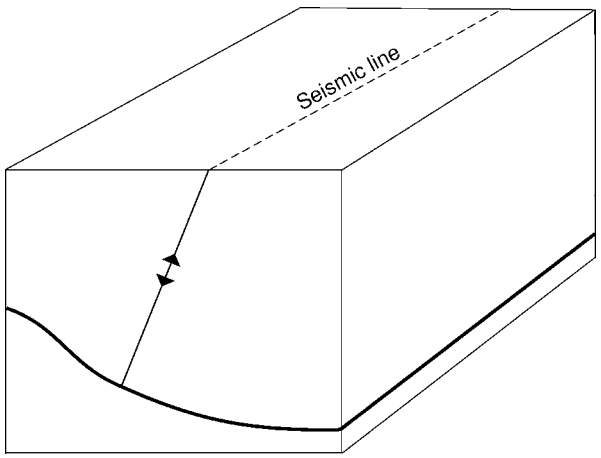

Figure 9 Reflection points for a seismic line may not be verti cally below it.

Such 3D surveys are routinely being undertaken, primarily for petroleum exploration, which can support the high cost of acquisition. The output from the processing of such a survey will be a cube of data, made up of traces plotted vertically below points on a square grid. At a typical trace spacing of 25 m × 25 m, a surface area of 200 km^2 would contain 320 000 traces. There are two further benefits from such a survey, besides the 3D imaging.

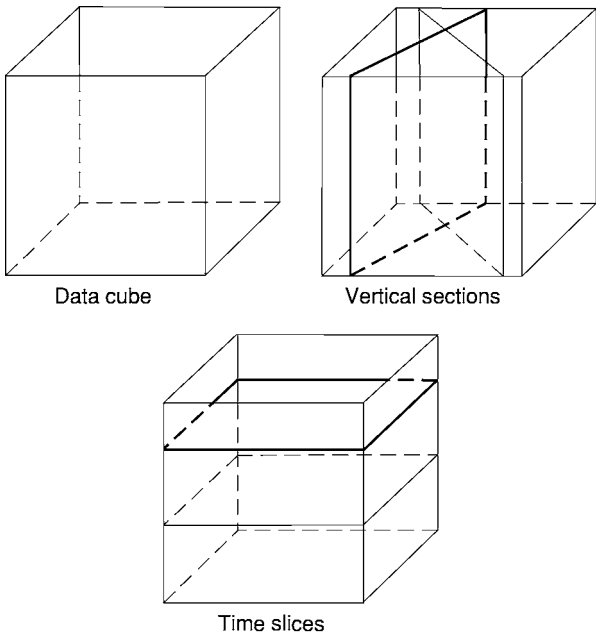

Figure 10 A 3D data cube can be viewed as slices in any direction.

1. The density of the data makes it easy to follow features from line to line across the cube. For example, the development of a fault can be studied across the cube as its throw grows and diminishes, or the detailed geometry of a sedimentary channel can be mapped.
2. Given sufficient computational power, it is easy to construct slices through the data cube in any direction (Figure 10). Vertical sections can be chosen in any direction; for example, sections perpendicular and parallel to a given fault may be helpful in understanding its geometry. The plan view (time slice) can be particularly helpful in understanding depositional systems. It is also possible to view a depositional body in 3D (Figure 11).

These displays extracted from the cube contain a great deal of information. There are, however, two limitations that need to be borne constantly in mind. One is the limited vertical and horizontal resolution. The vertical traces consist of seismic 'wiggles'; each reflecting interface is marked by a signal that represents the source signal, modified by its passage through the Earth and modified further by data processing. Figure 12 shows a typical response for a thin layer, representing perhaps a sand encased in shale. As the layer thins, there comes a point where the reflections from the top and base of the layer start to coalesce. Beyond this point, the layer is thinner than the separation of the apparent top and base wiggles would suggest. The amplitude response is a maximum when the bed thickness is one-quarter of

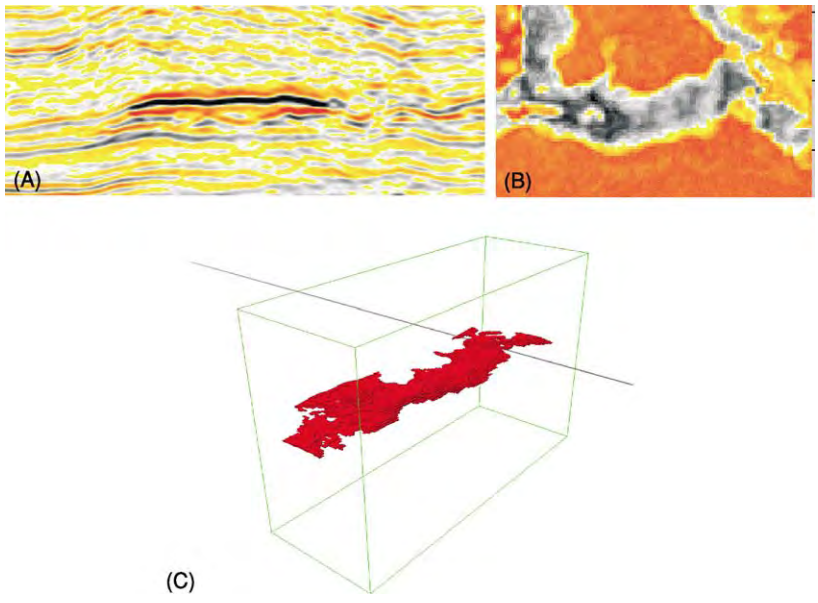

Figure 11 Displays created from a 3D data cube: (A) vertical section, (B) map view and (C) 3D perspective view.

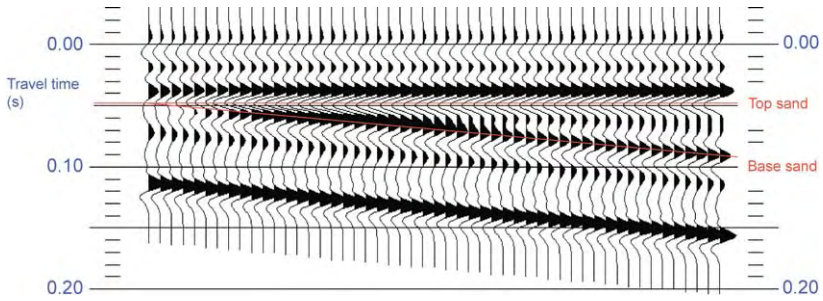

Figure 12 Modelled traces showing the seismic response of a sand of varying thickness.

the seismic wavelength: if a typical wavelength is about 100 m, the amplitude maximum is at a thickness of 25 m. This will be the approximate limit of vertical resolution. Various processes can be applied to the trace data to try to sharpen up the wiggles, but at depths of a few thousand metres it is hard to achieve a better resolution than about 12 m. Horizontal resolution is also limited. The resolution achievable depends on the accuracy with which seismic velocities are known: errors in the velocities degrade the focusing of the migrated seismic image. In practice, the resolution might be 50–100 m at a depth of a few thousand metres.

The second limitation is that the vertical axis of the traces represents travel time, not distance. If we know the seismic velocities, we can of course convert the travel times into depths. However, if there is no well control the velocities may be fairly uncertain. The resulting errors may not be important for mapping on a basin scale, but are often critical in the detailed work of oil and gas prospecting. Even when no detailed depth conversion is intended, it is essential to have a rough idea of the depth scale corresponding to the travel-time scale whenever a seismic section is being interpreted. This is because displays with considerable vertical exaggeration are often used: true-scale seismic sections are usually much wider than they are high, leading to display problems on the typical workstation computer screen with an aspect ratio near to one. If unrecognized, this distortion will hinder the understanding of depositional and tectonic features.

Interpretation

Seismic reflection allows us to see and map layering within the subsurface. We usually need to put some stratigraphic label on the mapped interfaces. Sometimes, distinctive interfaces such as a major angular unconformity are easy to recognize (Figure 13). If some boreholes have been drilled and wireline logs have been run in them to record seismic velocity and density, we can calculate the acoustic impedance of each layer and hence the expected seismic response. We also know the travel time from the surface to the reflecting interfaces, either from direct observation (e.g., in a VSP) or by integration of the sonic log. The interfaces that give rise to the largest reflection amplitudes can thus be related to the sequence drilled by the well. If there are several boreholes, reflectors can be tracked from one to another to establish a consistent identification scheme. Usually, seismic reflectors are time-lines, at least on the broad scale. The overall depositional setting can be inferred from interpretation of seismic sequences. Relative sea-level fall and rise can be inferred from variation in the pattern of onlap, and this provides information about the overall depositional environment.

Figure 13 Seismic section showing a prominent angular unconformity.

Structure mapping is often quite easy provided deformation is not extreme. Reflecting interfaces can be followed through a cube of 3D seismic, or around a grid of intersecting 2D lines, and a map constructed. Seismic reflection works best for interfaces with dips of up to 30° or so. Fault planes are therefore seldom imaged directly; they are recognized from the displacement of sedimentary layering across them

(Figure 14). Steeply dipping bedding, for example in an overthrust zone or against the flank of a salt or mud diapir, will often not be imaged.

Depositional environments can often be recognized and mapped from the external geometry of a feature (the shape of its envelope) and from the geometry and character of the reflections within it. For example, within a fluvial system it may be possible to recognize channels by mapping reflection amplitude on a slice through a 3D cube, parallel to the regional dip; the channel fill often has a different acoustic impedance from the rest of the unit. By making a series of such slices, it is possible to follow the evolution of the channel system through time. If seismic resolution permits, it may be possible to see internal depositional geometry, such as the downlap geometry of a laterally accreting point bar. Discrimination between sand and shale infill may be possible: sands often have a mounded appearance due to differential compaction.

In carbonate systems, it is often possible to recognize reefs from seismic reflections. A reflection is usually obtained from the top of a reef, though it may be discontinuous if the topography is complex. The interior is usually quite transparent. Often the reef has separated different depositional environments, so there is a sharp change in the reflection character of the contemporaneous package from one side to the other.

Salt and shale diapirs are often inferred from the deformation of the layered sediments around them. The salt or shale itself is usually acoustically homogeneous and therefore appears as a transparent body on seismic sections. Imaging sedimentary layering below the overhanging top of a mushroom-shaped salt diapir is difficult, because of the complicated paths that seismic waves follow, owing to the much higher seismic velocities in the salt.

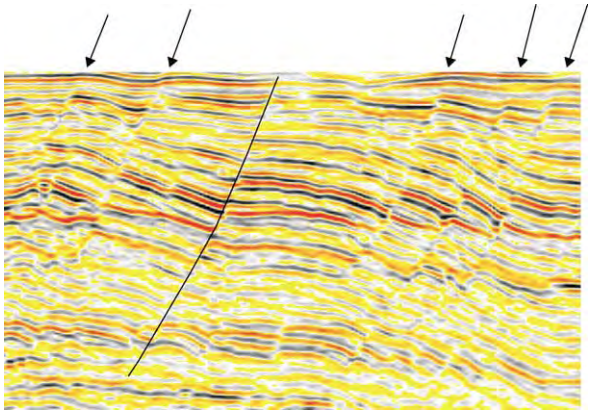

Figure 14 Seismic section showing faults, imaged as discontinuities in reflectors. One fault is shown interpreted; some others are indicated by arrows.

Seismic Reflection in the Oil and Gas Industry

The primary use of seismic reflection in the oil and gas industry is for mapping structure. In exploration **Petroleum Geology:** Exploration, this is mainly a matter of looking for the closed anticlinal features that form potential hydrocarbon traps. These may be either pure (four-way) dip closures or combination fault–dip closures. If a possible trap is fault bounded, it will be necessary to look into the juxtaposition of beds across the fault, to see whether the reservoir is always juxtaposed against a seal (e.g., a shale), or whether it is in places in contact with another reservoir (e.g., a sand). In the latter case, it may still be possible for the trap to work if the fault plane itself provides a seal, but this is inherently more risky. 3D seismic, with its high trace density, is well suited to making a juxtaposition analysis along the whole length of a fault. When a hydrocarbon discovery has been made, seismic reflection can be used to define the internal geometry of the reservoir. Small faults or thin (but laterally extensive) shales may be significant barriers to hydrocarbon flow when the reservoir is put on production, so it is important to plan development wells with this in mind.

Sometimes, it is possible to see directly from the seismic reflections whether hydrocarbons are present in a particular reservoir. When oil or gas replaces brine in the pore space of a reservoir, the acoustic impedance of the material is reduced. This can be a large effect (Figure 15), particularly for gas in high-porosity reservoirs. If the brine sand has an impedance that is less than that of the overlying shale, then the impedance of an oil or gas sand will be much less. The consequence is that the reflection amplitude from the top of the reservoir will be higher where the hydrocarbon is present. Such a 'bright spot' is

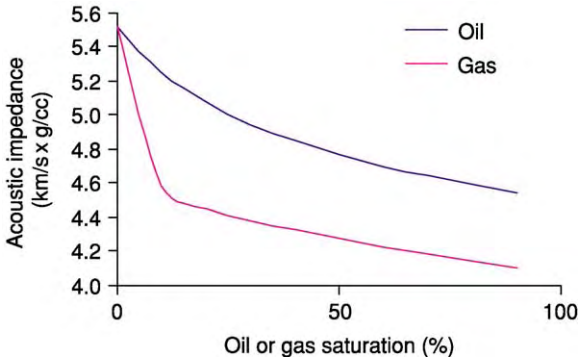

Figure 15 Effect of oil or gas on the acoustic impedance of a high porosity sandstone.

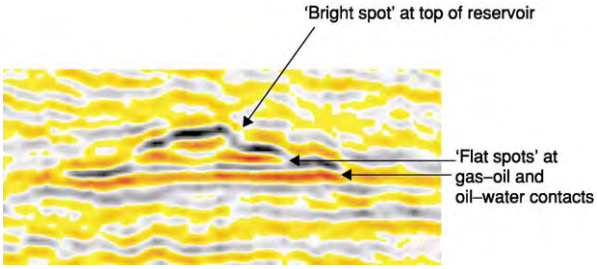

Figure 16 Examples of bright spot and flat spot direct hydro carbon indicators.

a direct hydrocarbon indicator (DHI). Of course, the brightening might be due to a lateral change in lithology, perhaps an increase in the porosity of the reservoir sand. If the brightening is a DHI, then the amplitude increase will follow a particular depth contour, at the hydrocarbon–water contact. Another type of DHI is the 'flat spot', which is a reflection from a fluid (e.g., oil–water) contact. This should be flat and consistent with the amplitude change at the top of the reservoir (Figure 16).

When these effects of fluid fill were first recognized, they were used to reduce the risk of exploration prospects. More recently, it has become possible to use this principle to follow the way that fluids are moving through an oil or gas reservoir as the hydrocarbons are being produced. This is done by acquiring a survey before production starts, and then repeating the survey after some production has taken place. The difference between the two surveys (after careful matching to remove the effects of any differences in acquisition) will be due to fluid movement, for example an oil–water contact rising because some of the oil has been produced. This is useful information if the reservoir has internal barriers to fluid movement, for example due to faulting. In such a case, oil may be produced from some fault blocks and not others; the seismic differences would be confined to the blocks where production is occurring. Such seismic surveys are almost always shot as 3D surveys, because the high trace density is important in identifying small DHI effects, and the repeat survey is often called 4D seismic (elapsed time being the fourth dimension).

Huge amounts of 3D seismic reflection data are acquired by the oil and gas industry. In the year 2000, some 300 000 km^2 were shot offshore, and 30 000 km^2 onshore. This is targeted on hydrocarbon resources, of course, and therefore confined to sedimentary basins with proven or potential hydrocarbon generation and migration. Within such basins, seismic reflection has revealed a great deal about subsurface geology.

SEQUENCE STRATIGRAPHY

P P McLaughlin Jr, Delaware Geological Society, Newark, DE, USA

Introduction: What is Sequence Stratigraphy?

Sequence stratigraphy is one of the major unifying concepts of the geosciences to arise in the twentieth century. Rooted in the cross-fertilization of regional facies mapping and geophysics, sequence stratigraphy provides an invaluable approach to practical problems in applied geology and fundamental scientific questions in Earth history. It incorporates a variety of disciplines of stratigraphic geology (i.e. lithofacies analysis, biostratigraphy, and chronostratigraphy) and is intrinsically related to a number of other areas of Earth history, notably sea-level change, tectonics, and palaeoclimate.

Sequence stratigraphy is defined as the study of rock relationships within a chronostratigraphic framework of repetitive genetically related strata bounded by surfaces of erosion or deposition or their correlative conformities. The fundamental starting point for sequence stratigraphy is the sedimentary facies, which is a lithostratigraphic body characterized by distinct lithological or fossil characteristics, generally reflecting a certain origin. A group of sedimentary facies genetically linked by common processes and environments comprises a depositional system. These depositional systems can be grouped together within a framework of unconformity-bound relatively conformable stratigraphic packages called sequences.

Early publications on sequence stratigraphy emphasized the relationships between global sea-level change, or eustasy, and large-scale stratigraphic patterns. This work provoked serious debate about the importance of global sea-level change as a genetic control on stratigraphy. Recent work integrating sequence-stratigraphic analysis with isotope data is providing new insights into the relationships between ice-sheets, climate, and sea-level, and is helping to clarify the role of eustasy in the evolution of stratigraphic successions.

However, sequence stratigraphy is more than a record of global sea-level: it is a practical stratigraphic tool. Sequences are a product of the interplay of eustasy, tectonics, and sediment supply. As a result, they can be recognized and correlated regionally, regardless of whether global sea-level change was the dominant control. With an understanding of these controls, the sequence concept provides a framework for understanding the evolution of depositional systems through time, making it a powerful predictive tool for stratigraphic analysis.

Development of the Concept

Sequence stratigraphy has seen major growth and development since the 1970s. However, the roots of the field extend back to the 1940s, when LL Sloss coined the term 'stratigraphic sequence' in his regional facies mapping of the Palaeozoic of North America. Sloss defined stratigraphic sequences as "rock stratigraphic units of higher rank than group, megagroup, or supergroup, traceable over major areas of a continent and bounded by unconformities of interregional scope". He recognized six sequences and gave them Native American names derived from localities where they are well developed: Sauk, Tippecanoe, Kaskaskia, Absaroka, Zuni, and Tejas.

In the 1960s and 1970s, the concept of the stratigraphic sequence was applied to the geophysical data collected by oil companies that were using new seismic-imaging tools to obtain a picture of basin and stratigraphic architecture. Under the leadership of former Sloss student Peter Vail, researchers at Exxon and its predecessors recognized stratigraphic patterns on seismic lines that they believed corresponded to the same types of sequences and unconformities mapped by Sloss. In addition, they identified 'onlap unconformities' within marine successions in basins on different continents and inferred global sea-level control and a worldwide extent for 'onlap cycles'.

These seismic-derived sequence-stratigraphic concepts were brought into the public domain with the 1977 publication of seminal papers by Vail and collaborators in AAPG Memoir 26. The 'depositional sequence' was defined as a stratigraphic unit composed of a relatively conformable succession of genetically related strata bounded at its top and base by unconformities or their correlative conformities. Conceptually, depositional sequences resemble Sloss cratonic sequences, but represent much shorter time intervals. The AAPG memoir also provided the first published documentation of the Exxon group's view of the relationship between inter-regional unconformities and global cycles of sea-level, including documentation of coastal onlap curves established from seismic stratigraphic records on different continental margins. Other papers detailed methods for determining sea-level change from coastal onlap and for

interpreting sequence stratigraphy and facies from seismic-reflection patterns. The second major treatise on the subject, SEPM Special Publication 42, was published in 1988. This volume elevated the significance of sequence stratigraphy as a means of understanding Earth history and as a practical tool in petroleum geology. Included articles further defined the key elements of sequence stratigraphy, documented the ages of sequences, examined theoretical aspects, and discussed both outcrop and subsurface examples.

Although these two volumes helped to bring sequence stratigraphy into the mainstream of geological thought, there was notable criticism of the concepts and cycle charts. One of the more contentious issues was the hypothesis that eustasy is the primary control on the timing and patterns of deposition of sequences. Critics argued that the accuracy and precision of chronostratigraphic control are inadequate to demonstrate synchronicity of sequences from around the world and thereby establish the uniqueness of eustatic control.

The late 1980s and 1990s saw the evolution of sequence stratigraphy into a tool for investigating increasingly detailed stratigraphic problems. Studies examined factors controlling sedimentation in specific basins or time intervals and dealt with increasingly finer-scale stratigraphic problems in a variety of depositional environments beyond the marine continental margins. This approach can be used for finer-scale reservoir- and aquifer-scale stratigraphy problems integrating well log, core, and outcrop-based datasets.

Parasequences: The Building Blocks of Sequences

The parasequence is the fundamental building block of a sequence. A parasequence is a relatively conformable succession of genetically related strata bounded by marine flooding surfaces. It is normally a progradational or aggradational package that reflects a shoaling-upwards trend. The succession of facies within a parasequence generally follows Walther's Law, which states that a normal vertical facies succession mirrors the lateral distribution of facies in a sedimentary environment.

The parasequence boundary is the key to correlation in a sequence-stratigraphic framework. It is an approximately planar marine flooding surface commonly characterized by non-deposition or minor erosion. It may be marked by significant burrowing by organisms and may have an associated lag deposit of coarse material such as shells, gravel, authigenic minerals, or rip-up clasts formed by erosion and winnowing in the course of the flooding event.

In shallow-marine successions, parasequences typically coarsen upwards with an increase in sand content and a general increase in the thicknesses of the sand beds. Sedimentary facies trace a regular succession of shallower-water sedimentary environments. For example, in a river-dominated deltaic environment, facies could reflect shoaling from prodelta to delta front to stream-mouth bar (**Figure 1A**); for a wave-dominated shoreline, a parallel succession from offshore to lower-shoreface to upper-shoreface environments might be expected (**Figure 1B**).

In some cases, fining-upwards parasequences can be recognized. For example, in marginal-marine settings, the base of the parasequence may be marked by the abrupt appearance of marine sand above marginal-marine muds, above which the percentage of sand decreases and the sand beds become thinner. The facies trace a succession of shallower-water environments, in this example shoaling from subtidal to intertidal to supratidal non-marine facies (**Figure 1C**).

Parasequence-Stacking Patterns

Just as a normal succession of genetically related beds make up a parasequence, so a normal succession of parasequences can be grouped into a unit called a parasequence set. The pattern of changes between successive parasequences in a parasequence set is termed the parasequence-stacking pattern. The concept of accommodation is fundamental to understanding parasequence-stacking patterns. Accommodation is the space available for potential sediment to accumulate and is a function of eustasy and subsidence (**Figure 2**). Sediment influx controls the rate at which this space is filled. The interplay between accommodation and sedimentation rates controls whether the shoreline advances or retreats and the resulting vertical facies changes.

Three types of parasequence-stacking pattern are progradational, retrogradational, and aggradational. A progradational parasequence set is recognized where parasequence stacking reflects overall shoaling and basinwards advance of a depositional system. Progradation occurs when the rate of deposition exceeds the rate of accommodation: the lack of vertical space for sediment accumulation forces sedimentation basinwards (**Figure 3A**). A retrogradational parasequence set reflects the opposite case, in which parasequences are stacked in a pattern that reflects overall deepening and a landwards retreat of the depositional system. Retrogradation reflects a sedimentation rate that is lower than the rate of accommodation: the inability of sedimentation to fill the available vertical space shifts sedimentation landwards (**Figure 3B**). An aggradational stacking

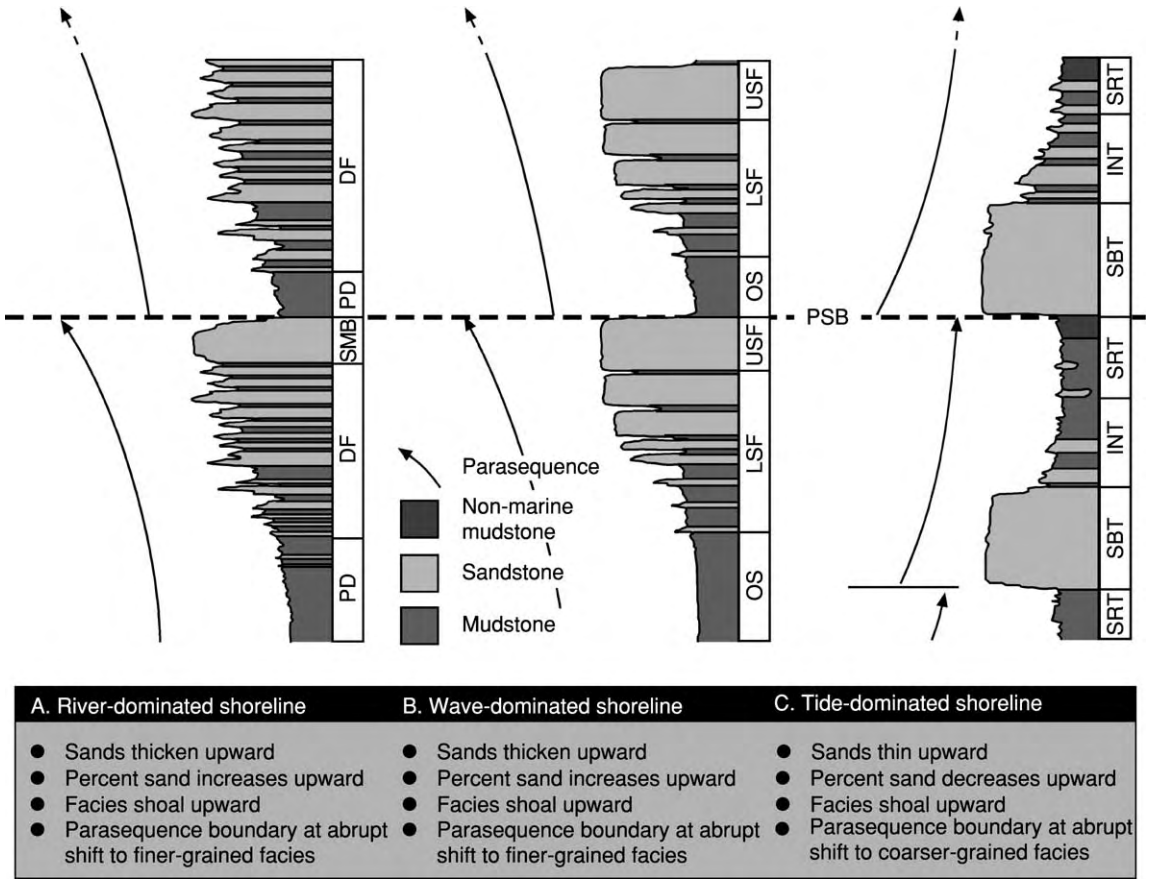

Figure 1 Characteristics of parasequences in various coastal environments: (A) deltaic parasequence on river dominated shore line; (B) offshore to shoreface parasequence on wave dominated shoreline; and (C) subtidal to intertidal parasequence on muddy tide dominated shoreline. Figure 2 Accommodation as a function of eustasy (sea level changes) and subsidence (tectonics). Horizontal grey surfaces represent positions of sea level. Dashed arrow indicates the additional accommodation at the higher sea level.

pattern is recognized where the facies reflect steady accumulation of sediments without significant shifts basinwards or landwards. Aggradation occurs where the sedimentation rate and accommodation rate are approximately in balance (Figure 3C).

Parasequences are useful tools for chronostratigraphic correlation. Correlations based on sequence stratigraphy may differ significantly from lithostratigraphic correlations. Conventional lithostratigraphic correlations typically emphasize the linkage of similar lithologies, with the underlying philosophy of tracing mappable rock stratigraphic units; in the lithostratigraphic-correlation example in Figure 4A, the sand intervals in each well are correlated. In contrast, correlation of parasequences places the sedimentary section in a chronostratigraphic reference frame. Parasequence boundaries are correlated as local time-lines and provide a basis for connecting genetically linked strata. In the example of chronostratigraphic correlation shown in Figure 4B,

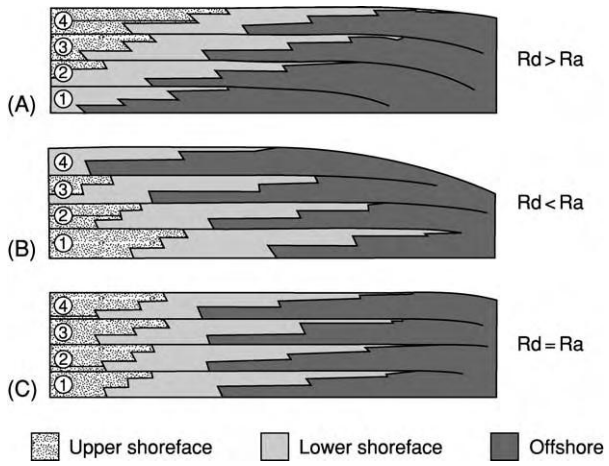

Figure 3 Parasequence stacking patterns for (A) progradational, (B) retrogradational, and (C) aggradational parasequence sets. Stacking patterns are indicated by the movement of facies in successive parasequences (numbered) in each diagram. Rd, rate of deposition; Ra, rate of accommodation. (Adapted from Van Wagoner JC, Posamentier HW, Mitchum RM Jr, *et al.* (1988) An overview of the fundamentals of sequence stratigraphy and key definitions. In: Wilgus CK, Hasting BS, Kendall CStCC, *et al.* (eds.) *Sea Level Changes: An Integrated Approach*, pp. 39 45. Special Publication 42. Tulsa: Society of Economic Paleontologists and Mineralogists.)

the resulting stratigraphic interpretation provides an improved understanding of stratigraphic geometry by demonstrating the connection of the thinner shallow-marine sands to thicker sand beds in a landwards direction.

Recognition of Sequences and Systems Tracts

A sequence is a succession of genetically related relatively conformable strata bounded by unconformities or their correlative conformities. Based on parasequence-stacking patterns and facies trends, a number of distinct sequence components called systems tracts can be defined. A systems tract is a linkage of contemporaneous depositional systems, with a depositional system defined as a three-dimensional assemblage of lithofacies. The five systems tracts most commonly recognized are lowstand fan, lowstand wedge, shelf-margin wedge, transgressive, and highstand (Table 1 and Figure 5). These systems tracts are separated by significant stratigraphic surfaces, the most important being the sequence boundary, transgressive surface, and maximum flooding surface.

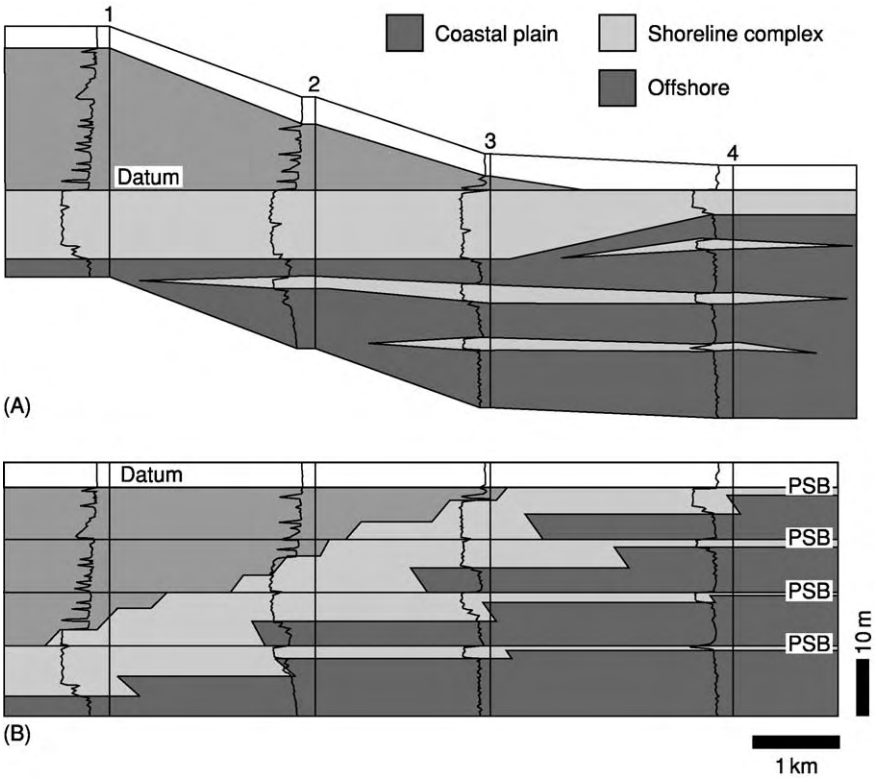

Figure 4 Comparison of (A) lithostratigraphic and (B) chronostratigraphic correlation styles for a prograding parasequence set. The correlation datum for the lithostratigraphic section is the top of the sandstone; the datum for the chronostratigraphic section is the uppermost parasequence boundary. PSB, parasequence boundary. (Adapted from Van Wagoner JC, Mitchum RM, Campion KM, and Rahmanian VD (1990) Siliciclastic sequence stratigraphy in well logs, cores, and outcrops. *American Association of Petroleum Geologists Methods in Exploration Series* 7: 1 55.)

Table 1 Characteristics of systems tracts

Systems tract	*Stacking pattern*	*Bounding surfaces*	*Stratal terminations*	*Location of best development*
Highstand	Aggradational to progradational	Base: maximum flooding surface Top: sequence boundary	Downlap basinwards, toplap or truncation at top landwards	Landwards of the offlap break
Transgressive	Retrogradational	Base: transgressive surface Top: maximum flooding surface	Downlap basinwards, onlap landwards	Landwards of the offlap break
Shelf margin wedge	Weakly progradational	Base: sequence boundary Top: transgressive surface	Onlap landwards, downlap basinwards	Near the offlap break
Lowstand wedge	Progradational to aggradational	Base: sequence boundary or downlap surface at top of underlying lowstand fan Top: transgressive surface	Onlap landwards, downlap basinwards	Basinwards of offlap break where one exists; or in incised valleys and basinward end of ramp
Lowstand fan	Aggradational	Base: sequence boundary Top: flooding surface at top of fan	Onlap landwards, or bidirectional downlap	Deep water basinwards of offlap break

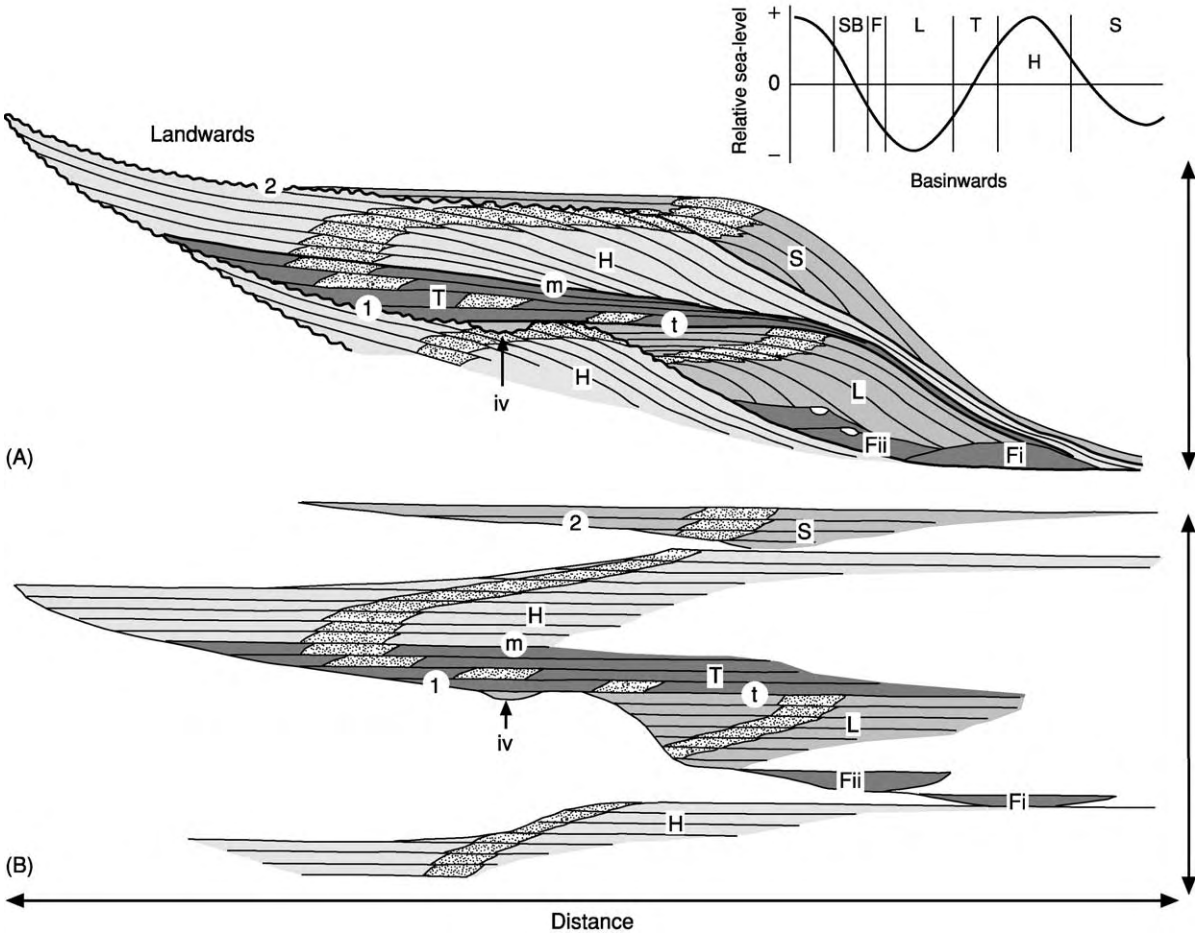

Figure 5 (A) Stratigraphic cross section and (B) chronostratigraphic section through a conceptual clastic sequence. Systems tracts, in white boxes: Fi, lowstand basin floor fan; Fii, lowstand slope fan; L, lowstand wedge; T, transgressive; H, highstand; S, shelf margin wedge. Surfaces, in white circles: 1, type 1 sequence boundary; t, transgressive surface; m, maximum flooding surface; 2, type 2 sequence boundary. Other features: iv, incised valley. Stippled pattern represents sandy shoreline complex. Relative sea level curve indicates period of deposition for each systems tract. Descriptive Terminology

Most of the descriptive terms for larger-scale features are derived from seismic stratigraphy (Figure 6). One of the more common geometries for a sequence is a wedge-shaped slug of sediments, with a thin zone of gently dipping strata on the landwards end, a thicker zone of more steeply seawards-dipping strata in the middle, and another thin zone of gently dipping strata on the basinwards end. The term topset is applied to the relatively flat zone of sediments on the proximal part of the basin margin. More steeply inclined strata called clinoforms characterize the thicker zone, and the reflection pattern is termed offlap. The relatively flat thinner zone basinwards of the clinoforms is referred to as the bottomset.

A fundamental principle of sequence stratigraphy is that seismic reflections are produced by contrasts in sonic velocity at chronostratigraphically significant stratal surfaces and unconformities; therefore, they are considered to approximate time-lines in the sedimentary record. Identifying terminations of these reflections is fundamental to the definition of systems tracts and key surfaces (Figure 6). Some reflection types terminate against an underlying surface. Onlap is defined by the termination of a reflection against a more steeply inclined underlying reflection, most commonly in a landwards direction. Downlap is interpreted where an inclined reflection terminates against a less inclined underlying reflection, for example the basinwards termination of prograding clinoforms. Other reflection types terminate against an overlying surface. Toplap is a subtle low-angle termination where a seismic reflection terminates against an overlying reflection without significant erosional truncation. Toplap may reflect the disappearance of an interval in a landwards direction due to sediment bypass or thinning of the bed to below seismic resolution. In contrast, erosional truncation is more abrupt, where a reflection exhibits an angular truncation against a younger surface. This generally signifies an erosional contact.

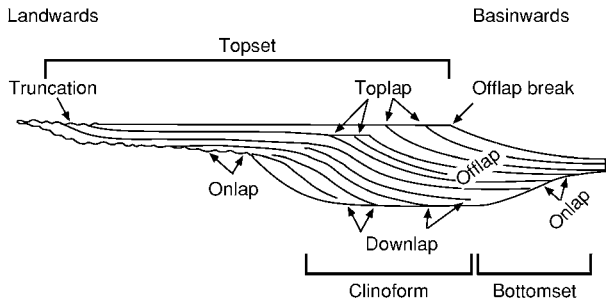

Figure 6 Seismic terminology used in sequence stratigraphic analysis. Truncation, toplap, offlap, onlap, and downlap are seismic terminations; topset, clinoform, and bottomset are zones of basin margin succession. (Adapted from Mitchum *et al.* (1977) Copyright © 1977 by The American Association of Petroleum Geologists; used by permission of AAPG whose permission is required for further use.)

An important point of reference for the description of sequences is called the offlap break. Offlap is a term sometimes used to describe clinoforms. The offlap break is the main break in slope in the depositional profile and is located at the boundary between the topset and the clinoform. In many sequence-stratigraphy publications, this is referred to as the shelf edge; however, this has created some confusion with the actual topographical break at the edge of a continental shelf, and so the term offlap break is a clearer term for this feature.

Surfaces

Sequence boundary The sequence boundary is the defining surface in sequence stratigraphy. A typical sequence boundary is an areally extensive unconformity above which there is a basinwards shift in facies, a downwards shift in coastal onlap, and onlap of underlying strata (Figure 5).

The facies shift at a sequence boundary commonly does not follow the order predicted by Walther's Law and may have a gap of an environment or two. In such cases, the sequence boundary reflects a significant basinwards shift produced by a rapid decrease in accommodation. It is commonly expressed as an unconformity produced by subaerial erosion that occurs across extensive areas both landwards and basinwards of the offlap break. Such a surface is termed a type 1 sequence boundary (Figure 7A).

In other cases, the characteristics of a sequence boundary are not as distinct, and the area affected by exposure and subaerial erosion is minimal. Although such sequence boundaries generally exhibit some onlap of underlying strata, a downwards shift in coastal onlap, and a change in facies-stacking patterns, the resulting unconformity usually has limited areal extent and the basinwards shift in facies is minor. This is termed a type 2 sequence boundary (Figure 7B). The modest reduction in accommodation permits accumulation of subsequent lowstand sediments landwards of the offlap break, in contrast to the shift of sedimentation off the shelf that occurs at the more significant type 1 sequence boundaries. In early sequence-stratigraphical publications, global sequence charts labelled individual sequence boundaries as either type 1 or type 2 and considered this to be a function of the rate of global sea-level fall; however, it is now understood that a given sequence

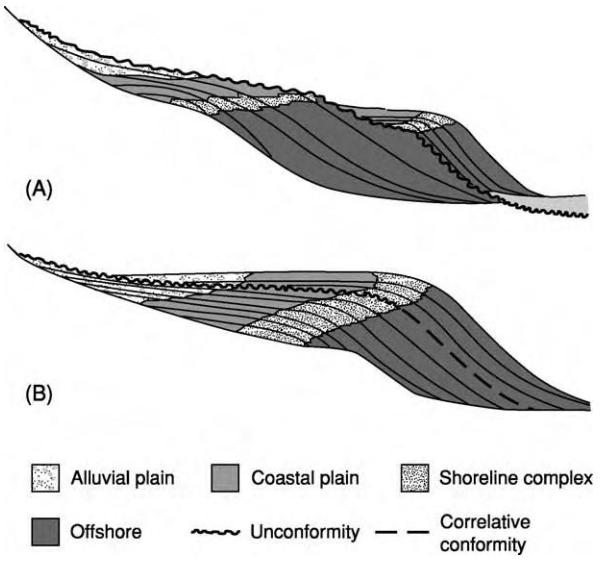

Figure 7 Physical expressions of (A) type 1 and (B) type 2 sequence boundaries. The type 1 boundary exhibits an abrupt downward shift in facies; the type 2 boundary exhibits more a gradual downward shift. (Adapted from Posamentier HW and Vail PR (1988) Eustatic controls on clastic deposition II: sequence and systems tract models. In: Wilgus CK, Hastings BS, Kendall CStCC, *et al.* (eds.) *Sea Level Changes: An Integrated Approach*, pp. 125 154. Special Publication 42. Tulsa: Society of Economic Paleontologists and Mineralogists.)

boundary may be of either type depending on local accommodation and sedimentation rates.

The subaerially produced unconformity that occurs at a sequence boundary passes at some basinwards point into a genetically related conformable stratigraphic contact. Some workers contend that a sequence boundary should be recognized only where an unconformity exists. However, many workers correlate this as the same chronostratigraphic surface, potentially allowing a sequence to be recognized over an entire basin.

Transgressive surface The transgressive surface is the first marine flooding surface of significant areal extent landwards of the offlap break (Figure 5). In a complete sequence, it marks a change from progradational or aggradational parasequence stacking at the bottom of the sequence to retrogradation in the middle of the sequence. It may be somewhat diachronous, with the onset of transgression appearing earlier in more basinward areas and reaching more landward areas later.

Maximum-flooding surface The maximum-flooding surface reflects the maximum landward extent of transgression and is marked by a stacking-pattern change from retrogradational in the middle part of a complete sequence to progradational in the upper part (Figure 5). On seismic profiles, it is commonly marked by the downlap of younger horizons onto it and, as such, is sometimes termed the downlap surface. The maximum-flooding surface may have an associated condensed section characterized by strongly burrowed intervals or hardgrounds, in some cases with an associated marine hiatus, as well as enrichment of authigenic minerals such as glauconite or phosphate, a high organic content, and a peak in the abundance of deeper-marine fossils. The condensed section reflects slow sedimentation rates in basinward areas when the peak of the transgression focuses sedimentation in the heads of estuaries and in other landward areas. The elevated concentration of fossils in condensed sections commonly makes them important intervals for the occurrence of age-significant fossils such as ammonites, planktonic foraminifera, and calcareous nannofossils.

Systems Tracts

Lowstand systems tracts Three systems tracts can be deposited during a lowstand of relative sea-level: lowstand fan, lowstand wedge, and shelf-margin wedge (Figure 5). These lowstand systems tracts overlie the sequence boundary and express a basinwards shift in facies produced during periods of relative sea-level fall. The lowstand fan systems tract is the most basinward of the lowstand systems tracts and forms by the accumulation of clastic deposits in a deep-basin setting. During times of relative sea-level fall, large areas of the basin margin are exposed and subjected to erosion. Sedimentation mostly bypasses the basin margin and is fed directly to the basin through incised valleys and submarine canyons. As a result, lowstand fans are commonly detached from the depositional system that built the preceding highstand complex upslope. They may onlap the underlying sequence boundary in the landwards direction; the relief built during fan formation may also produce bidirectional downlap in other directions (Table 1). Aggradational to slightly retrogradational stacking patterns are the most common. The top of the fan may be marked by a shift in deposition to the overlying lowstand wedge systems tract, which produces a downlap surface between the units. In some deep-water systems, the lowstand fan can be divided into two parts: a basin-floor fan, which occurs on the basin floor and may be detached from the depositional system that built the preceding highstand complex, and a slope fan, which develops along the middle or lower part of the slope.

The lowstand wedge systems tract is composed of a prograding wedge basinwards of the offlap break and a thinner unit of incised-valley fill in the landwards direction (Figure 5). The base of the unit is marked by onlap onto the sequence boundary along the landward end of the wedge and in areas of lowstand incised-valley fill (Table 1). In a basinwards direction, it commonly exhibits downlap onto the underlying sequence boundary or the lowstand fan systems tract. The top of the unit is defined by the transgressive surface. The facies-stacking pattern is progradational to aggradational. Because lowstand wedge deposition is generally focused basinwards of the offlap break formed by the preceding sequence, landward areas may be subaerially exposed and subject to fluvial incision, especially during sea-level fall. However, during later parts of the lowstand, the rebound of relative sea-level may result in some sediment accumulation in the incised valleys.

The shelf-margin wedge systems tract represents an accumulation of lowstand deposits near the offlap break of the preceding sequence. Like other lowstand systems tracts, it is produced when a fall in relative sea-level causes a basinwards shift in facies, but the reduction in accommodation is not rapid enough to force sedimentation into the basin. The base of this systems tract is defined by a type II sequence boundary, onto which it onlaps in a landwards direction and downlaps in a basinwards direction (Table 1). The top is marked by the transgressive surface. Facies-stacking patterns are typically weakly progradational.

Recent works have proposed several unique systems tracts for deposits produced during periods of sea-level fall. One of the more commonly cited, the forced regressive wedge systems tract, describes a complex of downstepping shorelines and subaerial erosion overlying a sequence boundary. Successive shorelines partly cannibalize sand through erosion of previous shorelines, producing stranded shoreline sand bodies. Another type, the falling-stage systems tract, is similar but differs in part in the placement of the sequence boundary at the top of the unit. However, these systems tracts are not yet consistently used by sequence stratigraphers.

Transgressive systems tract The transgressive systems tract traces a landward shift in depositional environments that reflects a rise in relative sea-level (Figure 5). The base of this unit is the transgressive surface, and the top is defined by the maximum-flooding surface (Table 1). Because sediment input is overwhelmed by accommodation, a retrogradational facies-stacking pattern is produced. The deposits of transgressive systems tracts are best developed landwards of the underlying offlap break; they onlap the merged sequence boundary–transgressive surface in a landwards direction and downlap onto the transgressive surface in a basinwards direction. They may comprise a thin sheet of deposits that reflect the landwards migration of drowned shoreface complexes; in cases where they directly overlie a sequence boundary with significant erosive relief, they may comprise more laterally variable incised-valley fill.

Highstand systems tract The highstand systems tract traces the basinwards march of deposition over the transgressive systems tract as the rate of sediment input overtakes a slowing rate of relative sea-level rise (Figure 5). It is bounded by the maximum-flooding surface below and the sequence boundary above (Table 1) and is commonly characterized by a prograding topset–clinoform system, the toes of which downlap onto the maximum-flooding surface. The top of the highstand systems tract may be marked by toplap or truncation under the overlying sequence boundary. The facies-stacking patterns change upward from aggradational to progradational, reflecting decreasing accommodation; as a result, accumulation patterns are increasingly driven basinwards rather than vertically, producing a regressive succession (Figure 5).

Variations by Depositional System

The descriptions of sequence-stratigraphic elements in this article have been principally focused on shallow-marine clastic successions. However, sequence concepts are applicable to a variety of other depositional systems. Carbonate systems are very responsive to changes in relative sea-level, but differ from clastic systems in that they generate most of their own sediment from biological sources in the photic zone. When sea-level rises, carbonate systems build upwards to fill the available space, commonly creating thick transgressive systems tracts (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves); in some cases, very rapid transgression may drown the carbonate system, resulting in a thinner transgressive interval. During highstands, carbonate sedimentation typically continues to be vigorous, but the waning increase in accommodation causes sediment accumulation to prograde basinwards, a phenomenon termed 'highstand shedding'. When sea-level subsequently falls, little carbonate sediment is produced and little is physically eroded; in wet climates, meteoric diagenesis may produce karst and/or cementation, whereas, in arid climates, evaporites may form in the basin.

Sequence concepts can also be applied to nonmarine depositional systems. In alluvial environments, the base level (the surface to which erosion

and deposition respond), subsidence (or uplift), sediment supply, and climate all affect the stratigraphic evolution of the system. Sequence interpretation is complicated by the abundance of erosion surfaces, which may be difficult to differentiate from a sequence boundary. Falling base level typically results in sediment bypass and erosion. Lowstand deposits may be characterized by high-gradient stream deposits with sand-rich amalgamated alluvial facies. Where low base level in the early lowstand is accompanied by a low water table, heavily weathered palaeosols may be formed in interfluvial areas; the rise in the water table that accompanies base-level rise in the late lowstand may be conducive to widespread peat formation. Transgressive deposits may reflect decreasing fluvial gradients, which can be expressed as more isolated fining-upwards fluvial sands and crevasse splays upward, with a shift from aggradational to retrogradational facies successions. If accompanied by a rising water table, peat-forming conditions would wane as mires are flooded, and poorly drained gleyed palaeosols would typify interfluvial areas. Highstand deposits may be thick and trace a shift back to aggradational and even progradational facies successions. Fluvial sands are mostly isolated, but amalgamation is increasingly common upwards. Slowing of the water-table rise can provide good conditions for peat formation, but the beginning of base-level (and probably water-table) fall at the end of the highstand would make conditions less favourable.

Sequence stratigraphy of lacustrine deposits has some parallels with marine sequence stratigraphy but is generally independent of changes in sea-level. Instead, tectonically driven accommodation and climate-driven variations in lake level and sediment supply can combine in many different ways to control lacustrine sequence expression (*see* **Sedimentary Environments:** Lake Processes and Deposits). Reduced precipitation reduces both lake level and sediment supply, creating lowstand deposits that are characterized by evaporites in the basin centre surrounded by an exposure surface with little erosion. However, where sediment influx is significant, the lowstand systems tract may be composed of erosive fluvial systems feeding deep-lacustrine turbidite successions. Where lake-level is raised by increased precipitation, increased sediment input may produce a transgressive systems tract of back-stepping lacustrine deltas; where relative lake-level is raised owing to basin subsidence, it may instead be characterized by low clastic input and a thin interval of fine-grained deposits. Highstand deposits may be composed of deltas and associated deep-lacustrine turbidites if high precipitation creates a large influx of clastic sediments; when precipitation is lower, low sediment influx may produce aggradational carbonate packages in shoreline areas and thin fine-grained successions in the lake basin.

Palaeontological Expression of Sequences

Palaeontology is essential to sequence-stratigraphic analysis, and sequence stratigraphy is a useful frame of reference for understanding the fossil record. Fossils provide information on two essential elements of sequence stratigraphy: environment and age. Understanding facies change is also an essential element of sequence-stratigraphic analysis. Biofacies provide palaeoenvironmental constraints that, like lithofacies, trace the facies changes that define sequence-stratigraphic surfaces and systems tracts. Transgression and regression can be readily demonstrated by palaeontological data, providing important information when lithofacies criteria are not definitive. Although coarse clastics reveal palaeoenvironmental information through sedimentary structures that reflect unique hydrodynamic regimes, environmental differences may be more difficult to discern in mudstones. Biofacies analysis can be especially useful in such fine-grained facies, providing critical criteria for differentiating mudstones from different water depths or different depositional systems (e.g. marine versus freshwater).

In addition, some sequence elements have unique biofacies signals. The maximum-flooding surface is one of the most distinctive. Because the maximum-flooding surface commonly has an associated condensed section on basin margins, it typically exhibits an especially high concentration of fossils due to slow sedimentation rates. The fauna and flora typically reflect the culmination of transgression and may indicate the maximum water depth. The condensed section is also commonly marked by a peak in diversity of common marine microfossils (such as foraminifera), the highest abundance of oceanic planktonic microfossils, and the greatest foraminiferal planktonic–benthic ratios. In some cases, a peak of low-oxygen benthic microfossils occurs in the condensed section. Maximum-flooding surfaces can be ideal locations for age control because of the abundance of fossils, particularly of more age-diagnostic oceanic types, such as planktonic foraminifera and ammonites, and of shell material suitable for isotopic analyses. The maximum-flooding surface is especially important in continental margin sequences because it commonly contains the most landward occurrences of biostratigraphically useful open-marine fossils.

The lowstand systems tract may exhibit a distinctly different biofacies signal. Reworked assemblages may be common: falling relative sea-level exposes older sediments higher on the margin and subjects them, and the microfossils in them, to erosion and

basinwards redeposition. Lowstand deposits can also have relatively high abundances of terrestrial microfossils, such as pollen, owing to the more direct transport of terrestrial material to the ocean basin.

Chronostratigraphic Aspects of Sequence Stratigraphy

Sequence stratigraphy and chronostratigraphy are intimately entwined. Sequence stratigraphy provides a framework for understanding the relationships between depositional systems in both time and space.

Sequences are chronostratigraphically significant units. Early papers on the subject considered sequence boundaries to be globally synchronous time lines corresponding to times of sea-level fall and provided detailed ties of biostratigraphic schemes to the global sequence record. Although the ages of some sequence boundaries can be established using biostratigraphy, they are often difficult to date because of a paucity of age-significant open-marine fossils in the associated regressive intervals. In contrast, maximum flooding surfaces mark the landwards incursions of open-marine environments and can be well dated because of the abundance of open-marine fossils in the associated condensed sections.

Global and regional sequence records are shown on a type of chronostratigraphic chart referred to as a cycle chart (Figure 8). Cycle charts commonly show the ages of the sequences, the magnitudes of coastal onlap, and the interpreted eustatic changes. Coastal onlap is defined as the progressive landwards onlap of coastal deposits in a depositional sequence; by definition, it excludes marine onlap such as the onlap of lowstand fan deposits. Coastal-onlap curves have their origin in the analysis of seismic-reflection profiles and trace the migration of the point of coastal onlap across a basin margin for each seismic reflection. The migration of this point reflects rises and falls in relative sea-level through time. Sequence boundaries stand out prominently on cycle charts as the horizontal lines at the jagged edge of the saw-tooth curve. The ages of the sequences are indicated by their positions on the time axis, and on some charts the sequences are also tied to biochronostratigraphic zonations. Global and regional cycle charts are derived by comparing coastal-onlap profiles from multiple basin margins. With some understanding of the tectonic history of each basin and a consistent age framework, differences in subsidence can be accounted for in creating a composite global or regional coastal-onlap curve. The first such global cycle chart, produced by Vail *et al.*, assumed that the coastal onlap curves were actually sea-level curves. These workers assumed that the saw-tooth pattern of the curve represented asymmetric rates of sea-level change, with slow sea-level rises and nearly instantaneous sea-level falls. It is now understood that the abrupt basinwards shift of coastal onlap at a sequence boundary reflects the jump of deposition from the topsets of the highstand systems tract, over the offlap break, and into the basin for the lowstand. Later versions of the cycle charts added a more symmetric eustatic curve to represent estimated global sea-level changes.

Our understanding of the chronostratigraphy of global sequences continues to improve. Integration of isotope stratigraphy and biostratigraphy from marine and onshore boreholes drilled as part of the Ocean Drilling Program has resulted in significant refinements to the dating of the sequence record of the Cenozoic and Late Cretaceous. For many Cenozoic sequences, ages of sequence boundaries can be determined at a resolution of 0.5 Ma or better.

Genesis of Sequence-Stratigraphic Units

To understand the genesis of sequence-stratigraphic units, three essential factors need to be considered: sea-level change, tectonics, and sediment supply.

Sea-Level Change

The importance of sea-level as a causal mechanism in the development of sequences is well understood, and it is important at different periodicities and scales (Table 2A). Supercontinent cycles operate at a scale of hundreds of millions of years and exercise a fundamental control on the volume of the ocean basins and hence on sea-level. These drive first-order sea-level cycles. Second-order cycles may be influenced in part by changes in rates of seafloor spreading on a scale of tens of millions of years. Faster seafloor spreading creates a greater volume of hot and more buoyant mid-ocean ridge material, decreasing the volume of the ocean basins and raising sea-level; slower seafloor spreading creates less mid-ocean ridge material, increasing the volume of the ocean basins.

At the period of third-order sequences, generally 1–10 Ma, mechanisms of sea-level change are more problematic. In times of significant continental glaciation, gross patterns of ice volume may provide a mechanism. Growth of continental glaciers decreases the volume of water in the oceans, lowering sea-level; melting of ice-sheets releases water into the oceans, raising sea-level. Continental glaciation was the major factor controlling sea-level in the Pleistocene, and its importance as early as the Miocene is widely accepted. Recent results from the study of

(B)

Cycle	*Duration*	*Mechanism*
Eccentricity	100 Ka and 400 Ka	Variations in degree of roundness of orbit of Earth around Sun
Obliquity	41 Ka	Variations in angle of tilt of axis of Earth relative to Sun
Precession	19 23 Ka	Variations in wobble of rotation of Earth

Ocean Drilling Program sites suggest that continental ice-sheets may have existed even earlier, with significant volumes as early as the middle Eocene and small- to moderate-sized sheets as far back as the Late Cretaceous. However, during periods of Earth history without significant glaciation, mechanisms for eustatic change are less clear. Variation in intraplate stress has been proposed as a mechanism for inducing apparent sea-level changes of as much as 100 m on the flanks of passive margins. Variation through time in the irregularities of the geoid (equipotential surface of the gravitational field) has been postulated to cause sea-level changes at different times in different parts of the globe. A more exotic mechanism invoked is an asteroid or comet impact that induces the global release of stress at plate boundaries and a resultant isostatic response of continental margins.

Fourth-order and higher cycles have periods of hundreds of thousands of years or less. Cyclic variations in the tilt and wobble of the Earth's axis, called Milankovitch cycles, cause variations in the intensity of solar radiation, which can strongly influence climate on the scale of fourth- and fifth-order cycles (*see* **Earth:** Orbital Variation (Including Milankovitch Cycles)). Milankovitch cycles include three components with different periods: eccentricity, obliquity, and precession (Table 2B). Milankovitch-related climate changes affect the size of the polar ice-caps and thus global sea-level change. They can also influence monsoonal fluctuations and hence vary the amount of water delivered to and stored in lakes, aquifers, and soils over periods as short as tens of thousands of years. During the opening of the South Atlantic Ocean in the Early Cretaceous, the Parana-Benue basin is estimated to have been able to store enough water to vary sea-level by 3.46 m. It is thought that obliquity is more important at high latitudes, and precession is more important in tropical latitudes.

Small eustatic changes associated with higher-order cycles may be overprinted by larger-scale changes associated with lower-order cycles, resulting in quite different stratigraphic expressions of the same order sequence. Figure 9 shows that the effect of a small (10 m amplitude) fourth-order sea-level fall can be significant if it occurs during a period of overall limited accommodation (e.g. on the falling leg of a third-order sea-level cycle), enhancing the expression of sequence boundaries (Section I). In contrast, during a period of overall high accommodation (e.g. on the rising leg of a third-order sea-level cycle), the fourth-order fall is muted and difficult to detect in the section, while flooding surfaces are enhanced (Section II).

The early cycle charts of Vail *et al.* proposed sea-level falls for third-order sequences from as little as tens of meters to more than 300 m. Second-generation charts by Vail *et al.* indicated smaller variations, but still with some pre-Pleistocene changes of more than 100 m. More recent work arising from the Ocean Drilling Program suggests that these earlier estimates may be too high. Based on analysis of oxygen isotope records and backstripping of continental-margin sites, Cenozoic sea-level changes are estimated to be less than 100 m, approximately one-quarter the older estimates.

The relative importance of self-regulating (autocyclic) and externally forced (allocyclic) cycles in the formation of fourth- and higher-order sequences is an important consideration in sequence-stratigraphic analysis. In a clastic system, a delta lobe normally produces an upward shoaling package as it progrades

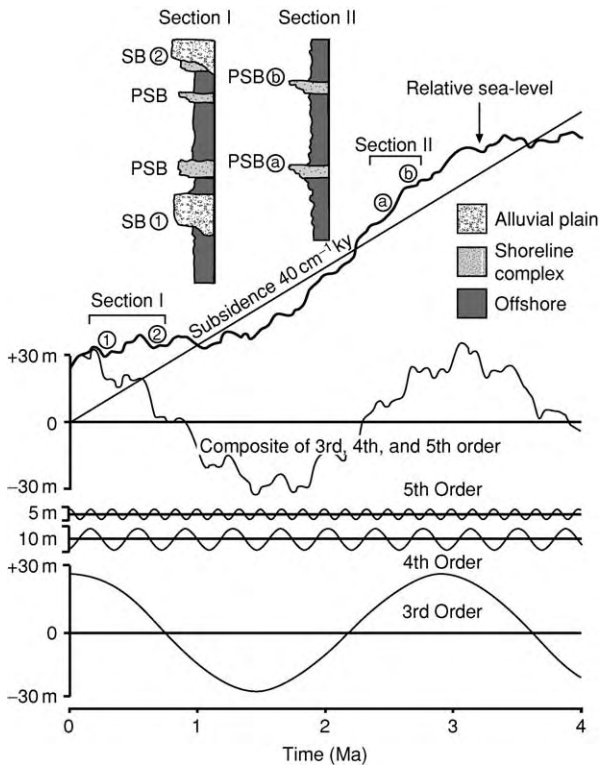

Figure 9 Interaction between subsidence and multiple orders of eustatic cyclicity, and the effect on sequence stratigraphy. Third , fourth , and fifth order eustatic changes combine with subsidence to produce a relative sea level curve, which controls the character of the sequence expression. Section I reflects de position during a period of lower accommodation related to the third order sea level fall; points 1 and 2 identify fourth order sea level falls corresponding to sequence boundaries (SB). Section II reflects deposition during a period of greater accommo dation related to the third order sea level rise; points a and b designate fourth order sea level rises corresponding to para sequence boundaries (PSB). (Adapted from Van Wagoner JC, Mitchum RM, Campion KM, and Rahmanian VD (1990) Siliciclastic sequence stratigraphy in well logs, cores, and outcrops. *American Association of Petroleum Geologists Methods in Exploration Series* 7: 1 55.)

into an area, and is capped by a flooding surface after sedimentation shifts to another lobe and the abandoned lobe sinks through subsidence and compaction. In a carbonate system, upward growth of carbonate sediments normally produces an upward shoaling pattern until all the available accommodation space is used; carbonate production is then shut off until subsidence provides space for carbonate growth to resume. These successions may occur repeatedly at scales of tens of thousands of years, similar to the time scales of higher order sea-level cycles. Thus, differentiating autocyclicity from allocyclicity in high-resolution sequence analysis may be difficult.

Tectonics

Tectonics is another major factor that contributes to accommodation; subsidence creates space for sediment accumulation, and uplift takes it away. Subsidence patterns vary according to tectonic setting. In an extensional basin, subsidence may be a response to lithospheric thinning and cooling following rifting. Subsidence due to extensional faulting is typically greatest in the early phases and decreases with time. In a foreland basin, subsidence may be a response to lithospheric flexure due to loading in the adjacent fold-thrust belt. Subsidence in foreland basins commonly accelerates over time as the load on the lithosphere increases during thrusting, followed by post-orogenic rebound. In cratonic basins, subsidence may be due to a subtler regional warping.

Tectonics is considered to be generally too slow a process to cause third- and higher-order sequences. Certainly, movement on individual faults can be significant at shorter time scales. However, overall, changes in rates of basin subsidence tend to occur on a time scale of tens of millions of years, which is a broader period than third-order sea-level variations. As a result, tectonics exerts a broader-brush influence on the nature of expression of the sequences, upon which higher-frequency sea-level events are superimposed (Figure 9).

Sediment Supply

Sediment supply controls how rapidly the accommodation space is filled, and the balance between accommodation and sediment supply controls sediment stacking patterns and thus the expression of sequences. In a setting with a high input of sediments, such as a delta, sedimentation may fill the available space in the two systems tracts with lower accommodation, the lowstand wedge and the highstand systems tract. As a result, these intervals will be characterized by aggradational and progradational packages. The sequence boundary reflects low accommodation relative to sediment input. Retrogradation of the depositional system will probably occur only at the peak of transgression, and condensed sections will be developed only in offshore locations. In settings with a low influx of sediments, accommodation may exceed the ability of the sedimentary system to fill it. In such cases, only during the part of the sequence when sea-level is falling and accommodation is lowest will sediment advance basinwards. The transgressive and highstand systems tracts will probably be characterized by sediment starvation and represented as a condensed section. Climate changes arising from Milankovitch cycles can exert a strong influence on sediment supply.

Climate variations can affect precipitation rates and vegetation patterns, which in turn influence erosion rates and sediment supply.

Conclusions

Sequence concepts provide a genetic frame of reference that has made stratigraphy a more dynamic process-based field of study compared with the static nomenclatural emphasis of traditional approaches. Sequence stratigraphy encourages an integrative approach, bringing together lithofacies analysis, geophysics, biostratigraphy, and chronostratigraphy. It provides a stratigraphic record of changes in sea-level, tectonics, and climate on local to global scales. The significant volume of jargon common in sequence-stratigraphic literature can be a barrier to understanding, and the key to wider understanding of sequence-stratigraphic concepts is to focus on the processes that create these genetically related rock units rather than on the nomenclature.

The historical association of the sequence concept with a universal explanation of global sea-level change may also hinder the acceptance of the discipline. It is important to recognize that accommodation, rather than sea-level, is the key concept in sequence stratigraphy. Because the interplay of accommodation and sediment supply controls sequence expression, the concepts of sequence-stratigraphic interpretation can be used to correlate and understand genetically related stratigraphic units regardless of whether the units are global or regional in extent.

Research drilling on coastal plains and margins will provide important new data to advance our understanding of Earth history. Continuous cores provide complete records of sequence expression, together with age data, in different geological settings. The isotopic records from such continuous-core material can provide unique insights into ice volume and palaeoceanographic changes, which shed light on the relationship between global sea-level change and sequence stratigraphy.

The nature of lithologic heterogeneities in reservoirs and aquifers and their impact on fluid flow will be better understood through the integration of sequence concepts with process-based geological models and increasingly powerful computer-based 3D-visualization technology. This detailed information allows numerical characterization of vertical and lateral heterogeneities that influence fluid flow. Sequence stratigraphy hold great growth potential as a tool for detailed stratigraphic analysis in petroleum exploration and production and in ground water resource management.

SHIELDS

K C Condie, New Mexico Tech, Socorro, NM, USA

General Features

Precambrian shields are stable parts of the continents composed of Precambrian rocks with little or no sediment cover (Figure 1). Rocks in shields range in age from 0.5 to >3.5 Ga. Metamorphic and plutonic rock types dominate, and temperature-pressure regimes recorded in rocks now exposed at the surface suggest burial depths ranging from as shallow as 5 km to as deep as 40 km or more. Shield areas, in general, exhibit very little relief and have remained tectonically stable for long periods of time. They comprise about 11% of the total crust by volume, with the largest shields occurring in Africa, Canada, and Antarctica (Figure 1). Platforms are also stable parts of the crust with little relief. They are composed of Precambrian basement similar to that exposed in shields, but overlain by 1 to 3 km of relatively undeformed sedimentary rock. Sedimentary rocks on platforms range in age from Precambrian to Cenozoic and reach thicknesses up to 5 km, as, for instance, in the Williston basin in the north-central United States. Platforms comprise most of the crust in terms of volume (35%) and most of the continental crust in terms of both area and volume. The largest platform is the Eurasian platform (Figure 1). Shields and the Precambrian basement of platforms are collectively referred to as cratons. A craton is an isostatically positive portion of the continent that is tectonically stable relative to adjacent orogens.

Seismic Characteristics

Shields and platforms have similar seismic wave velocities and layers (Figure 2). The difference in their mean thickness reflects primarily the presence of the sediment layer in the platforms with P-wave velocities $\leq 5\ \mathrm{km\ s^{-1}}$. Upper layer thicknesses range from about 10 to 25 km and each of the lower layers ranges from 16 to 30 km. The P-wave velocities in both layers are rather uniform, generally ranging from 6.0 to

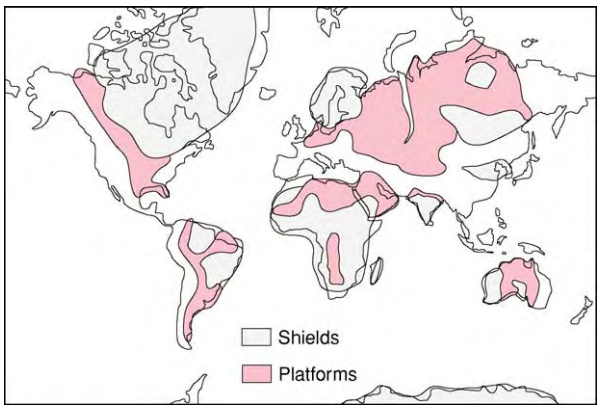

Figure 1 Map showing the distribution of Precambrian shields and platforms.

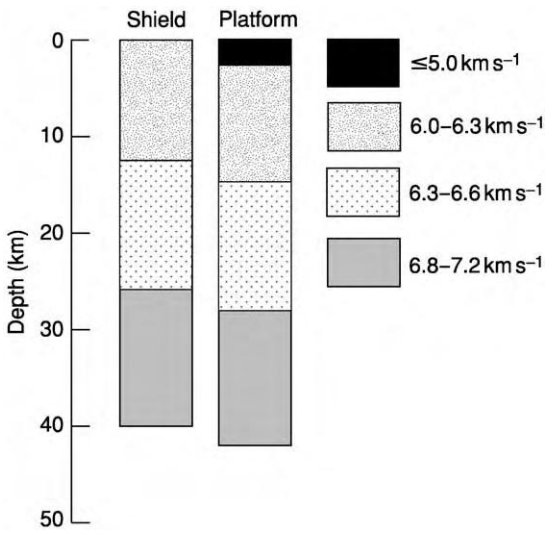

Figure 2 Seismic cross sections of shield and platform crust with typical P wave velocity distributions.

6.3 km s ^{1} in the upper layer, 6.3 to 6.6 km s ^{1} in the middle layer, and 6.8 to 7.2 km s ^{1} in the lower layer. Upper mantle velocities beneath shields and platforms are typically in the range of 8.1–8.2 km s ^{1}, rarely reaching 8.6 km s ^{1}. Seismic reflection studies show an increase in the number of reflections with depth, and generally weak, but laterally continuous, reflections at the Moho, the seismic discontinuity defining the base of the crust.

[a]Major elements in weight percent of the oxide; trace elements in parts per million.

Composition of the Crust in Cratons

Several approaches have been used to estimate the chemical and mineralogical composition of the crust. One of the earliest methods to estimate the composition of the upper continental crust is based on chemical analysis of glacial clays, which were assumed to be representative of the composition of large portions of the upper continental crust. Probably the most accurate estimates of the composition of the upper continental crust come from extensive sampling of rocks exhumed from varying depths in Precambrian shields and from the composition of Phanerozoic shales. Because the lower continental crust is not accessible for sampling, indirect approaches must be used. These include (1) measurement of seismic-wave velocities of crustal rocks in the laboratory at appropriate temperatures and pressures, and comparing these to observed velocity distributions in the crust, (2) sampling and analysing rocks from blocks of continental crust exhumed from middle to lower crustal depths, and (3) analysing xenoliths of lower crustal rocks brought to the surface during volcanic eruptions.

The average chemical composition of the upper continental crust is reasonably well known. An average composition is similar to granodiorite (Table 1), although there are differences related to the age of the crust. The composition of the middle and lower continental crust is much less well constrained. Uplifted crustal blocks, xenolith populations, and seismic velocity data suggest that the middle crust is intermediate (andesitic) in composition and that the lower crust is mafic (basalt-like) in overall composition. The estimate of total continental crust composition in Table 1 is a mixture of upper, middle, and lower crustal averages in equal amounts. The composition is similar to other published total crustal compositions indicating an overall intermediate composition. Incompatible elements, which are elements that are strongly partitioned into the liquid phase on melting, are known to be concentrated chiefly in the continental crust. During melting in the mantle, these elements are enriched in the magma, and thus are transferred upward into the crust as magmas rise. Between 35 and 65% of the most incompatible elements (such as Rb, Th, U, K, and Ba) are contained in the continents, whereas

continents contain <10% of the least incompatible elements (such as Y, Yb, and Ti).

Cratonization

Cratonization refers to the process of craton formation. Collisional orogenesis occurs when plates carrying blocks of continental crust collide with each other, producing major mountain chains such as the Himalayas. Cratons are the end product of collisional orogenesis, and thus they are the building blocks of continents. Collisional mountain chains are eroded away in 200–400 Ma, leaving the roots exposed at Earth's surface as 'sutures' between pre-existing crustal blocks. The complex amalgamation of crustal blocks and orogen roots comprises today's cratons.

Using a variety of radiogenic isotopic systems and estimated closure temperatures in various minerals, it is possible to track the cooling and uplift histories of cratons. Results suggest a wide variation in cooling and uplift rates, with most orogens having cooling rates of $<2^{\circ}C\,My^{-1}$, whereas a few (such as southern Brittany) have cooled at rates of $>10^{\circ}C\,My^{-1}$ (Figure 3). In most cases, it would appear to take a minimum of 300 My to make a craton. Some terranes, such as Enderbyland in Antarctica, have had very long, exceedingly complex cooling histories lasting for more than 2 Ga. Many orogens, such as the Grenville Orogen (*see* **Grenvillian Orogeny**) in eastern Canada, have been exhumed as indicated by unconformably overlying sediments, and then reheated during subsequent burial and then re-exhumed. In some instances, postorogenic thermal events such as plutonism and metamorphism have thermally overprinted earlier segments of the cooling history of an orogen, such that only the very early high-temperature history (>500°C) and, perhaps, the latest exhumation record (<300°C) are preserved. Fission track ages suggest that final uplift and exhumation of some orogens, such as the 1.9-Ga Trans-Hudson Orogen in central Canada, may be related to the early stages of supercontinent fragmentation.

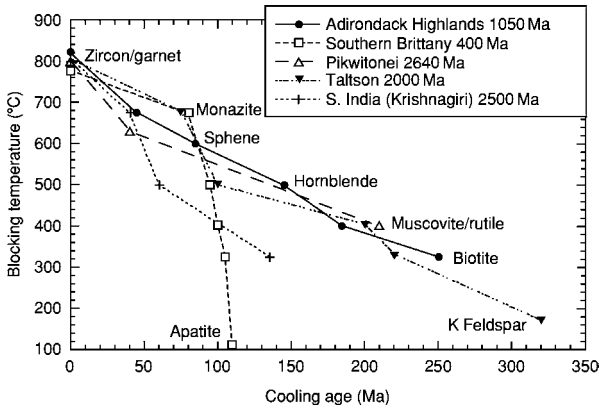

Figure 3 Cooling histories of several orogens leading to the production of stable cratons. Blocking temperature is the temperature at which the daughter isotope is captured by the indicated host mineral.

Crustal Provinces and Terranes

The Canadian Shield can be subdivided into structural provinces based on differences in structural trends and style of folding. Structural trends are defined by foliation, fold axes, and bedding, and sometimes by geophysical anomalies. Boundaries between the provinces are drawn where one trend cuts across another, along either unconformities or structural-metamorphic breaks. Large numbers of isotopic ages from the Canadian Shield indicate that structural provinces are broadly coincident with age provinces. Similar relationships have been described on other continents and lead to the concept of a crustal province (Figure 4).

Terranes are fault-bounded crustal blocks that have distinct lithologic and stratigraphic successions and that have geological histories different from neighbouring terranes (*see* **Terranes, Overview**). Most terranes have collided with continental crust, either along transcurrent faults or at subduction zones, and have been sutured to continents. Many terranes contain faunal populations and palaeomagnetic evidence indicating they have been displaced great distances (thousands of kilometres) from their sources prior to continental collision. For instance, Wrangellia, which collided with western North America in the Late Cretaceous, had travelled many thousands of kilometres from what is now the South Pacific and is now represented in Vancouver Island. Results suggest that as much as 30% of North America was formed by terrane accretion in the past 300 Ma and that terrane accretion has been an important process in the growth of continents.

Terranes form in a variety of tectonic settings, including island arcs, oceanic plateaus, volcanic islands, and microcontinents. Continental crust may be fragmented and dispersed by rifting or strike-slip faulting. In western North America, dispersion is occurring along transform faults such as the San Andreas and Fairweather faults, and in New Zealand movement along the Alpine Transform Fault is fragmenting the Campbell Plateau from the Lord Howe Rise. Baja California and California west of the San Andreas Fault were rifted from North America about 4 Ma, and today this region is a potential terrane moving northwards, perhaps on a collision course with Alaska. Terranes may continue to fragment and

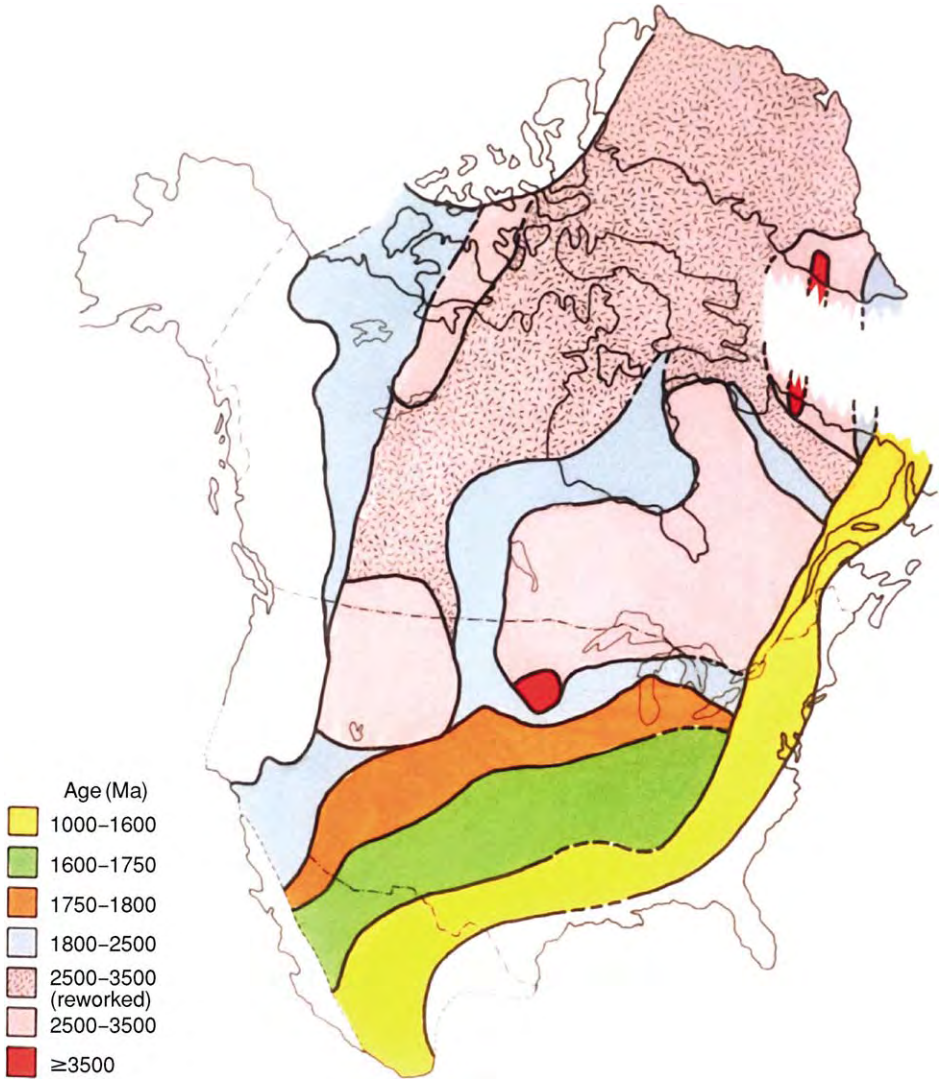

Figure 4 Crustal provinces in North America.

disperse after collision with continents, as did Wrangellia, which is now distributed in pieces from Oregon to Alaska. The 1.9-Ga-old Trans-Hudson Orogen in Canada and the 1.65- to 1.75-Ga-old Yavapai Orogen in the south-west United States are examples of Proterozoic orogens composed of terranes, and the Alps, Himalayas, and American Cordillera are Phanerozoic examples of orogens composed of terranes. Most crustal provinces are composed of terranes, and in turn, cratons are composed of exhumed orogens. In fact, terranes might be considered as the basic building blocks of continents, and terrane collision as a major means by which continents grow in size.

A crustal province is an orogen, active or exhumed, composed of terranes, and it records a similar range of isotopic ages and exhibits a similar postamalgamation deformational history (Figure 4). Shields and platforms are composed of exhumed crustal provinces. Structural trends within provinces range from linear to exceedingly complex swirling patterns reflecting multiple deformation superimposed on differing terrane structural patterns. Exhumed crustal provinces that have undergone numerous episodes of deformation and metamorphism are old orogens. Isotopic dating using several isotopic systems is critical to defining and unravelling the complex, polydeformational histories of crustal provinces.

The definition of 'crustal province' is not always unambiguous. Most crustal provinces contain rocks of a wide range in age and record more than one period of deformation, metamorphism, and plutonism. For instance, the Trans-Hudson orogen in North America includes rocks ranging in age from about 1.7 to 3.0 Gy and records several periods of

complex deformation and regional metamorphism. Likewise, the Grenville province in eastern North America records a polydeformational history, with rocks ranging in age from 1.0 to 2.7 Ga. Some parts of crustal provinces are new mantle-derived crust, known as juvenile crust, whereas other parts represent reworked older crust. Reworking, also known as overprinting or reactivation, describes crust that has been deformed, metamorphosed, and partially melted more than once. There is increasing evidence that crustal reworking results from continental collisions, and large segments of continental crust appear to have been reactivated by such collisions. For instance, much of central Asia at least as far north as the Baikal Rift, which is in a craton, was affected by the India–Tibet collision beginning about 50 Ma. Widespread faulting and magmatism at present crustal levels suggest that deeper crustal levels may be extensively reactivated. In Phanerozoic collisional orogens where deeper crustal levels are exposed, such as the Appalachian and Variscan orogens, there is isotopic evidence for widespread reactivation.

Sediments Deposited on Cratons

Rock assemblages deposited on cratons are mature clastic sediments, chiefly quartz arenites and shales, and shallow marine carbonates. In Late Archaean and Palaeoproterozoic successions, banded iron formation may also be important. Cratonic sandstones are relatively pure quartz sands, reflecting intense weathering, low relief in source areas, and prolonged transport across subdued continental surfaces. Commonly associated marine carbonates are deposited as blankets and as reefs around the basin margins. Transgression and regression successions in large cratonic basins reflect the rise and fall of sea level, respectively.

Depositional systems in cratonic basins vary depending on the relative roles of fluvial, aeolian, deltaic, wave, storm, and tidal processes. Spatial and temporal distribution of sediments is controlled by regional uplift, the amount of continent covered by shallow seas, and climate. If tectonic uplift is important during deposition, continental shelves are narrow and sedimentation is dominated by wave and storm systems. However, if uplift is confined chiefly to craton margins, sediment yield increases into the craton, and fluvial and deltaic systems may dominate. For transgressive marine clastic sequences, shallow seas are extensive and subtidal, and storm-dominated and wave-dominated environments are important. During regression, fluvial and aeolian depositional systems become dominant.

The rates of subsidence and uplift in cratons are a function of the time interval over which they are measured. Current rates are of the order of a few centimetres per year, whereas data from older successions suggest rates 1–2 orders of magnitude slower. In general, Phanerozoic rates of uplift appear to have been 0.1–1 cm year ^{1} over periods of 10^4–10^5 years and over areas of 10^4–10^6 km^2. Craton subsidence can be considered in terms of two stages: in the first stage, subsidence rate varies greatly, whereas the second stage subsidence is widespread. After about 50 Ma, the depth of subsidence decreases exponentially to a constant value.

Several models have been suggested to explain cratonic subsidence. Sediment loading, lithosphere stretching, and thermal doming followed by contraction are the most widely cited mechanisms. Although the accumulation of sediments in a depression loads the lithosphere and causes further subsidence, calculations indicate that the contribution of sediment loading to subsidence must be minor compared to other effects. Subsidence at passive margins may result from thinning of continental crust by progressive creep of the ductile lower crust towards the suboceanic upper mantle. As the crust thins, sediments accumulate in overlying basins.

Supercontinents and Cratons

Supercontinents are large continents that include several or all of the existing cratons. Matching of continental borders, stratigraphic sections, and fossil assemblages are some of the earliest methods used to reconstruct ancient supercontinents. Today, in addition to these methods, we have polar wandering paths, seafloor spreading directions, hotspot tracks, and correlation of crustal provinces. The use of computers in matching continental borders has resulted in more accurate and objective fits. One of the most definitive matching tools in reconstructing plate positions in a former supercontinent is a piercing point. A piercing point is a distinct geologic feature such as a fault or terrane that strikes at a steep angle to a rifted continental margin, the continuation of which should be found on the continental fragment rifted away.

The youngest supercontinent is Pangaea (*see* **Pangaea**), which formed between 450 and 320 Ma and includes most of the existing continents (Figure 5). Pangaea began to fragment about 160 Ma and is still dispersing today. Gondwana (*see* **Gondwanaland and Gondwana**) was a southern hemisphere supercontinent composed principally of South America, Africa, Arabia, Madagascar, India, Antarctica, and Australia. It formed in the latest Proterozoic and was largely completed by the Early Cambrian (750–550 Ma). Later it became incorporated in Pangaea. Laurentia, which is also part of Pangaea,

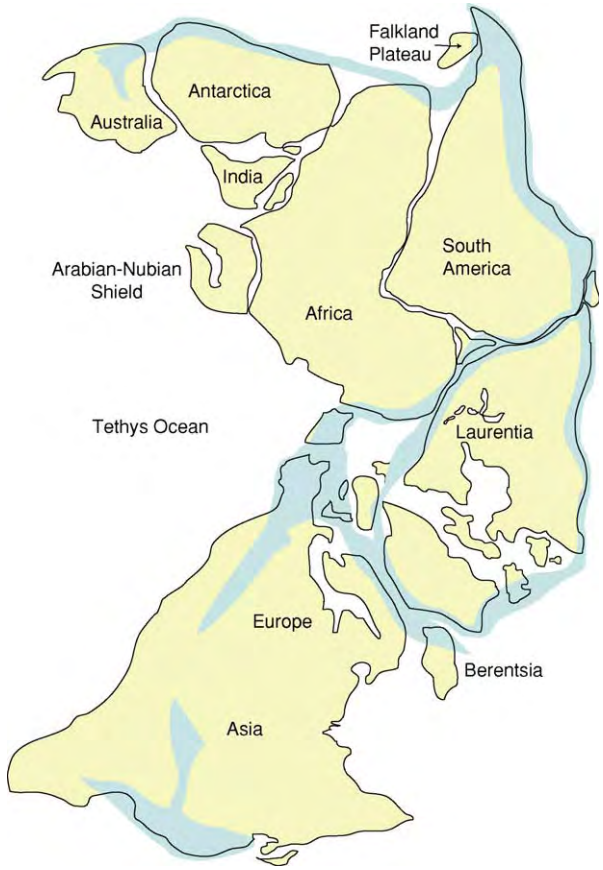

Figure 5 Pangaea, a supercontinent that formed between 450 and 320 Ma and began to fragment about 160 Ma. The major collisional orogens are indicated.

includes most of North America, Scotland, and Ireland north of the Caledonian suture, and Greenland, Spitzbergen, and the Chukotsk Peninsula of eastern Siberia. Although the existence of older supercontinents is likely, their configurations are not well known. Geological data strongly suggest the existence of supercontinents in the Proterozoic and in the Late Archaean. Current thinking is that supercontinents have been episodic, giving rise to the idea of a supercontinent cycle. A supercontinent cycle consists of rifting and break up of one supercontinent, followed by a stage of reassembly in which dispersed cratons collide to form a new supercontinent, with most or all fragments in different configurations, compared to the older supercontinent. The supercontinent cycle provides a record of the processes that control the formation and redistribution of cratons throughout Earth history.

SHOCK METAMORPHISM

P S DeCarli, SRI International, Menlo Park, CA, USA

Introduction

The term 'shock metamorphism', synonymous with 'shock wave metamorphism' or 'impact metamorphism', refers to the range of effects produced by the collision of two bodies, e.g., by the collision of an asteroid with the Earth. These effects include fracturing, the formation of planar deformation features (PDF), the formation of high-pressure phases, melting, and vaporization. Our knowledge of shock metamorphism, currently quite incomplete, is derived from laboratory shock experiments, static high-pressure experiments, studies of naturally impacted materials, theoretical analyses, and numerical computations.

It is generally accepted that the history of the solar system is one of repeated collisions between orbiting bodies. Lunar craters, now widely accepted as impact craters, provide a partial record of that history. Only during the past 50 years has it become evident that the Earth, because of its higher gravity, should have experienced about twice as many large craters per unit area as the Moon. Most of these craters on the continental crust have been deformed, modified by erosion, and buried by sediments or volcanism.

Between 1960 and 2003, about 170 terrestrial impact craters were identified, and three to five newly identified craters are added to the list each year.

The minimum velocity of an encounter between the Earth and a body within our solar system is 11.2 km s $^{-1}$, the escape velocity of the Earth. Photographic measurements of meteors, the familiar shooting stars, indicate that they enter the atmosphere at velocities in the range 13–30 km s $^{-1}$; this is an appropriate velocity range for encounters with asteroids. Comets encounter the Earth at velocities in the range of 30 km s $^{-1}$ (short period comets) to 70 km s $^{-1}$ (very long period comets).

The fate of a body entering the Earth's atmosphere at very high velocity depends on such details as the strength and density of the body, its velocity, and its angle of entry. If the body is non-spherical, details of shape and orientation must also be considered, e.g., whether an elongated body enters the atmosphere in point-first or side-first orientation. To simplify further discussion, only vertical impacts of spherical bodies that are strong enough to survive passage through the atmosphere are considered. The interaction of a fast-moving fragile body with the atmosphere can produce an effect equivalent to a large nuclear explosion at an altitude above 20 km. Resultant pressures at the surface may knock down trees, but are too low to produce shock metamorphic effects in minerals.

A very large body, greater than 10 km in diameter, will not be sensibly retarded by the atmosphere. Impact with the Earth will result in the formation of a large crater, greater than 100 km in diameter. Only two craters larger than 100 km in diameter are known to have formed within the past 150 million years. The larger of the two, the 65-million-year-old Chicxulub crater, Yucatan, Mexico, is buried under more than 300 m of carbonate rocks, and was identified in 1981 by the recognition of circular patterns in gravity and magnetic field data. Shock metamorphic features in drill cores have confirmed the identification. The iridium-rich Cretaceous–Teritary K–T boundary layer, which contains shock metamorphosed minerals, coincides with the mass extinction (including dinosaurs) at the end of the Cretaceous, and is believed to be associated with this impact event. Many impact specialists are convinced that the environmental effects of the Chicxulub impact were the primary cause of an abrupt mass extinction. However, many palaeontologists disagree. They argue that the extinction was not abrupt and that there is evidence for other causes. The one matter on which all agree is that the iridium-rich boundary layer serves as an excellent worldwide common time marker that will be essential to further studies of K–T extinctions. Impact specialists continue to search for evidence of large impacts that could be related to other mass extinctions.

Smaller impact events are much more frequent, but the resultant craters are more easily eroded or obscured. Four craters having diameters in the range 7–18 km have been identified as less than 6 million years old. These craters were formed by the impact of bodies in the diameter range of about 300 m to 2 km, sufficiently large to minimize retardation by the atmosphere. Atmospheric retardation becomes significant only for bodies having diameters less than about 10 m, corresponding to masses less than about 1000 tons.

Thus, the velocity of a stony object of 10 m diameter might be reduced from approximately 15 km s $^{-1}$ on atmospheric entry to 10 km s $^{-1}$ on impact with the Earth. The impact would deposit the energy equivalent of approximately 36 000 tons of trinitrotoluene (TNT), and the resultant crater would have a diameter in the range of 100–200 m.

As noted by Melosh in his book on impact cratering (see Further Reading), relationships between crater dimensions and impact parameters are poorly constrained. There are a variety of empirical scaling relations extrapolated from small-scale laboratory impact experiments, high explosive and nuclear experiments, and large-scale computer calculations. Here, we apply the observation that, for a variety of impact conditions, many scaling relations predict D/d, the ratio of the crater diameter to the impactor diameter, to be in the range of 10–20.

Small objects with a mass in kilograms are slowed by atmospheric drag to terminal velocities in the region below about 200 m s^{-1}. The resultant impact pressure of about 1 GPa for an impact on rock is too low to produce shock metamorphic effects other than fracture. Thus, 20 GPa shock metamorphic effects found in some small meteorites may be interpreted as the result of impacts on a meteorite parent body. The exception to this general rule is when there is evidence that a small meteorite is a fragment of a much larger body that impacted the Earth at high velocity. Iron meteorites found in the vicinity of the Meteor Crater (northern Arizona, USA) (1.3 km in diameter) are interpreted as fragments of the rear surface of a 100 000 ton (approximately 30 m in diameter) iron meteorite that is estimated to have impacted the Earth at approximately 20 km s^{-1}.

The bulk of this meteorite was melted or vaporized as a result of very high shock pressures. Intuitively, it might be expected that the entire meteorite would be exposed to the same peak pressure, as predicted by some low-resolution calculations. However, the most recent high-resolution calculations predict that rarefactions originating at free surfaces (the meteorite–air interface) will interact to create low-pressure regions near the rear surface of the meteorite. At least 20 tons of meteorite fragments have been recovered from the vicinity of Meteor Crater. Some of these fragments have shock metamorphic features indicative of peak pressures of less than 10 GPa. Other fragments have shock metamorphic features, including shock-synthesized diamond, indicative of pressures in excess of 100 GPa.

Shock Waves and Large Impacts

Pressure scale definitions: the modern unit of pressure, the pascal, is defined as 1 N m^{-2}. Atmospheric pressure on the Earth at sea-level is approximately 10^5 Pa (100 000 Pa); shock pressures are usually stated as gigapascals (GPa), 10^9 Pa. Earlier literature may refer to bars, kilobars (kb or kbar), atmospheres (atm), dynes per square centimetre (dyn cm^{-2}), kilograms per square centimetre (kg cm^{-2}), and pounds per square inch (psi).

$$1 \text{ bar} = 10^5 \text{ Pa} = 10^6 \text{ dyn cm}^{-2} = 0.9869 \text{ atm} = 1.0197 \text{ kg cm}^{-2} = 14.504 \text{ psi}$$

$$1 \text{ GPa} = 10 \text{ kbar} = 10^{10} \text{ dyn cm}^{-2} = \sim 145\,000 \text{ psi}$$

A collision between two bodies produces a high pressure (shock wave) at the point of impact. The shock wave propagates into both bodies and is attenuated by rarefaction waves originating at free surfaces. The magnitude of the peak pressure depends on both the impact velocity and the relative stiffness of the impacting bodies, as shown in Table 1. The pressure calculations are based on material properties extrapolated from much lower pressures.

Table 1 Parameters of typical Asteriod Earth and Comet Earth Impacts

Impactor target	*Velocity (km s^{-1})*	*Peak pressure (GPa)*	*Fate of impactor*	*Fate of target*
Iron water (ice)[a]	20	~360	Completely molten	Total vaporization of water or ice
Iron alluvium (1.5 g cm^{-3})	20	~400	Completely molten	Total vaporization
Iron granite	20	~750	Partial vaporization	Total vaporization
Iron peridotite	20	~950	Partial vaporization	Total vaporization
Peridotite water (ice)	20	~280	Partial vaporization	Total vaporization
Peridotite alluvium	20	~300	Partial vaporization	Total vaporization
Peridotite alluvium over granite[b]	20	~300, then ~400, shock reflection	Partial vaporization	Total vaporization of alluvium Partial vaporization of granite
Peridotite granite	20	550	Total vaporization	Total vaporization
Peridotite peridotite	20	650	Total vaporization	Total vaporization
Snow (0.6 g cm^{-3}) ice[c]	40	~500	Total vaporization	Total vaporization
Ice alluvium[c]	40	~600	Total vaporization	Total vaporization
Ice ice	40	~650	Total vaporization	Total vaporization

[a] At these very high pressures, the properties of ice and water are indistinguishable.
[b] Shock interactions occur at interfaces between materials having different properties. The 300 GPa shock in alluvium is reflected at the granite interface as a 400 GPa shock moving back into the alluvium. A 400 GPa shock is transmitted into the granite.
[c] The properties of a comet are approximately bracketed by the properties of snow and ice.

The maximum duration of the pressure peak occurs at the point of impact and depends on such details as the relative sizes and shapes of the two bodies, their properties at very high pressure, the impact velocity, and the angle of impact. One popular approximation is that the duration is equal to the impact velocity divided by the diameter of the smaller body. The peak pressure duration for the 20 km s $^{-1}$ impact on the Earth of an asteroid of 20 km in diameter would thus be about 1 s, i.e., between about 0.5 and 2 s, depending on the material properties and the geometry of the impact.

To put these very high impact pressures and durations into perspective, it should be noted that the pressure at the centre of the Earth is about 350 GPa and the effective high-pressure duration of a very large buried thermonuclear explosion is less than 1 ms.

The very high pressures at the point of impact decay in amplitude as they propagate into the Earth. There are two causes of pressure decay. The first is geometric. If the shock front is considered as an expanding hemispherical shell, the peak pressure would be expected to decay as the radius of the hemisphere increases. The second cause of pressure decay is that rarefaction waves originating from the free surface overtake the shock front and reduce the pressure. Melosh's book cites a number of approximate methods for estimating pressure decay in a homogeneous geological environment. Another approach is to perform large-scale computer calculations with 'hydrocodes', computer programs designed to calculate shock wave propagation in various media. These codes were developed for national defence-related purposes to calculate the attenuation of the shock waves produced by large chemical or nuclear explosions. Numerous comparisons of calculations with experimental measurements have shown that agreement within about $\pm 20\%$ can now be achieved over the pressure range between about 1 and 100 GPa, the range over which geological media have been well characterized by Hugoniot (compressional) and release adiabatic measurements. In order to achieve such agreement, the details of geology (including faults and layering) and accurate material properties must be incorporated into the calculation. It is particularly important to include the details of dynamic phase transitions, including the pressure hysteresis between the forward transitions on loading and the reverse transitions on release. The most detailed calculations require extraordinary computer power.

There are many pitfalls in the use of hydrocodes to calculate large impacts on Earth. One problem is the scale of the event. The 20 km s $^{-1}$ impact of a stony asteroid of 10 km in diameter on the Earth releases an energy of approximately 6.3×10^{28} J, about a million times greater than the sum of all nuclear arsenals. The scope of the calculation must be reduced to bring it within the range of even our fastest of current computers. The details of the geological setting must be ignored and the spatial resolution of the calculation must be very coarse, about 1 km. A second problem is that the calculation requires a knowledge of detailed material properties at very high pressures, well above the range of current experimental data. Data on the compression and release behaviour of geological media are virtually non-existent for the pressure range above 100 GPa. Furthermore, most existing data for the range below 100 GPa were obtained in experiments of submicrosecond duration. A few experiments at longer duration, up to 10 μs, have been performed to explore the effects of pressure duration on dynamic phase transitions; kinetic effects were not observed. However, it may be inferred from static high-pressure studies that kinetic effects could possibly be significant in large impact events where the shock duration may exceed 1 s.

Although the equations governing shock wave propagation are simple, the details of shock wave propagation through a typical polymineralic rock are extraordinarily complex. The shock properties of individual minerals can differ substantially; shock interactions occur at mineral boundaries and in the vicinity of pores and cracks. Recent high-resolution hydrocode calculations have studied the details of pressure and temperature equilibration in a rock-like material. On a time-scale of nanoseconds (10^{-9} s) and a distance scale of micrometres, the shock front appears chaotic. Shock collisions around a pore produce nanosecond duration pressure spikes that may be ten times the amplitude of the pressure within an adjacent millimetre-sized grain. These initial pressure inhomogeneities equilibrate within less than a microsecond (for a mineral grain size of about 1 mm) to a uniform pressure. In general, these initial pressure inhomogeneities are ignored. The term 'peak pressure', as it is commonly used (e.g., in Table 1), refers to the pressure after equilibration of the nanosecond duration spikes. However, a knowledge of the complexity of pressure equilibration may be very useful to the researcher who uses microscopic techniques to study shock metamorphic effects on a micrometre scale.

Although accurate high-resolution calculations of a specific large impact may be presently beyond reach, there is nevertheless an excellent qualitative understanding of generic impacts from the study of numerous low-resolution calculations, from small-scale laboratory experiments, and from theoretical considerations, as summarized by Melosh. Figure 1 shows a

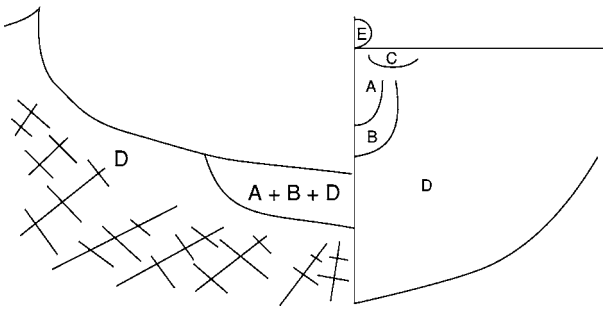

Figure 1 Diagram showing zones of damage by the high velocity impact of a large meteorite. Right: at moment of impact. Left: after cratering is complete. Zone A: very high pressure region above approximately 100 GPa; all minerals melted or va porized. Zone B: high pressure region, approximately 7 100 GPa; most minerals show distinctive shock metamorphic effects. Zone C: near impactor near surface region. Together with the atmos phere, material is ejected at high velocity into a high angle trajec tory. The ejected material can range from strongly shocked (even molten) to weakly shocked. This is the probable source region for tektites, natural glasses of crustal composition. Zone D: weakly shocked fractured region, approximately 0.1 7 GPa; radial and circumferential fractures. Most of the material ejected from the crater originates from this zone and is not strongly shocked. However, block motion in this region can produce localized melting caused by frictional heating. The resultant sheet like formations are called pseudotachylites. Zone E: the impacting body. Melted or vaporized, for the most part, but a small fraction may survive in a relatively unshocked condition. The melted and vaporized material can be ejected into the upper atmosphere and subsequently deposited over a large area. Left: A + B + D, breccia lens; an intimate mixture of shock metamorphosed clasts with melt and weakly shocked material. If melt predominates, the breccia is called tagamite. If the melt is less dominant, the breccia is called suevite.

diagram depicting the effects of an impact, referenced to the pre-impact setting and approximately scaled to the diameter of the impacting body.

Shock Metamorphic Effects

The impact event depicted in Figure 1 can produce numerous shock metamorphic effects. Ejected material, including solid, solidified melt, and condensed vapour, can serve as a stratigraphical marker. The breccia lens provides most of the evidence to distinguish an impact crater from a volcanic crater. As noted above, the breccia lens is a heterogeneous mixture of high-pressure and lower pressure material. This is advantageous in that the lower pressure clasts have been subjected to only minor shock heating and serve to quench the more strongly shock-heated and shock-melted material. Quenching helps to preserve more fragile high-pressure phases, such as stishovite. Some common shock metamorphic effects are presented in Table 2.

Controversial Issues

There are numerous controversies in the literature on shock metamorphism, as should become evident to the person who reads more than one of the items in the Further Reading section at the end of this article. The controversies are, in general, a measure of the incompleteness of our knowledge. Almost without exception, published experimental data and observations are trustworthy and reproducible. The majority of controversies centre on the interpretations of the data, inferences from hydrocode calculations, or the validity of often unstated assumptions.

For example, tektites (distinctive forms of natural glass showered down on the Earth) show unequivocal signs of sculpturing by aerodynamic forces during high-speed entry into the Earth's atmosphere. Although the detailed chemical composition of tektites implies an Earth origin, simple physical arguments indicate that it is impossible to propel tektites into space through the Earth's atmosphere. Those who therefore argued against a terrestrial origin of tektites failed to consider the possibility that a large impact on Earth could melt crustal material and propel it into space, together with a portion of the atmosphere. Large-scale hydrocode calculations indicate that this latter possibility is plausible. The chemical evidence for a terrestrial origin of tektites is so strong that it overwhelms concerns that a calculation having a resolution of 1 km is used to predict the fate of centimetre-sized objects.

There is a related controversy over the minimum shock pressure to which Martian meteorites have been exposed. There is very strong chemical evidence that certain meteorites found on the Earth actually originated on Mars. Some scientists have argued that any meteorite ejected from Mars by a large impact would have melted on release from the requisite high pressure, about 150 GPa. Although various investigators have disagreed about the peak pressure implied by shock metamorphic effects, they have agreed that the meteorites were not melted by their ejection from Mars. Subsequent calculations have indicated that the Martian meteorites could have been accelerated to the Martian escape velocity of 5 km s ^{1} by shock pressures as low as 65 GPa. Some investigators have interpreted these calculations as evidence that all Martian meteorites must necessarily have been exposed to shock pressures of 65 GPa or higher. However, one Martian meteorite shows remanent magnetism that would have been destroyed by shock pressures exceeding about 20 GPa. If the magnetic data and the evidence for a Martian origin are accepted, there must be an even lower pressure mechanism for accelerating a Martian rock to escape

Table 2 Shock metamorphic effects

Effect	*Source material*	*Pressure (GPa) (single shock)*	*Comments*
Melting	Iron	>170	Melts on release of pressure
Melting	Olivine, pyroxene	>100	Melts on release of pressure
Melting	Quartz, granite	>50	Melts on release of pressure
Melting	Sand, soil	>20, possibly as low as 7	Energy increase on shock compression much greater for porous materials
Diaplectic glass	Quartz, feldspars	>15, possibly as low as 7	Diaplectic glass forms by solid state transformation. It is amorphous, but retains original crystal form and usually has a higher refractive index than melt glass. Lower bound pressure from PDF formation
Stishovite, hollandite	Quartz, feldspars	>15, possibly as low as 7	Stishovite, hollandite, polymorphs of quartz, and feldspar found in impact craters and meteorites. Lower bound pressure from PDF formation
Coesite	Quartz	>15, possibly as low as 3	Coesite found in impact craters in association with diaplectic glass, implying that it formed on release of pressure. Could conceivably be found in a pseudotachylite that solidified under pressure
Ringwoodite, wadsleyite	Olivines	>15	Found in meteorite melt veins; pseudotachylite like structures that were quenched at high pressure
Akimotite, majorite	Pyroxenes	>17	Found in meteorite melt veins; pseudotachylite like structures that were quenched at high pressure
Diamond, cubic and hexagonal mixture	Graphite	>25	Found in meteorites; $P \sim 100$ GPa from graphite in iron meteorites. Found in impact craters; $P \sim 30$ GPa from graphite in gneiss. Made in laboratory shock experiments
Cubic diamond	Porous carbon	>15	Made in laboratory shock experiments
Planar deformation features (PDFs)	Quartz, feldspar predominantly. Also other minerals	>7	PDFs in quartz are a primary diagnostic for impact. A PDF is a lamellar feature aligned with a low index crystallographic plane. A number of different orientations may appear in the same grain. There is evidence that the lamellae contain high pressure phases that invert to low pressure forms during electron microscopy
Fractures	All rocks	>~0.1	Laboratory shock experiments show dynamic fracture strength comparable (~1.5 times) to static strength
Pseudotachylite formation	All rocks	>~0.1	Pressure estimate based on observation of pseudotachylites in the fractured zone

Numerous other high pressure minerals have been observed in meteorites and impact craters. The most common and readily observed are listed. The book by French (see Further Reading) contains numerous micrographs of shock metamorphosed quartz.

velocity. Melosh has suggested one such mechanism: entrainment of the rock in the vapour plume formed by strongly shocked material (see **Table 1**).

Finally, there are long-standing controversies over the peak pressures associated with various metamorphic effects. Shock metamorphic effects in rocks and minerals have been studied in numerous laboratory shock experiments over the past 45 years. It was initially hoped that a peak shock pressure calibration could be established based on the presence of various metamorphic effects. The assumption that the peak shock pressure is the only significant parameter seems to be incorrect, as may be inferred by analyses of apparent conflicts in research reports. These conflicts can usually be resolved by considerations of experimental differences between the experiments. Samples loaded to the same peak pressure via different loading paths (single shock vs. a sequence of shock reflections) often show marked differences in metamorphic effects. Although the pressure duration of laboratory shock experiments is in the range of a microsecond, the shock pressure duration for a large natural impact may exceed a second. The interpretation of metamorphic effects on the basis of laboratory static high-pressure data may be more appropriate in this regime. Some controversies over the precise peak pressure to which a given natural sample has been exposed may not be resolvable on the basis of present knowledge. However, there is usually no argument about whether a given sample has been shock metamorphosed at all.

SOIL MECHANICS

J Atkinson, City University, London, UK

Soil and Mechanics

Engineering Soils

Soil mechanics describes the mechanical behaviour of granular materials. Mechanical behaviour covers strength, shear stiffness, volumetric compressibility, and seepage of water. Granular materials include powders, grain, and other foodstuffs, mineral ores and concentrates, as well as natural soils.

The simple theories of soil mechanics are intended for collections of grains which are uncemented or only very slightly cemented and which contain fluid, usually water or air, in the pore spaces. This covers dense and loose sands and soft and stiff clays. Rock mechanics describes the behaviour of strongly bonded grains whose overall behaviour is governed by joints and fractures. There is a range of materials between these, including weathered rocks, weak rocks, and cemented soils for which simple theories of soil mechanics have limited application.

The theories of soil mechanics apply equally to sands (coarse-grained soils) and clays (fine-grained soils). Figure 1 shows samples of sand and clay under load in unconfined compression. In each case the strength arises from suctions in the pore water. The clay is stronger than the sand because it can sustain larger suctions: otherwise their behaviour is fundamentally the same.

In describing theories for the behaviour of materials some mathematics is unavoidable. In the following, the mathematics is kept as simple as possible and does not extend beyond simple algebra. Only the most basic and fundamental equations and parameters are included.

Mechanics: Strength, Stiffness, Compressibility, and Permeability

Soils are highly compressible. The volume decreases significantly as it is compressed under an isotropic stress state. This is illustrated in Figure 2C. Soils also change volume when they are sheared and distorted.

Strength is basically the maximum shear stress a soil can sustain before it fails. Stiffness is the distortion which occurs as the soil is loaded before it fails. These are illustrated in Figure 2(D). G is the shear modulus and describes stiffness: τ_f is the shear stress after large distortion and it is the strength. In soils both strength and stiffness increase with increasing mean stress.

The frictional nature and the coupling between shear and volume change are the two main differences between the mechanical behaviour of granular materials and the mechanical behaviour of metals and other similar materials.

Figure 1 Unconfined compression of sand and clay.

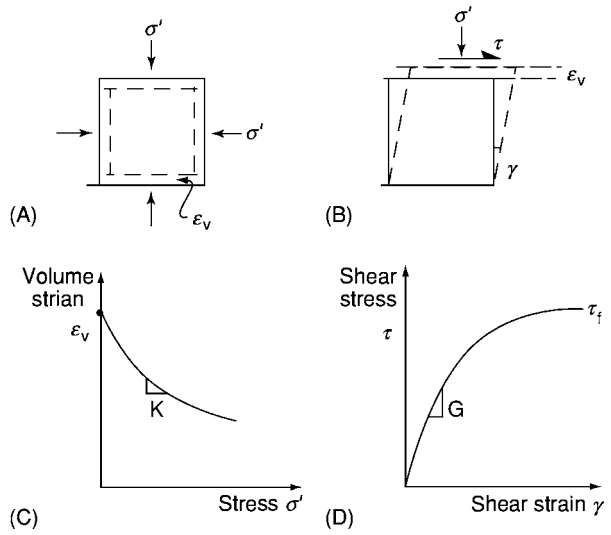

Figure 2 Compression and distortion.

A Brief History of Soil Mechanics

Coulomb and Soil Strength

Theories for soil mechanics originated around the middle of the eighteenth century. Coulomb was a military engineer and he was concerned with calculating soil loads on masonry retaining walls. He carried out experiments on the strength of soils and he found that the resistance of soil to shear loading had two components, one cohesive and the other frictional. Coulomb tested unsaturated samples and his analyses were in terms of forces, not stresses. Methods for analysis of stress discovered later by Mohr were incorporated into Coulomb's results and this is the basis of the well-known Mohr–Coulomb strength equation:

$$\tau_f = c + \sigma \tan \phi \qquad [1]$$

Neither Coulomb not Mohr had a clear understanding of the importance of pore pressures and effective stresses and the original Mohr–Coulomb equation is in terms of total stress. It is now known that the Mohr–Coulomb equation for soil strength is limited but it is still widely used.

Terzaghi and Effective Stress

Karl Terzaghi was an Austrian civil engineer. The major contribution which he made to soil mechanics was to set out a clear theory in the 1920s for accounting for the influence of pore pressure on soil strength and deformation. He proposed an effective stress σ' which controls all soil behaviour and he discovered that for saturated soil this is related to total stress σ and pore pressure u by:

$$\sigma' = \sigma - u \qquad [2]$$

The Terzaghi effective stress equation has been found to apply for a very wide range of loadings and soils, and it is used universally for geotechnical analysis of saturated soils.

Plasticity and Cam Clay

In the 1960s Andrew Schofield and Peter Wroth were lecturers at Cambridge University. They applied the then relatively new theories of plastic flow to frictional materials and created a complete stress-strain theory for soils. The model they developed they called Cam Clay and this remains the basis for many of the current constitutive equations for soils.

These theories of frictional strength, effective stress, and plastic flow are the basic buiding blocks for modern soil mechanics.

Effective Stress and Drainage

Principle of Effective Stress

The Principle of effective stress first proposed by Terzaghi in 1923, states that the stress which is effective in determining strength, stiffness, and compressibility, the effective stress, σ' is given by eqn [2].

Total stresses arise from external loads due to foundations and walls and loads from self weight. Pore pressures are the pressures in the fluid in the pore spaces. For dry soils the pore pressure is the pressure in the air in the pores. For saturated soil it is the pore water pressure. For soils which are not fully saturated and which contain both air (or gas) and water in the pores the equivalent pore pressure is some combination of the air and water pressure. At present there is no simple and robust theory for determining the equivalent pore pressure and effective stress in unsaturated soils.

So far as is known, the principle of effective stress and the effective stress equation (eqn [2]) holds for all dry or saturated soils over a very wide range of stress and pore pressure up to several tens of MPa. The strength and stiffness of soil 1 m below the bed of the deep ocean, where the depth of water may exceed 5 km, will be the same as that of soil 1 m below the bed of a duck pond.

Drainage and Consolidation

Because water is relatively incompressible in comparison with soil, volume changes in soil can occur only if water can flow into or out from the pore spaces. Whether or not this happens depends on the rate of drainage and the rate of loading.

If water cannot drain from the soil it is said to be undrained: its volume must remain constant but pore pressures will change in response to the loading. If water has time to drain freely from the soil it is said to be drained: pore pressures remain constant and volume changes occur. Hence:

$$\text{Undrained loading}: \quad \delta V = 0 \text{ and u changes}$$

$$\text{Drained loading}: \quad \delta u = 0 \text{ and volume changes}$$

where the symbol δ means 'a change of.' In many cases soil in the ground is neither fully drained not fully undrained but simple soil mechanics theories are applicable only for fully drained or fully undrained cases.

If soil is loaded undrained the resulting pore pressures will not be in equilibrium with the long-term groundwater pressures. As the excess (out of balance) pore pressures dissipate under constant total stress there will be changes of effective stress and volume changes. This process is known as consolidation. Because the rate of drainage during consolidation depends on hydraulic gradient, which decreases as excess pore pressures dissipate, the rate of consolidation diminishes with time.

Description and Classification of Engineering Soils

There are standard schemes for description and classification of soils for engineering purposes. These essentially classify soils under the two main headings: the nature of the grains and how they are packed together. For natural soils, descriptions are added for structure including bonding, bedding, and discontinuities.

The Nature of the Soil: Characteristics of the Grains

The most important characteristic is the grain size or grading. Figure 3 shows the range of grain sizes commonly found in natural soils and their descriptions (e.g., sand is 0.06 m to 2 mm). The range is very large. Clay grains are of the order of 1000 times smaller than coarse sand grains. Since permeability is related to the square of the size; sands are of the order of 1 million times more permeable than clays. If a soil is essentially single sized it is poorly graded (or well sorted). If it contains a range of sizes it is well graded (or poorly sorted). In a well graded soil it is usually the 10% smaller than (D_{10}) size which governs drainage.

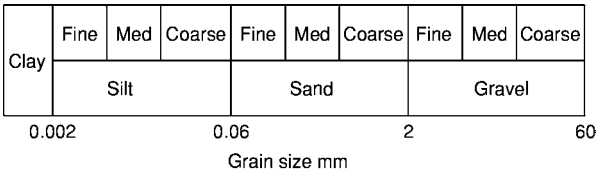

Figure 3 Grain size descriptions.

Grains of silt size and larger normally consist of rock fragments. They may be rounded or angular, rough or smooth. Grains of clay size are normally made of a clay mineral belonging to one of the major families which are kaolinite, illite, and montmorillonite (smectite). These may be distinguished by their Atterberg Limits and Activity (see below). The characteristics of the grains do not effect the fundamental behaviour of soils but they do influence numerical values of strength and stiffness parameters.

Rates of Loading and Drainage

In soil the rate of drainage depends primarily on the permeability which itself depends on the grading of the soil. The Hazen formula for coefficient of permeability k is

$$k \propto D_{10}^2 \qquad [3]$$

where D_{10} is the size of the grains with 10% smaller. Typical values for coefficient of permeability range from greater than 10^{-2} ms^{-1} (approx. 1.5 m in a minute) for coarse-grained soils to less than 10^{-8} ms^{-1} (approx 1 m in 3 years) for fine-grained soils. This very large difference (more than 1 million times) in rate of drainage between coarse-grained and fine-grained soils accounts for many of the differences in observed behaviour of sands and clays.

The rate of loading also varies widely. Some natural processes, such as deposition and erosion, occur relatively slowly (over decades) while others, such as earthquakes, occur relatively rapidly (over a few seconds). In construction, a shallow trench might be dug in a few hours and a large dam built in a few years.

In determining whether a certain event applied to a certain soil is drained or undrained, it is necessary to consider both the rate of drainage and the rate of loading. During earthquakes, coarse-grained sandy soils may be undrained causing liquefaction failure. In construction it is usual to take fine-grained clay soils as undrained and coarse-grained sand soils as drained.

Atterberg Limits

If a clay soil has a very high water content it will flow like a liquid; if it has a low water content it will become brittle and crumbly. For intermediate water contents it will be plastic. The Atterberg Limits, the Liquid Limit, W_l, and the Plastic Limit, W_p, define the range of water content over which a clay soil is plastic. The Plasticity Index, I_P, is the difference between the Liquid and Plastic Limits:

Table 1 Typical values for some characteristic soil parameters

Parameter	*Symbol and units*	*Kaolinite clay (China clay)*	*London clay*	*Alluvial sand (Thames)*	*Carbonate sand*	*Decomposed granite (Dartmoor)*
Liquid Limit	W_l	65	75			
Plastic Limit	W_p	35	30			
Plasticity Index	I_p	30	45			
Activity	A	0.4	1			
Maximum specific volume	V_{max}	2.72	2.98	2.2	3.2	
Minimum specific volume	V_{min}	1.92	1.80	1.5	2.0	
Coefft of compressibility	Cc	0.44	0.37	0.37	0.78	0.21
Coefficient of swelling	Cs	0.11	0.14	0.03	0.01	0.01
Specific volume on NCL at σ' 1 kPa	Vn	3.26	2.68	3.17	4.8	2.17
Specific volume on CSL at σ' 1 kPa	Vc	3.14	2.45	2.99	4.35	2.04
Critical state friction angle	ϕ'c degrees	25	23	32	40	39
Very small strain shear modulus at σ' 100 kPa on the NCL	G′o MP_a	40	15	60	60	60

(Data from research at City University, London.)

$$I_P = W_l - W_p \quad [4]$$

For a natural clay soil, which may contain silt and sand sized grains, the Activity is

$$A = \frac{I_P}{\%clay} \quad [5]$$

and this is related to the mineralogy of the clay, as shown in Table 1. Many numerical values for soil parameters are related to the clay mineralogy and to the Atterberg Limits.

State: Liquidity Index and Relative Density

Grains in a soil may be densely packed or loosely packed or in an intermediate state of packing. The packing influences strength and stiffness, as shown in Figure 4. In a clay soil, the loosest packing corresponds to the Liquid Limit and the densest to the Plastic Limit. Intermediate states are described by the Liquidity Index:

$$I_l = \frac{w - W_p}{I_P} \quad [6]$$

where w is the water content. At the Liquid Limit, the Liquidity Index is 1.0 and at the Plastic Limit it is 0, as shown in Figure 4.

In a coarse-grained soil the loosest packing corresponds to the maximum water content, w_{max}, and the densest to the minimum water content, w_{min}. Intermediate states are described by the relative density:

$$I_d = \frac{w_{max} - w}{w_{max} - w_{min}} \quad [7]$$

At the loosest state the Relative Density is 0 and at the densest state it is 1.0, as shown in Figure 4.

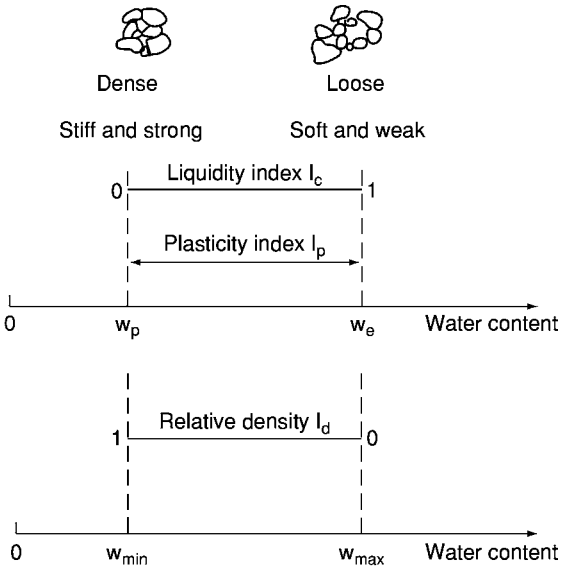

Figure 4 Packing: plasticity index and relative density.

Because soil strength and stiffness are essentially frictional they depend on the current effective stress. Packing, described by Liquidity Index or Relative Density, is not sufficient itself to describe soil behaviour. Soil state will be defined by a combination of packing and stress, as discussed later.

Behaviour in Compression: Change of Size

Isotropic Compression and Swelling

As saturated soil is loaded and unloaded under drained conditions water flows from and into the soil as it compresses and swells, rather like a sponge. The change in volume with changing effective stress is

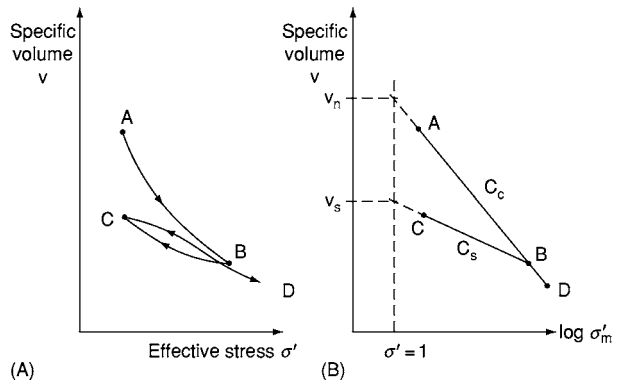

Figure 5 Isotropic compression and swelling.

illustrated in Figure 5(A). The soil is first loaded from A to B and it compresses. The compression of the soil skeleton is due mostly to particles rearranging and also to weak coarse grains fracturing or clay grains bending. The soil is unloaded from B to C and reloaded back to B. Some strains are recovered and there is a hysteresis loop. Volume changes in coarse-grained soils will be small because grains do not 'un-rearrange' or 'unfracture' but may be significant in clay soils as the grains can unbend.

In Figure 5B, effective stresses are plotted to a logarithmic scale and the compression and swelling curves have been idealised. The volume axis is the Specific Volume defined as

$$v = \frac{V}{V_s} \qquad [8]$$

where V_s is the volume of soil grains in a volume V of soil. For many soils v will range from about 1.2 if the soil is dense to over 2 if it is loose. The linear normal compression line ABD is given by

$$v = v_n - C_c \log \sigma' \qquad [9]$$

and the linear swelling and recompression line CB is given by

$$v = v_s - C_s \log \sigma' \qquad [10]$$

The Compression Index, C_c, the Swelling Index, C_s, and the Specific Volume, v_n, at unit stress are material parameters and are related to the characteristics of the grains. Typical values are given in Table 1. The location of a swelling line is given either by the maximum stress, σ'_m, or the specific volume, v_s, at unit stress.

A soil whose state lies on the line ABD is said to be normally compressed and ABC is the normal compression line (NCL). Soil whose state is on the NCL has not experienced a larger stress. A soil whose state is on a swelling line, such as CB, is said to be overconsolidated; it has experienced a greater stress, σ'_m. The overconsolidation ratio is

$$R_0 = \frac{\sigma'_m}{\sigma'} \qquad [11]$$

Equations [9] and [10] relate volume to stress for isotropic loading and unloading. Since the stress scale is logarithmic, the stress-strain behaviour is non-linear; the bulk modulus is not a constant but varies with both stress and overconsolidation.

The idealization of the hysteresis loop in Figure 5A to the line CB in Figure 5(B), common in simple soil mechanics theories, is unrealistic for many soils. Soil stiffness will be discussed later.

One-dimensional Compression in the Ground

Below level ground, the state of stress is not isotropic but one-dimensional, with zero horizontal strain during deposition and erosion; the vertical and horizontal effective stresses σ'_v and σ'_h are related by the coefficient of Earth pressure, K_o, given by

$$K_o = \frac{\sigma'_h}{\sigma'_v} \qquad [12]$$

For normally consolidated soil ($R_o = 1$) K_{onc} is given by

$$K_{onc} = (1 - \sin \phi'_c) \qquad [13]$$

where ϕ'_{cs} is the critical state friction angle. K_o increases with overconsolidation ratio. Horizontal effective stresses given by eqn [12] are for level ground with zero horizontal strain. Near slopes, foundations, and other underground construction stresses will be modified by the stresses imposed by the slope and the structure.

Calculations of settlement in the ground are often carried out in terms of a coefficient of compressibility, m_v, or a one-dimensional modulus, M, given by

$$M = \frac{1}{m_v} = \frac{\Delta\sigma'_v}{\Delta v/v} \qquad [14]$$

where Δv is the change of specific volume observed in a laboratory test on a soil sample with initial specific volume, v, when subjected to an increment of vertical stress, $\Delta\sigma'_v$. Since soil stiffness is non-linear, M is not a soil constant and the increment of stress applied in the test should correspond to the expected change of stress in the ground.

State: Stress and Packing

The behaviour of a particular soil depends on both the current effective stress and on the Relative

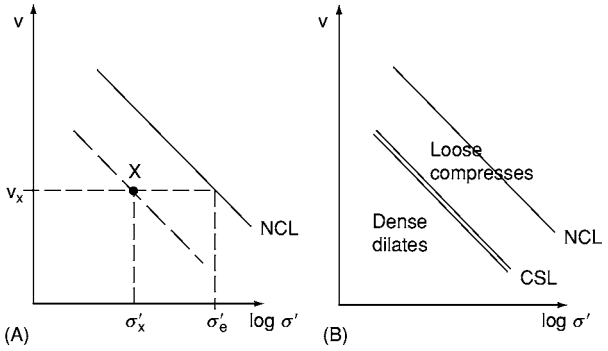

Figure 6 States and state parameters.

Density or Liquidity Index. These may be combined into a state parameter.

Figure 6A, which is similar to Figure 5B, shows the state of an overconsolidated sample at X and the normal compression line. All samples with states on the broken line through X parallel to the NCL will behave in a similar way. These states can be described by a stress state parameter S_σ given by

$$S_\sigma = \frac{\sigma'_x}{\sigma'_e} \qquad [15]$$

where σ'_e is the equivalent stress on the NCL at the same specific volume as that at X. The state parameter describes the distance of the state from the NCL. If the swelling index C_s is small, S_σ is approximately equal to the overconsolidation ratio, R_0. The concept of state is of fundamental importance for soils which are both frictional and which change volume during loading, as it combines both relative density and stress into a single parameter.

Dense and Loose States

After shearing, soils reach ultimate or critical states in which they continue to distort at constant state (i.e., at constant stress and volume). The relationship between specific volume and effective stress gives a critical state line (CSL) parallel to the normal compression line, as shown in Figure 6(B). The critical state line is given by

$$v = v_c - C_c \log \sigma' \qquad [16]$$

Soil states which are above the CSL are known as 'loose of critical' and the soil will compress on shearing. Soil states which are below the CSL are known as 'dense of critical' and the soil will dilate on shearing.

The CSL separates regions of fundamentally different behaviour of the same soil. A soil which has a relatively low specific volume and the grains are relatively closely packed will compress if the effective stress is very large. Similarly, a soil which has a relatively high specific volume and the grains are relatively loosely packed will dilate if the effective stresses are very small.

Sediments at great depth deform plastically. Near-surface soils often behave in a brittle manner and crack. Relative Density, or Liquidity Index, on its own is not sufficient to predict the behaviour on subsequent shearing; the effective stress must be taken into account as well.

Strength of Soil

Behaviour of Soil During Shearing

Figure 7A shows a block of soil with a constant normal effective stress σ' subjected to an increasing shear stress τ'.

The soil is drained and it distorts with a shear strain γ and a volumetric strain ε_v. If the soil is undrained, there are no volume changes but the pore pressures change. The block of soil represents conditions inside a slip zone in the slope illustrated in Figure 7B or in a foundation illustrated in Figure 7C. If the slope is created by excavation or erosion the normal stress decreases and, since soil strength is frictional, it will weaken, whereas below the loaded foundation the normal stress increases and the soil becomes stronger.

The behaviour of soil initially loose and initially dense of critical is illustrated in Figure 8. The loose soil (marked L) compresses during shearing even

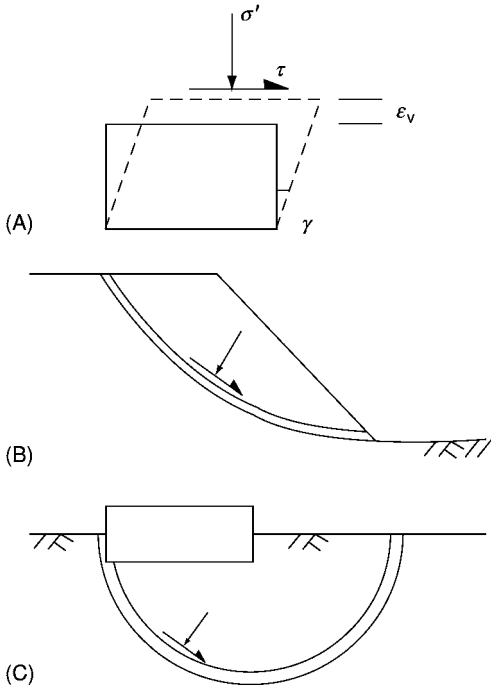

Figure 7 Shearing of soil.

though the normal stress remains constant and the dense soil (marked D) dilates. The rate of dilation is given by an angle of dilation ψ, given by

$$\tan\psi = -\frac{d\varepsilon_v}{d\gamma} \qquad [17]$$

(The negative sign is required as ψ is positive for negative (dilation) volumetric strains.)

Critical State Strength

The samples shown in Figure 8 have the same effective stress and they reach the same critical shear stress and the same critical specific volume after relatively large strains. Figure 9 shows critical states for a number of samples. There are unique relationships between the critical shear stress τ'_f, the critical normal stress σ'_f, and critical specific volume v_f, given by

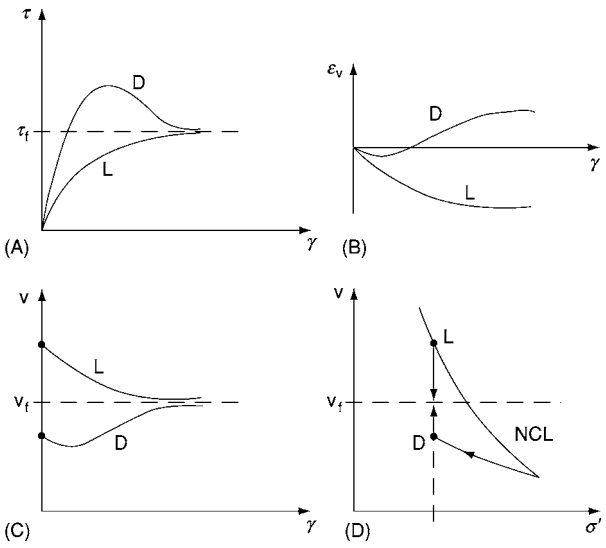

Figure 8 Stress and volume change in shearing soil.

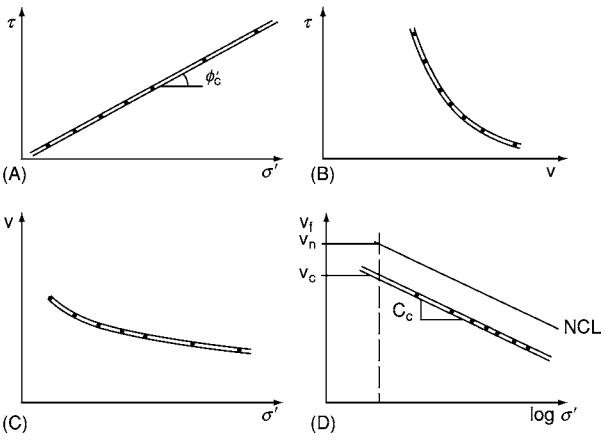

Figure 9 Critical states.

$$\tau_f = \sigma'_f \tan\phi'_c \qquad [18]$$

$$\tau_f = v_c - C_c \log\sigma'_f \qquad [19]$$

These equations define a critical state line and the parameters ϕ'_c, C_c, and v_c are material parameters. (Critical state lines are usually shown as double lines, as in Figure 9). Typical values are given in Table 1. During shearing distortions, all soils will ultimately reach a critical state; if they did not they would continue to change state indefinitely, which is impossible. In simple soil mechanics theories, the critical states reached by a particular soil, given by eqns [18] and [19], are independent of the starting state and whether the soil is drained or undrained.

Undrained Strength

Figure 9B shows that the shear stress at failure, which is the shear strength, decreases as the specific volume at failure increases. If soil is undrained the water content and the undrained strength remain unchanged for any changes in total normal stress. The undrained strength.

$$\tau_f = s_u \qquad [20]$$

depends on the water content. In practice, samples are taken from the ground and tested without change of water content. The undrained strengths measured can be used for design so long as the water content in the ground does not change.

It is common knowledge that soils become weaker as their water content increases. This is shown in Figure 10 in which the undrained strength, with a logarithmic scale, decreases linearly with water content. The strength of soil at its Liquid Limit is approximately 1.5 kPa and the undrained strength

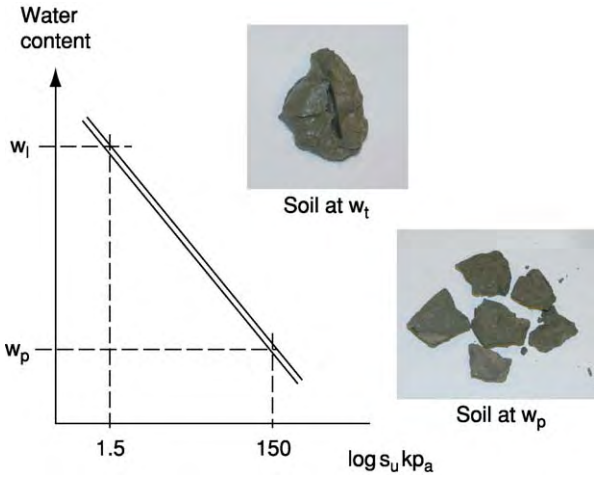

Figure 10 Undrained strength and water content.

of soil at its Plastic Limit is approximately 150 kPa (i.e., the strength of soil changes by about 100 times as the water content changes from the Liquid Limit to the Plastic Limit).

Peak Strength

Soils whose initial states are dense of critical have a peak strength before they reach a critical state, and they dilate during drained shear, as shown earlier in Figure 8. The peak strengths vary with effective normal stress and specific volume, as shown in Figure 11.

Samples which reach their peak states at the same specific volume have peak strengths on an envelope shown in Figure 11A. The envelope is often approximated by a straight line, shown in Figure 11A given by

$$\tau_p = c'_p + \sigma'_p \tan \phi'_p \qquad [21]$$

The peak friction angle, ϕ'_p, is a material parameter and, from Figure 11A $\phi'_p < \phi'_c$. The cohesion intercept, c'_p, is not a material parameter and its value depends on the specific volume. Moreover c'_p is not the strength at zero effective normal stress, as this must be zero for an uncemented granular material.

The linear approximation for peak strength given by eqn [21] is applicable only within the range for which data are available. Figure 11B shows additional data at smaller normal effective stresses; there the envelope is now distinctly curved and passes through the origin. The curved peak failure envelope, shown in Figure 11C, can be represented by a power law of the form.

$$\tau_p = A\sigma'^b \qquad [22]$$

where b is a material parameter and A depends on the specific volume.

From analyses of the stresses and strains in the soil block, shown in Figure 7A, peak shear strength is given by

$$\tau_p = \sigma' \tan (\phi'_c + \psi) \qquad [23]$$

At the critical state, $\psi = 0$ and τ'_c is given by eqn [18]. At the peak state, the angle of dilation is at a maximum. The maximum rate of dilation is governed by the state parameter so the peak strength increases as the initial state moves away from the critical state line.

Equations [21, 22 and 23] are alternative theories for the peak strength of soils. They all contain a combination of material parameters and state dependent parameters. Equations [22 and 23] correctly give zero strength at zero effective stress. Equation [21] is most commonly applied in practice.

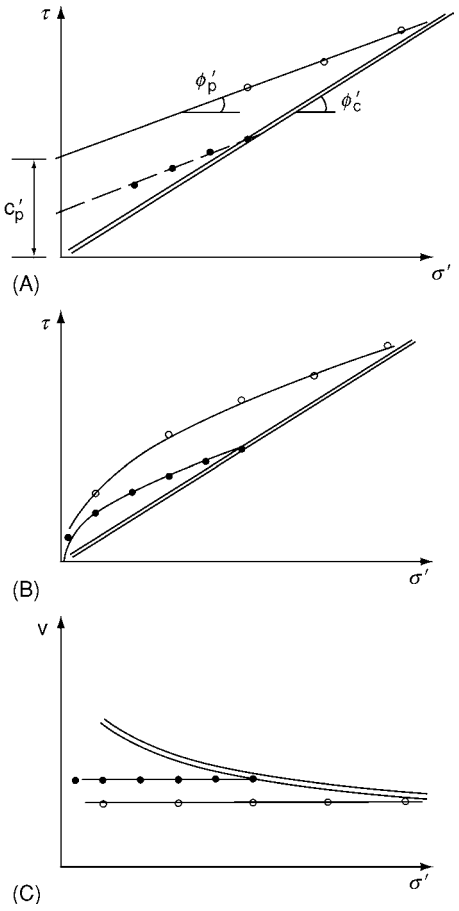

Figure 11 Peak strength.

Stiffness of Soil

Figure 5A shows non-linear isotropic unloading and reloading behaviour. Similar non-linear behaviour occurs during shearing, as shown in Figure 12A. The tangent shear modulus G′ is the gradient of the stress-strain curve given by

$$G' = \frac{d\tau}{d\gamma} \qquad [24]$$

At the start of shearing near the origin the shear modulus is G'_o and at failure the shear modulus is zero.

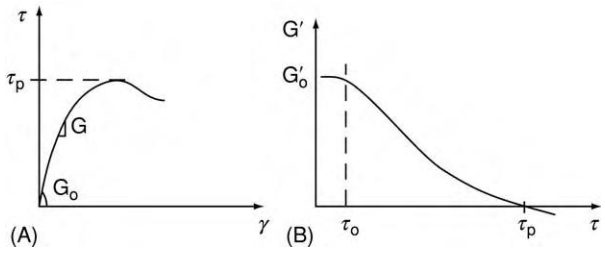

Figure 12 Stiffness and shear modulus.

Figure 12B shows the variation of shear modulus G′ with the progress of loading. There is a very small range up to a shear stress τ_o, in which G'_o is constant and the soil is linear, but over the remainder of loading the shear modulus decays with loading. For a particular soil the value of G'_o and the shear modulus at a particular strain, vary with the effective stress and with the state parameter.

For modest compression the bulk modulus, K′, and the one-dimensional compression modulus, M, both decay with normal stress in a manner similar to the decay of shear modulus with shear stress, shown in Figure 12B. At large compressive stresses the stiffness is the modulus corresponding to states on the NCL. At very large compressive stresses, the stiffness becomes very large as the specific volume approaches 1.0.

Consolidation

As soil is loaded or unloaded undrained, there are no volume changes but there are changes of pore pressure. These create excess pore pressures which are not in equilibrium with the surrounding pore pressures and so they dissipate with time. As they dissipate, under constant total stress, there are changes of effective stress which cause volume changes accompanied by drainage of water.

The basic theories for consolidation are for one-dimensional loading and drainage, illustrated in Figure 13A, in which all movements of soil and water are vertical. In practice this corresponds to conditions below a wide foundation or embankment.

Solutions for the rate of consolidation are given in terms of the degree of consolidation, U_t, and the time factor, T_v, given by

$$U_t = \frac{\rho_t}{\rho_\infty} \qquad [25]$$

$$T_v = \frac{c_v t}{H^2} \qquad [26]$$

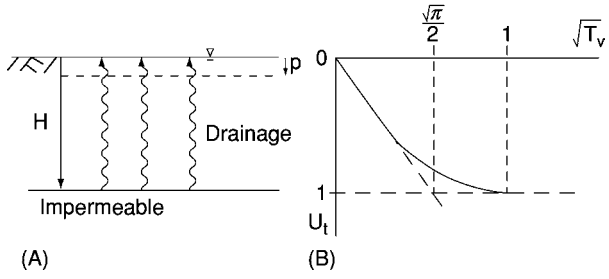

Figure 13 Consolidation.

where ρ_t is the settlement at time t, ρ_∞ is the settlement after a very long time, H is the length of the drainage path, and c_v is the coefficient of consolidation given by

$$c_v = \frac{Mk}{\gamma_w} \qquad [27]$$

where M is the one-dimensional modulus, k is the coefficient of permeability, and γ_w is the unit weight of water. The relationship between degree of consolidation and time factor is shown in Figure 13B.

The rate of consolidation depends on soil characteristics of stiffness and permeability and also on the geometry of the consolidating layer. This is given by the drainage path length H which is the greatest distance water must move to reach a drainage layer. Consolidation times can be significantly reduced by installing drains into the ground to reduce H.

Consolidation is the principal cause of the settlement of foundations and embankments on clays long after construction is complete.

Normalization and a State Boundary Surface

Figure 14A and B shows some different soil states. There are peak states corresponding to two different specific volumes; these are the same as those shown in Figure 11. There are paths for shearing of normally consolidated loose samples: path LD is for drained shearing and path LU is for undrained shearing.

These soil states involve three parameters, shear stress τ, normal stress σ', and specific volume v. Soil states can be represented by a three-dimensional surface using these axes. They may be represented on a two-dimensional graph using an appropriate normalizing procedure. There are several possibilities and one is to divide the shear and normal stresses by the equivalent stress σ'_e, shown in Figure 6A.

Figure 13C shows the states normalized by the equivalent stress. The NCL and the CSL reduce to single points. The peak states fall on a unique curve. The state paths for drained and undrained shearing of normally consolidated samples fall on a unique curve. The full curve represents a boundary to all possible states, known as a state boundary surface.

The concept of a state boundary surface is employed in advanced soil mechanics theories to develop complete constitutive relationships for soils. The surface is taken to be a yield surface and as a plastic potential surface from which plastic strains are determined. For states inside the boundary surface, the behaviour is taken to be elastic. One such theory is known as Cam Clay, for which the state boundary surface is represented by a logarithmic spiral curve.

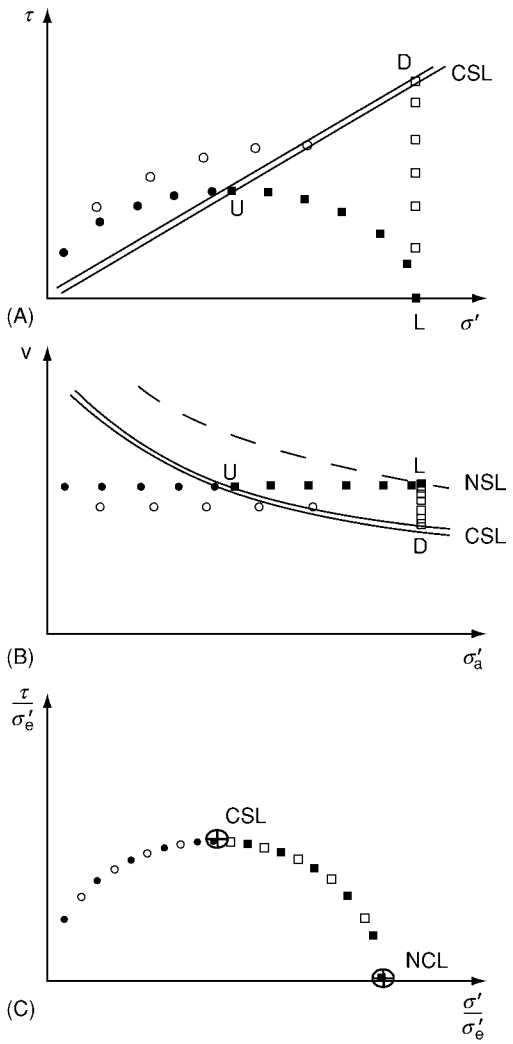

Figure 14 A state boundary surface.

Applications

The simple theories presented above for granular materials form the basis for analysis and design of engineering works which interact with the ground such as foundations, slopes, tunnels and retaining walls.

The basic theories for the mechanical behaviour granular materials are applicable equally to coarse-grained soils (sands and gravels) and fine-grained soils (clays). The principle factor to consider is the relative rate of loading and drainage. For routine analysis a particular case must be taken to be either fully drained or fully undrained.

If the soil is assumed to be fully drained, pore pressures can be determined and effective stresses calculated. Analyses are then carried out using *effective stresses* with effective stress strength and stiffness parameters. If the soil is assumed to be undrained, there are no changes in volume but there are changes in pore pressure which cannot be easily determined. In this case analyses have to be carried out using *total stresses* with undrained strength and stiffness parameters.

The critical state strength should be used to investigate ultimate failures. The peak strengths, with appropriate factors, should be used to investigate designs which are required to limit movements.

Simple analyses of foundation settlement are often carried out assuming one-dimensional conditions using the one-dimensional modulus, M, or using simple elastic theories using a shear modulus, G, and a bulk modulus, K. In all cases, it is necessary to take account of non-linear stress-strain behaviour and the appropriate drainage conditions. Simple analyses of rate of settlement due to consolidation can only be carried out assuming one-dimensional conditions.

The advanced soil mechanics theories, such as Cam Clay, are not used in simple analysis and design except for extremely simplified cases. Instead they form the basis for analyses using finite element or other comparable numerical methods.

Introduction

There are many soil-forming processes, which in varying combinations create the large array of soils forming at the surface of the Earth. The study of soils is aided by the observation that soil-forming processes are slow and seldom go to completion. The parent materials of soils are modified over thousands of years by physical, chemical, and biological influences. However, few of these processes can be observed directly. Podzolization is one of the few soil-forming processes that is rapid enough to be recreated in the laboratory. Soil-forming processes that operate over thousands of years are studied using a space-for-time strategy (that is, studying soils of differing ages that are subject to the same soil-forming regime). A set of soils of different ages with comparable climates, vegetation, topographical positions, and parent materials is called a chronosequence (Figure 1). Mathematical relationships between the development of particular soil features and time are called chronofunctions, and include the increased clayeyness produced by the soil-forming process of lessivage (Figure 2). While specifying the rate and progress of soil formation, chronofunctions can also be used to infer the ages of landscapes from undated soils by comparison with dated soils. Such estimates of soil age can be important in the study of the neotectonic deformation of landscapes and their suitability for long-term installations such as dams and nuclear power plants. Soil fertility also varies with soil age, and chronofunctions can guide agricultural use and rehabilitation of soils.

Soil-forming processes vary not only with time but also with parent materials, topographical relief, vegetation, and climate. For example, the fragments of volcanic glass in certain kinds of air-fall tuff are distinct from the minerals of most soils, and they bestow high fertility and low bulk density on some volcanic soils (the process of andisolization). Waterlogging in low-lying parts of the landscape prevents the rusting of iron minerals and imparts a grey-green colour to the soil (the process of gleization). Leachates from highly acidic vegetation, such as pine forest, create soils in which clays are destroyed but quartz and haematite accumulate (the process of podzolization). Finally, climate is also an important factor in

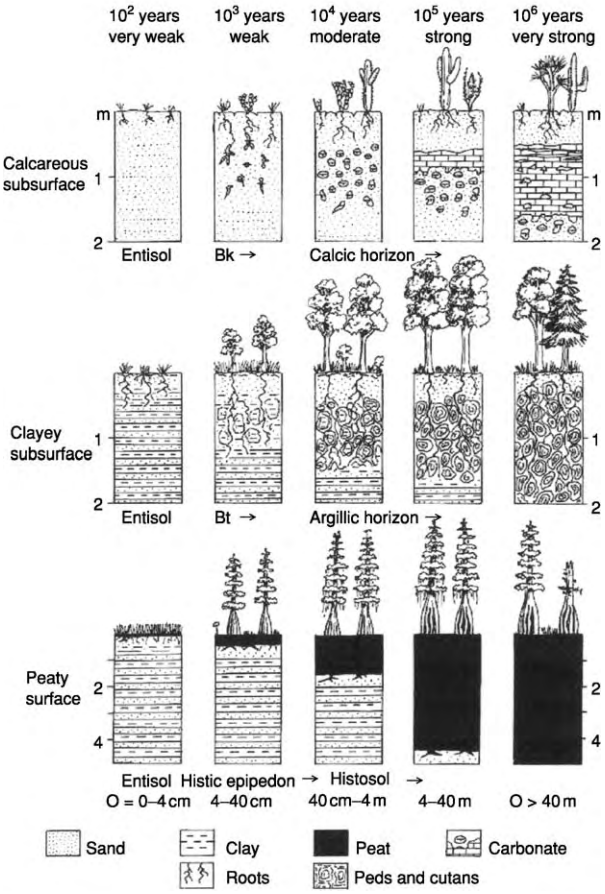

Figure 1 Soil development stages involving progressive calci fication (top), lessivage (middle), and paludization (bottom). Re produced with permission from Retallack GJ (2001) *Soils of the Past*. Oxford: Blackwell.

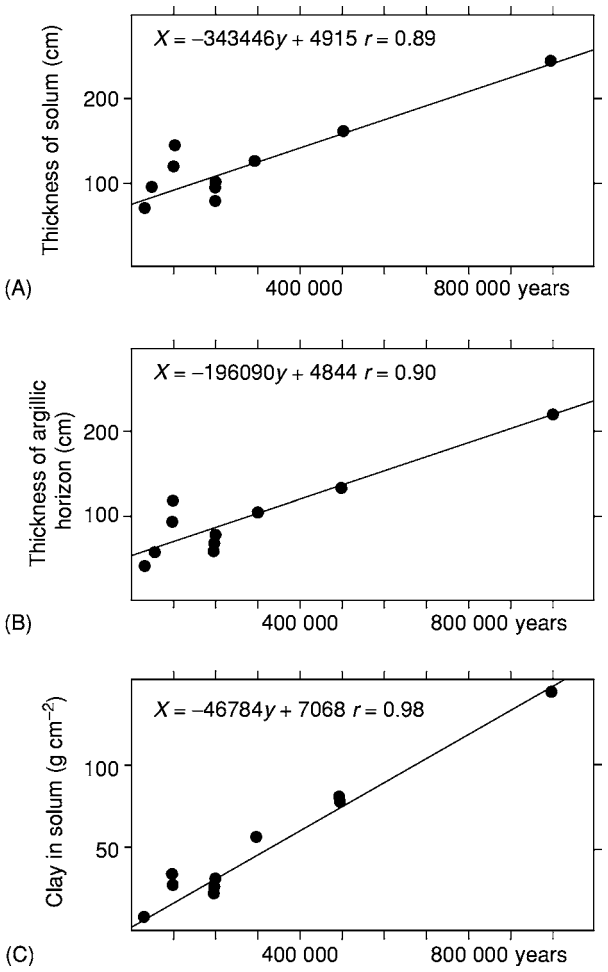

Figure 2 Chronofunctions for the progress of lessivage in soils of the Coastal Plain and Piedmont of south eastern USA over time: (A) solum thickness; (B) thickness of the argillic horizon; and (C) the amount of clay in the solum. The solum is the A and B horizons; the argillic horizon is the Bt horizon; and the total profile is the A, B, and C horizons as defined in **Table 2**. Reproduced with permis sion from Retallack GJ (2001) *Soils of the Past*. soil-forming processes, encouraging deeper and more thorough weathering in wetter and warmer climates (Figure 3).

The study of soil-forming processes has informed both soil taxonomy (Table 1) and soil-profile terminology (Table 2). The following outlines of soil-forming processes are presented in the order in which they would be encountered from warm wetlands to cold arid lands.

Gleization

Gleying or gleization is a process that produces and maintains unoxidized minerals in soils and is a term derived from a Russian term for the grey clay of swamps and bogs. Waterlogged peat-covered stagnant groundwaters allow the preservation of ferrous iron in clay minerals, such as grey smectite, carbonates, such as the siderite of freshwater bogs, and sulphides, such as the pyrite of mangrove swamps and salt marshes. In normally drained soils these minerals rust to produce red and brown clays, hydroxides such as goethite, and oxides such as haematite (Table 3). Goethite and haematite also form within gleyed soils when a short-term depression of the water table allows the atmospheric penetration of oxygen. Despite these red nodules and concretions, the dominant colour of gleyed soils is bluish or greenish grey (Figure 4).

Paludization

Paludization is literally ponding, but a pond would not be commonly understood as a soil. Paludization is soil flooding that is tolerated by swamp trees but not by most soil decomposers. Paludization is thus an accumulation of undecayed plant debris as peat in the waterlogged surface layer (O horizon of Table 2) of Histosols (Table 1). This process requires a balance between plant production and decomposition. If ponding is intermittent and the soil is moderately oxidized, usually because of a low subsidence rate, then fungal and other decay prevents the accumulation of plant debris. If, on the other hand, ponding is too deep or prolonged, because of high subsidence rates, then soil stagnation kills the roots of woody plants, thus cutting off the supply of vegetation for further peat accumulation. As swamp forests die from anoxia at the roots, peaty soils become overwhelmed by lakes, bayous, or lagoons. The rate of subsidence and accumulation of woody peats is generally between 0.5 mm and 1 mm per year, because of constraints on the growth rate of woody plants in low-fertility peaty substrates and the depth of penetration of air and decomposers within woody peats. Herbaceous plants and mosses are less constrained in their growth rates and form domed peats that rise well above the water table. Peat accumulation in both cases involves addition from the top, in the same way as sediment accumulation, and thus differs from soil-forming processes that modify pre-existing materials. The progress of paludization leads to progressively thicker peat (Figure 1).

Podzolization

Podzol in its original Russian means ‘under ash’ and refers to the light-coloured quartz-rich (E) horizon immediately beneath the humus. Many podzolic

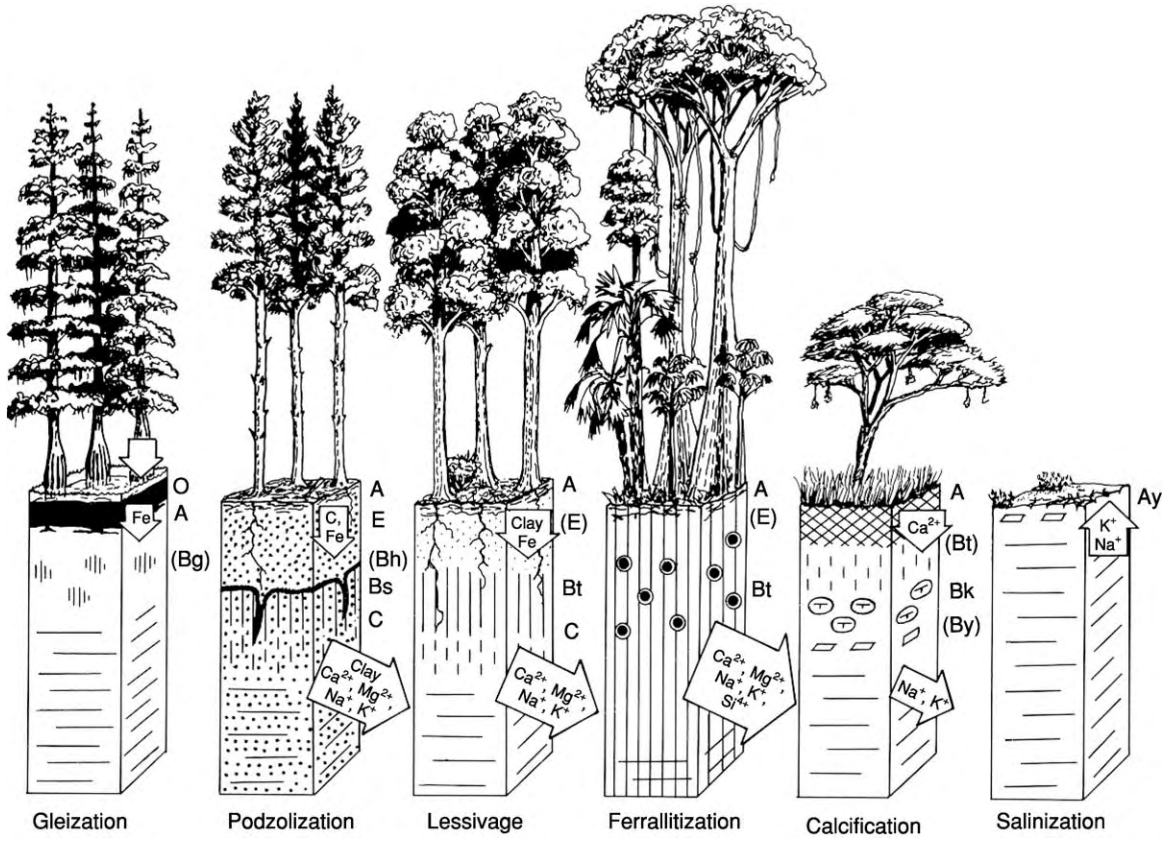

Figure 3 Selected common soil forming processes arranged along a climatic gradient. The ecosystems depicted are (from left to right): bald cypress swamp, spruce forest, oak forest, tropical rain forest, *Acacia* savannah, and saltbush scrub. Horizon nomenclature is described in **Table 1**, and the large arrows indicate the movement of key soil components. Reproduced with permission from Retallack GJ (2001) *Soils of the Past*. Table 1 Outline of soil taxonomy

Order	*Description*
Entisol	Very weakly developed soil with surface rooting and litter (A horizon) over weathered (C horizon) sediment with relict bedding or weathered igneous or metamorphic rock with relict crystals
Inceptisol	Weakly developed soil with surface rooting and litter (A horizon) over somewhat weathered (Bw horizon) clayey (Bt horizon) or calcareous (Bk horizon) subsurface
Andisol	Soil composed of volcanic ash with low bulk density and high fertility
Histosol	Peat (O horizon) over rooted grey clay (A horizon)
Spodosol	Quartz rich clay poor soil with bleached subsurface (E horizon) above a red black iron aluminia organic cemented zone (Bs horizon)
Vertisol	Very clayey profile with common swelling clay (smectite), laterally variable thickness of surface (A horizon), and strongly slickensided subsurface (Bt horizon)
Mollisol	Grassland soil with thick crumb textured carbon rich surface (A horizon)
Gelisol	Permafrost soil with frost heave and other periglacial features
Aridisol	Desert soil with a shallow subsurface accumulation of pedogenic carbonate (Bk horizon) and soluble salts (By horizon)
Alfisol	Fertile forest soil with clay enriched subsurface (Bt horizon) and high amounts of Mg, Ca, Na, and K
Ultisol	Infertile forest soil with clay enriched subsurface (Bt horizon) and low amounts of Mg, Ca, Na, and K
Oxisol	Deeply weathered tropical soil, often highly ferruginous and aluminous, but with very low amounts of Mg, Ca, Na, and K

For technical limits of soil orders see Soil Survey Staff (2000) *Keys to Soil Taxonomy*. Blacksburg: Pocahontas Press.

soils are now included in the USDA (United States Department of Agriculture) soil order Spodosol (Table 1), which refers to the red, brown, or black (Bs) horizon below the light coloured near-surface layer. This striking differentiation between white near-surface and dark subsurface horizons is created by podzolization, which effectively leaches iron and organic matter from the upper horizons and

reprecipitates them in a lower horizon. The resulting effect is as striking as the chromatographic separation of organic compounds, and podzolization is one of the few soil-forming processes that is rapid enough to have been recreated under controlled laboratory conditions. The process is particularly helped by highly acidic soil solutions (with a pH of less than 4) in well-drained soils of humid climates under acid-generating litter such as that of conifer forest (Figure 3). Under highly acidic conditions clay minerals are destroyed, so Podzols and Spodosols usually have a sandy texture.

Ferrallitization

The term ferrallitization is derived from iron (Fe) and aluminium (Al), which become enriched in minerals such as haematite, kaolinite, and gibbsite during intense weathering of well-drained tropical soils such as Oxisols (Figure 3). Much of the loss of major cations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}) by hydrolysis requires carbonic acid derived from the carbon dioxide of soil respiration, yet the soil pH remains above 4, so that clays are not destroyed. Mitigation of acidity and deep oxidation of these soils may in part be due to the activity of termites and tropical trees, as ferrallitization is primarily found in soils under tropical rainforest. The broad-leaved trees of tropical rainforests produce less acidic litter than conifers and other plants, and litter decomposition rates are high on humid and warm forest floors. Furthermore, ferrallitic soils commonly contain abundant microscopic (125–750 μm) spherical to ovoid pellets of oxidized clay, like the faecal and oral pellets of termites. Some ferrallitic soils appear to have passed through the guts of termites many times. Termites are unique in having extremely alkaline midguts (with a pH of 11–12.5).

Table 2 Standard acronyms for soil horizon description

Acronym	*Description*
O	Surface accumulation of peaty organic matter
A	Surface horizon of mixed organic and mineral material
E	Subsurface horizon rich in weather resistant minerals, e.g. quartz
Bt	Subsurface horizon enriched in washed in clay
Bs	Subsurface horizon enriched in organic matter, or iron or aluminium oxides
Bk	Subsurface horizon enriched in pedogenic carbonate
Bn	Subsurface horizon with domed columnar structure and sodium clays
By	Subsurface horizon enriched in salts such as gypsum and halite
Bo	Subsurface horizon deeply depleted of Ca, Mg, Na, and K
Bw	Subsurface horizon mildly oxidized and little weathered
C	Mildly weathered transitional horizon between soil and substrate
R	Unweathered bedrock

For technical limits of soil orders see Soil Survey Staff (2000) *Keys to Soil Taxonomy*. Blacksburg: Pocahontas Press.

Biocycling

Biocycling includes a variety of processes in which nutrient elements are exchanged by soil biota without reincorporation into soil minerals. In tropical soils such as Oxisols (Table 1) this is a very efficient process in which the decay of leaves and wood is orchestrated by waves of bacteria, fungi, ants, and termites, which excrete and die to feed a copious network of epiphytes and tree roots. Effective biocycling explains the spectacular luxuriance of tropical-rainforest ecosystems despite their extremely nutrient-depleted and humus-poor mineral soils (Oxisols). Comparable mechanisms operate in swamp forests growing in peat (Histosols), which also experience severe mineral-nutrient limitations. These mineral nutrients include the major cations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}), but these are seldom as limiting as nitrogen, which is derived largely from the microbial recombination of atmospheric nitrogen, or phosphorous, which is derived largely from the weathering of apatite. Biocycling of

Table 3 Common kinds of chemical reactions during weathering

Reaction	*Example*
Hydrolysis	$2NaAlSi_3O_8 + 2CO_2 + 11H_2O \rightarrow Al_2Si_2O_5(OH_4) + 2Na^{+} + 2HCO_3^{-} + 4H_4SiO_4$ albite + carbon dioxide + water → kaolinite + sodium ions + bicarbonate ions + silicic acid
Oxidation	$2Fe^{3+} + 4HCO_3^{-} + 1/2O_2 + 4H_2O \rightarrow Fe_2O_3 + 4CO_2 + 6H_2O$ ferrous ions + bicarbonate ions + oxygen + water → haematite + carbon dioxide + water
Dehydration	$2FeOOH \rightarrow Fe_2O_3 + H_2O$ goethite → haematite + water
Dissolution	$CaCO_3 + CO_2 + H_2O \rightarrow Ca^{2+} + 2HCO_3^{-}$ calcite + carbon dioxide + water → calcium ions + bicarbonate ions

Figure 4 Red and brown mottles of goethite in the upper part of the profile and dark stains of pyrite formed by gleization in the lower part of the profile of a gleyed Inceptisol, excavated as a soil column from a salt marsh on Sapelo Island, Georgia, USA. Hammer handle is 25 cm long.

Figure 5 Light brown near surface (E) and dark brown subsur face (Bt) horizons of an Alfisol produced by lessivage near Killini, Greece. Hammer handle upper right is 25 cm long.

nitrogen is especially important during the early development of soils such as Entisols and Inceptisols, which are developed over decades or centuries. Biocycling of phosphorous becomes increasingly important in very old soils such as oxisols and ultisols, which are depleted in apatite over thousands or millions of years.

Lessivage

Lessivage or argilluviation is the process of clay accumulation within a subsurface (Bt or argillic) soil horizon (**Figures 1, 2** and **3**). This is a common and widespread soil-forming process in the forested soils of humid climates, particularly Alfisols and Ultisols (**Figure 5**). The clay is primarily derived from a hydrolytic weathering reaction in which clays remain as a residuum and dissolved cations are removed in groundwater during the incongruent dissolution of feldspars and other minerals by carbonic acid (**Table 3**). Driving the reaction are abundant rainfall and high soil respiration rates fuelled by high primary productivity. Clay forms rinds around mineral grains of the sedimentary, igneous, or metamorphic parent material, but is also washed down cracks in the soil created by desiccation, roots, and burrows. This washed in or illuvial clay has a very distinctive banded appearance, which is obvious in petrographic thin sections. The clay is not washed any lower than the water table, where percolating rainwater ponds. Clay is less common near the surface of the soil, where unweathered grains are added by wind and water, and grains are leached of clay by plant acids. The net effect is a subsurface clayey horizon that becomes more clayey over time (**Figures 1, 2** and **3**).

Lixiviation

Lixiviation is a process of leaching of major cations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}) from soil minerals and their loss from the soil in groundwater. Lixiviation is a component of ferrallitization, podzolization, and lessivage, and represents the progress of the hydrolysis chemical reaction, in which hydronium ions (H^{+}) of a weak acid (usually carbonic acid) displace cations into solution and thus convert primary minerals such a feldspars into soil minerals such as clays (**Table 3**). The term lixiviation is primarily used to describe the beginnings of this process in soils such as Entisols and Inceptisols that have developed over

only decades or centuries. Such young soils have not yet acquired the distinctive deeply weathered and oxidized horizons produced by ferrallitization in Oxisols, the distinctive leached (E) and enriched (Bs) horizons produced by podzolization in Spodosols, or the distinctive clay-enriched subsurface (Bt) horizons produced by lessivage in Alfisols and Ultisols.

Melanization

Melanization is a process of soil darkening due to the addition of soil organic matter. The process is best known in Mollisols, the fertile dark crumb-textured soils of grasslands (Figure 6). In these soils melanization is largely a product of the activities of grasses and earthworms. Earthworms produce faecal pellets rich in organic matter and nutrients such as carbonate. Earthworms also produce slime, which facilitates their passage through the soil. Root exudates from grasses are also added to soil crumbs. Many soils have dark humic near-surface horizons, but a peculiarity of grassland soils is that dark organic fertile crumb-textured soil extends to the base of the rooting zone, which can be more than a metre deep in soils under tall-grass prairie. Melanization also occurs in swamp and marsh soils (gleyed Inceptisols and Entisols), where the decay of humus is suppressed by poor oxidation and waterlogging. Unlike the alkaline crumb-textured melanized surface of grassland soils, the melanized surface of wetland soils is nutrient-poor, acidic, and has a massive to laminated fabric. Melanization is not usually applied to the precipitation of amorphous Fe–Mn oxides (birnessite) in gleyed soils, which can also produce dark soil. The creation of these Fe–Mn-stained (placic) horizons is a process of gleization rather than melanization.

Figure 6 Dark organic rich surface (mollic epipedon) of a Mollisol formed by melanization near Joliet, IL, USA. The shovel handle is 15 cm wide at the top.

Andisolization

Andisolization is the formation of fertile mineralogically amorphous low-density horizons within soils of volcanic ash (Andisols). Many volcanic ashes are composed largely of small angular fragments (shards) of volcanic glass. Unlike soil minerals such as feldspar, volcanic glass weathers, not to crystalline minerals such as clay, but to non-crystalline compounds such as imogolite. The loosely packed angular shards and colloidal weathering products create a soil of unusually low bulk density (1.0–1.5 g cm ^{3}, compared with 2.5–3.0 g cm ^{3} for most common minerals and rocks). Furthermore, these colloidal compounds contain plant-nutrient cations, and particularly phosphorous, in a form that is more readily available to plants than those of other kinds of soils dominated by crystalline minerals such as apatite. Andisolization is not sustainable for more than a few thousand years unless there are renewed inputs of volcanic glass, because glass and other colloids (such as imogolite) weather eventually to oxides and clay minerals.

Vertization

Vertization is the physical soil overturning and mixing by means of the shrink–swell behaviour of clays. It occurs mostly in Vertisols but also in Entisols, Inceptisols, Mollisols, and Alfisols. It is especially characteristic of soils rich in swelling clays (smectites), which swell when wet and shrink when dry. Also characteristic is a climate with a pronounced seasonal contrast in precipitation. During the wet season the clays swell and buckle under the pressure of their inflation. During the dry season they open up in a system of cracks, which are then partly filled by wall collapse. This fill exacerbates the buckling in the next wet season so that the soil develops ridges or mounds with intervening furrows or pits, called gilgai microtopography. In a soil pit, the cracks of mounded areas divide areas of festooned slickensides under the furrows and pits in a distinctive arrangement called mukkara structure (Figure 7). Vertization is mainly a phenomenon of semiarid to subhumid regions. Soils of arid regions are generally not sufficiently clayey, whereas soils of humid regions are generally too deeply weathered to contain abundant smectite and are also stabilized by massive plant and animal communities.

Figure 7 Gilgai microrelief (low to left, high to right) and its subsurface mukkara structure (festooned intersecting slicken sided cracks) produced by vertization in the Branyon clay soil, a Vertisol, near New Braunfels, TX, USA. Scale to left shows 50 cm and 100 cm; red and white bands on pole to right are 10 cm wide.

Anthrosolization

Anthrosolization is the alteration of soil by human use, such as buildings, roads, cesspits, garbage dumps, terracing, and ploughing. Archaeological ruins and artefacts are important clues to prior occupation of a site, but many sites also contain impressive amounts of mollusc shells and mammal and fish bones. A distinctive soil structure of subsoil pockets of laminated clay between large soil clods is produced by moldboard ploughs. The primitive or ard plough also tends to disrupt the natural crumb structure to a fixed depth (plough line). Phosphorous content is an indicator of human use. Many soils have trace amounts of phosphorus (10–20 ppm by weight), but occupation floors and long-used garden soils and middens have large amounts of phosphorous (1000–2000 ppm). Anthrosolization is locally common worldwide in cities and fields, both ancient and new, but is scattered and local in deserts, polar regions, and high mountains.

Calcification

Calcification is the accumulation of calcium and magnesium carbonates in the subsurface (Bk) horizons of soils (Figures 1 and 3). The carbonate is usually obvious, appearing as soft white filaments, hard white nodules, and thick white benches within the soil. Calcification is largely a soil-forming process of dry climatic regions, where evaporation exceeds precipitation. It is characteristic of Aridisols but is also found in some Mollisols, Andisols, Vertisols, Inceptisols, and Alfisols. The source of the carbonate is the soil respiration of roots, soil animals, and microorganisms. Calcification requires soil respiration at levels greater than those in hyperarid soils, where halite and gypsum formed by salinization prevail, and less than those in humid soils, where lessivage prevails. The source of the cations of calcium and magnesium, which create the soil minerals calcite and dolomite, respectively, is the weathering of soil minerals by hydrolysis (Table 3). Some of these cations originate from feldspars and other minerals of the parent material, but dry regions of calcification have open vegetation and are often dusty, so that carbonate and feldspar dust is an important source of cations. Dissolved cations from hydrolytic weathering are commonly lost downstream in the groundwater in humid regions, but in arid lands the water table is commonly much deeper than the soil profiles, which are seldom wet much beyond the depth of rooting. The subsurface zone of groundwater evaporation and absorption is where the wisps of soil carbonate form, then coalesce into nodules and, eventually, thick layers.

Solonization

Solonization is a process by which clays rich in soda are formed within the soils of dry climates (Aridisols), where the hydrolytic mobilization of major cations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}) is weak. Hydrolysis removes cations from soils by lixiation in humid climates, but in dry climates the acidity created by soil respiration after rain storms is sufficient to remove cations from minerals such as feldspar without leaching them from the profile. Solonized soils commonly contain carbonate nodules of dolomite or low-magnesium calcite, formed by calcification, as well as salts of halite and gypsum, formed by salinization. Solonized soils have illitic clays rich in potassium and smectite clays rich in sodium, and the progress of solonization can be assessed by measuring the pH (which is usually around 9–10), by chemical analysis, or by X-ray diffraction to determine the mineral composition. A field indicator of solonization is the presence of domed columnar peds that run through most of the subsurface (natric or Bn) horizon of the soil (Figure 8). The sodium-smectite clays of solonized soils have some shrink–swell capacity, meaning that they form prismatic cracks as the soil dries out and swelling or domed tops to the prisms when the soil is wet. Solonization is common around desert playa lakes and salinas and in coastal soils affected by saltwater spray.

Solodization

Solodization is intermediate between solonization and lessivage, and creates profiles with acidic-to-neutral near-surface horizons but alkaline subsurface

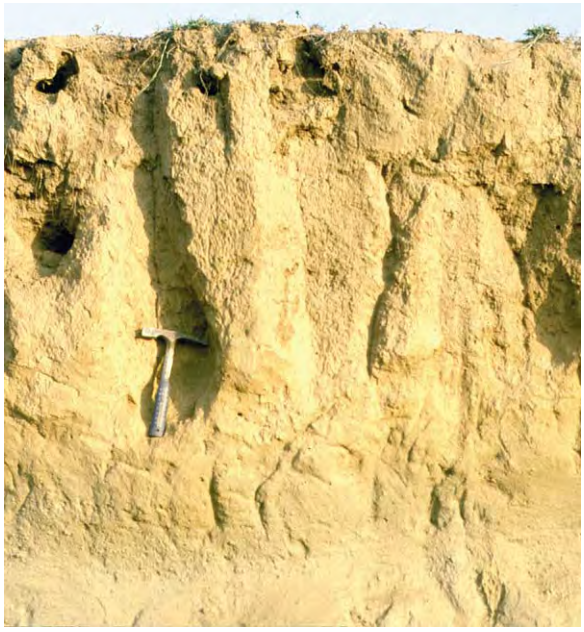

Figure 8 Domed columnar peds produced by solonization in an inceptisol near Narok, Kenya. Hammer handle is 25 cm.

horizons dominated by sodium-smectite. Solodized soils have domed columnar clayey peds in a subsurface (Bn) horizon, but these are sharply truncated by a granular leached (E) horizon. Solodization occurs in desert soils (Aridisols) with better vegetative cover and a more humid climate than solonized soils.

Salinization

Salinization is the precipitation of salts in soils (Figure 3) and is found mostly in desert soils (Aridisols). The most common salts are halite and gypsum, which can form either as clear crystals within soil cracks or as sand crystals that engulf the pre-existing soil matrix. Salts are easily dissolved by rain and so accumulate in regions where there is a marked excess of evaporation over precipitation, which is generally less than 300 mm per year. There is a strong relationship between mean annual precipitation and the depth of leaching of salts in soils. Salinized soils are sparsely vegetated or lack vegetation, and occur in playa lakes, sabkhas, and salinas. Although these are commonly regarded as depositional environments, they are significant soil environments as well.

Cryoturbation

Cryoturbation is the mixing of soils by the freezing and thawing of ground ice. The ice can form disseminated crystals, hair-like threads, thin bands, thick benches, or vertical cracks depending on the local climatic conditions. Soil mixing results from the expansion of water to ice during winter freezing and the relaxation of the deformation on summer melting. Ice-wedge polygons, for example, are wide polygonal cracks that are filled with ice in winter but can be filled with layered sediments in water during the summer in climates where the mean annual temperature is less than −4°C. Sand-wedge polygons form in colder climates where the mean annual temperature is less than −12°C; here, summer melting of ice is limited and sediment fills cracks between the ice and soil in a series of near vertical layers.

Conclusion

Soil-forming processes are varied and complex, and our understanding of them guides the classification, description, and management of soils. The processes are also of interest in simplifying the vast array of chemical reactions, biological processes, and physical effects that create soil. Some processes are more common and widespread than others. Lixiviation and its underlying hydrolysis chemical reaction is perhaps the most important weathering process on Earth, affecting geomorphology, sedimentation, ocean chemistry, and climate. Other processes are restricted to more specific climatic, biotic, geomorphological, geological, and temporal environments, but are no less important in their local environments.

Glossary

Alfisol A fertile forested soil with subsurface enrichment of clay.
Andisol A volcanic-ash soil.
Andisolization A soil-forming process that creates low-density non-crystalline fertile soil from volcanic ash.
Anthropic epipedon A soil surface modified by human use.
Anthrosolization A soil-forming process involving modification by human activities.
Argillic horizon A subsurface horizon of soil enriched in clay.
Argilluviation A soil-forming process that involves creating clay and washing it into a subsurface clayey horizon.
Aridisol A soil of arid regions, usually containing carbonate nodules.
Biocycling The recycling of nutrient elements by biota.
Birnessite A non-crystalline mixture of iron and manganese oxides.
Entisol A very weakly developed soil.

Ferrallitization A soil-forming process involving intense weathering that removes most elements other than iron and aluminium.
Gelisol A soil of permafrost regions, usually containing ground ice.
Gibbsite An aluminium hydroxide mineral ($Al(OH)_3$).
Gilgai A soil microrelief consisting of ridges or mounds alternating with furrows or pits.
Gleization A soil-forming process involving chemical reduction of the soil due to waterlogging.
Halite A salt mineral (NaCl).
Haematite An iron oxide mineral (Fe_2O_3).
Imogolite A colloidal weathering product of volcanic-ash soils.
Inceptisol A weakly developed soil.
Lessivage A soil-forming process that creates clay and washes it into a subsurface clayey horizon.
Lixiviation A soil-forming process that involves leaching nutrient cations from the soil.
Melanization A soil-forming process that involves darkening the soil with organic matter.
Mollic epipedon A humic fertile crumb-textured soil surface typical of grassland soils.
Mollisol A grassland soil with a humic fertile crumb-textured surface.
Mukkara A soil structure consisting of festooned and slickensided cracks between uplifted parts of the soil; the subsurface structures below gilgai microrelief.
Natric horizon A subsurface horizon of soil enriched in sodium-clay.
Oxisol A deeply weathered soil of tropical humid regions.
Paludization A soil-forming process involving peat accumulation in waterlogged soils.
Ped A clod, a unit of soil structure.
Placic horizon Iron- and manganese-stained bands and nodules in soils.
Plaggen epipedon A ploughed surface horizon of soils.
Podzol A sandy soil with a bleached near-surface horizon.
Podzolization A soil-forming process in which acid leaching creates a bleached sandy upper horizon and an iron- or organic-rich subsurface horizon.
Siderite An iron carbonate mineral ($FeCO_3$).
Solonization A soil-forming process that creates soda-rich clays and domed columnar peds in arid regions.
Spodosol A sandy clay-poor soil with an iron- or organic-rich subsurface horizon.
Ultisol A deeply weathered forest soil with subsurface enrichment in clay.
Umbric epipedon A humic acidic clayey massive-to-laminar soil surface found in wetland soils.
Vertisol Swelling clay soil.
Vertization A soil-forming process involving deformation and mixing due to the shrink–swell behaviour of clay during drying and wetting cycles.

Palaeosols

G J Retallack, University of Oregon, Eugene, OR, USA

Introduction

Palaeosols are ancient soils, formed on landscapes of the past. Most palaeosols have been buried in the sedimentary record, covered by flood debris, landslides, volcanic ash, or lava (Figure 1). Some palaeosols, however, are still at the land surface but are no longer forming in the same way that they did under different climates and vegetation in the past. Climate and vegetation change on a variety of time-scales, and the term relict palaeosol for profiles still at the surface should be used only for such distinct soil materials as laterites among non-lateritic suites of soils (Figure 2). Thus, not all palaeosols are fossil soils or buried soils.

An alternative spelling of paleosol has been adopted by the International Quaternary Association. Other terms such as pedoderm and geosol refer to whole landscapes of buried soils. These soil stratigraphical units are named and mapped in order to establish stratigraphical levels. The terms pedotype and soil facies are more or less equivalent and are used to refer to individual palaeosol types preserved within ancient buried landscapes. These terms are used to distinguish one type of palaeosol from another in environmental interpretations of palaeosols. Pedolith, or soil sediment, describes a sediment, as indicated by bedding and other sedimentary features, with distinctive soil clasts, such as ferruginous concretions. Pedoliths are uncommon in sedimentary sequences, because soils are readily eroded to their constituent mineral grains, which retain few distinctive soil microfabrics.

Recognition of Palaeosols

Palaeosols buried in sedimentary and volcaniclastic sequences can be difficult to distinguish from enclosing sediments, tuffs, or lavas and were not widely recognized before about 20 years ago. Three features of palaeosols in particular aid their identification: root traces, soil horizons, and soil structure.

Soil is often defined as the medium of plant growth. Geological and engineering definitions of soil are broader, but fossilized roots and traces of their former paths through the soil are universally accepted as diagnostic of palaeosols. Not all palaeosol root traces are permineralized or compressed original organic matter: some are tortuous infillings of clay with discoloured haloes or mineralized alteration (Figure 3). Both fossilized roots and root traces show the downward tapering and branching of roots. Soils also contain fossil burrows, but these are usually more sparsely branched and parallel-sided than root traces. The distinction between burrows and roots can be blurred in cases where soil animals feed on roots and where roots find an easier passage through the soft fill of burrows. For very old rocks, predating the Early Devonian evolution of roots, the criterion of root traces is of no use in identifying palaeosols.

Figure 1 The subtle colour banding in these cliffs is the result of a sequence of 87 Eocene and Oligocene palaeosols in 143 m of nonmarine silty claystones exposed in the Pinnacles area of Badlands National Park, South Dakota, USA.

Figure 2 The red rock exposures to the left on the beach are a lateritic palaeosol of Middle Miocene age. Even though these horizons are at the surface, they are considered to be palaeosols because soil horizons of this type are not currently forming in this area. The red rock in the background is a sequence of Early Triassic palaeosols in Bald Hill Claystone, near Long Reef, New South Wales, Australia.

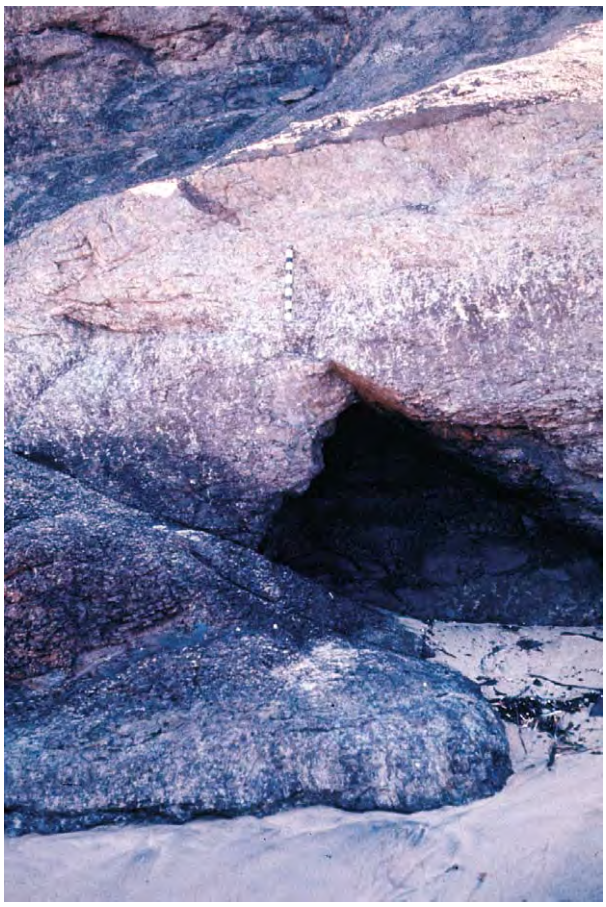

Figure 3 The sharply truncated top and abundant drab haloed root traces (A horizon) petering out downwards into red claystone (Bt horizon) are soil horizons of a palaeosol (Long Reef clay palaeosol, Early Triassic, Bald Hill Claystone, near Long Reef, New South Wales, Australia).

Palaeosols also have recognizable soil horizons, which differ from most kinds of sedimentary bedding in their diffuse contacts downwards from the sharp upper truncation of the palaeosol at the former land surface. Palaeosol horizons, like soil horizons, are seldom more than a metre thick and tend to follow one of a few set patterns. Subsurface layers enriched in clay are called Bt horizons in the shorthand of soil science (Figure 3). Unlike a soil, in which clayeyness can be gauged by resistance to the shovel or plasticity between the fingers, clayeyness in palaeosols that have been turned to rock by burial compaction must be evaluated by petrographic, X-ray, or geochemical techniques. Subsurface layers enriched in pedogenic micrite are called Bk horizons in the shorthand of soil science and are generally composed of hard calcareous nodules or benches in both soils and lithified palaeosols (Figure 4).

A final distinctive feature of palaeosols is soil structure, which varies in its degree of expression and

Figure 4 Two successive palaeosols overlain sharply by volcanic grits show crumb structured organic surfaces (A horizon) over calcareous nodule studded subsurfaces (Bk horizon). In the upper right corner is a comparable modern soil (Middle Miocene fossil quarry near Fort Ternan, Kenya).

replaces sedimentary structures such as bedding planes and ripple marks, metamorphic structures such as schistosity and porphyoblasts, and igneous structures such as crystal outlines and columnar jointing. Because they lack such familiar geological structures, palaeosols are commonly described as featureless, massive, hackly, or jointed. Palaeosols, like soils, have distinctive systems of cracks and clods. The technical term for a natural soil clod is a ped, which can be crumb, granular, blocky, or columnar, among other shapes. Peds are bounded by open cracks in a soil and by surfaces that are modified by plastering over with clay, by rusting, or by other alterations. These irregular altered surfaces are called cutans, and they are vital in recognizing soil peds in palaeosols that have been lithified so that the original cracks are crushed. The rounded 3–4 mm ellipsoidal crumb peds of grassland soils and palaeosols (Figure 4) are quite distinct from the angular blocky peds of forest palaeosols (Figure 3). Common cutans in soils and palaeosols include rusty alteration rinds (ferrans) and laminated coatings of washed-in clay (argillans). Cutans and other features of lithified palaeosols are best studied in petrographic thin sections and by electron microprobing and scanning electron microscopy. Some petrographic fabrics, such as the streaky birefringence of soil clays when viewed under crossed Nicols or sepic plasmic fabric, are diagnostic of soils and palaeosols.

Alteration of Soils after Burial

Palaeosols are seldom exactly like soils because of alteration after burial or exposure to additional weathering, and this can compromise their interpretation and identification with modern soils. Palaeosols,

like sediments, can be altered by a wide array of burial processes: cementation with carbonate, haematite, or silica; compaction due to pressure or overburden; thermal maturation of organic matter; and metamorphic recrystallization and partial melting. These high-pressure and high-temperature alterations of palaeosols are not as difficult to disentangle from processes of original soil formation as are three common early modifications: burial decomposition, burial reddening, and burial gleization.

Some soils are buried rapidly by chemically reducing swamps or thick lava flows, preserving most of their organic matter. In contrast, many palaeosols are covered thinly by floodborne silt or colluvium, and their buried organic matter is then decomposed by aerobic bacteria and fungi deep within the newly forming soil of the palaeosol sequence. For this reason many palaeosols have much less organic carbon (fractions of a weight per cent) than comparable modern soils (usually 5–10% by weight of carbon at the surface). Thus palaeosol A horizons are seldom as dark as soil surface horizons, and must be inferred from the abundance of roots rather than from colour and carbon content.

Soils vary considerably in their degree of redness, but most palaeosols are red to reddish brown from haematite (iron oxide) or occasionally yellowish brown from goethite (iron hydroxide). Soils become redder from the poles to the tropics, from moderately drained to well drained sites, and with increasing time for development, as iron hydroxides are dehydrated to oxides. The dehydration of iron hydroxides continues with the burial of soils, so that red palaeosols are not necessarily tropical, unusually well drained, or especially well developed.

In river-valley and coastal sedimentary sequences with abundant palaeosols, formerly well-drained soils can find themselves subsiding below the water table with root traces and humus largely intact. Burial gleization is a process in which organic matter is used by microbes as a fuel for the chemical reduction of yellow and red iron oxides and hydroxides. Comparable processes of biologically induced chemical reduction are common in swamp soils, but superimposition of this process on the organic parts of formerly well-drained soils produces striking effects in some palaeosols. The whole A horizon is turned grey, with grey haloes extending outwards from individual roots, which diminish in abundance down the profile (Figure 3). Burial gleization is especially suspected when the lower parts of the profile are highly oxidized and have deeply penetrating roots, as in well-drained soils, and when there is no pronounced clayey layer that would perch a water table within the soil.

The combined effect of burial decomposition, dehydration, and gleization can completely change the appearance of a soil. The gaudy grey-green Triassic palaeosol shown in Figure 3, for example, was probably modified by all three processes from an originally dark brown over reddish brown forest soil.

Palaeosols and Palaeoclimate

Many palaeosols and soils bear clear marks of the climatic regime in which they formed. The Berkeley soil scientist Hans Jenny quantified the role of climate in soil formation by proposing a space-for-climate strategy. What was needed was a carefully selected group of soils, or climosequence, that varied in climate of formation but were comparable in vegetation, parent material, topographical setting and time for formation. He noted that mean annual rainfall and the depth in the profile to calcareous nodules decline from St Louis west to Colorado Springs, in the mid-western USA, but that temperatures and seasonality at these locations are comparable. Also common to all these soils is grassy vegetation on postglacial loess that is about 14 000–12 000 years old. From these soils he derived a climofunction or mathematical relationship between climate and soil features. A 1994 compilation of comparable data showed a clear relationship between the depth from the surface of the soil of carbonate nodules (D in cm) and the mean annual precipitation (P in mm) according to the formula:

$$P = 139.6 + 6.388D - 1.01303D^2$$

Such climofunctions can be used to interpret palaeoclimate from the depth within palaeosols of calcareous nodules (Figure 4), once allowance is made for reduction in depth due to burial compaction.

Climatic inferences also can be made from ice deformation features, concretions, clay mineral compositions, bioturbation, and chemical analyses of palaeosols. The thick clayey palaeosol shown in Figure 5 is riddled with large root traces of the kind found under forests and is very severely depleted in elemental plant nutrients such as calcium, magnesium, sodium, and potassium. Comparable modern soils are found at mid-latitudes, yet this palaeosol formed during the Triassic at a palaeolatitude of about 70° S. This palaeoclimatic anomaly indicates pronounced global warming, in this case a postapocalyptic greenhouse effect following the largest mass extinction in the history of life at the Permian-Triassic boundary.

Palaeosols and Ancient Ecosystems

Just as soils bear the imprint of the vegetation and other organisms they support, so many aspects of

ancient ecosystems can be interpreted from palaeosols. The palaeosols shown in Figure 4, for example, have a dark crumb-textured surface horizon with abundant fine (1–2 mm) roots, comparable to the modern grassland soil seen forming on the outcrop to the upper left. Forest soils, in contrast (Figure 3), have large woody root traces, a blocky structure, and thick subsurface clayey horizons (Bt).

In some cases root traces in palaeosols are identifiable, although the species *Stigmaria ficoides* (Figure 6) is a form genus for roots of a variety of extinct tree lycopsids and not a precisely identified ancient plant. The tabular form of the roots of *Stigmaria* indicates a poorly drained soil, because roots do not photosynthesize, but rather respire using oxygen from soil air. Tabular, rather than deeply reaching, root traces (Figure 3) are characteristic of swamp palaeosols.

Some palaeosols also contain fossil leaves, fruits, wood, stones, bones, and teeth. These are direct evidence of soil ecosystems. Unlike fossils in deposits of lakes and shallow seas, fossil assemblages in palaeosols have the advantage of being near the place where the organisms lived. However, the preservation of fossils in palaeosols is seldom as ideal as complete skeletons in river-channel deposits or compressed leaves in carbonaceous shales. The carbon and carbonate contents of palaeosols can be used to evaluate the Eh and pH, respectively, of the palaeosol preservational environments of the fossils.

Figure 5 An unusually warm palaeoclimate is indicated by this palaeosol, which is unusually thick, clayey, and deeply weathered for its palaeolatitude of 70°S and is comparable to soils now forming no further south than 48°S (Early Triassic Feather Conglomerate, Allan Hills, Victoria Land, Antarctica).

Figure 6 Swamp forests of tree lycopsids (*Stigmaria ficoides*) grew in waterlogged soils, in which lack of oxygen forced the roots to form planar mats rather than reaching deeply into the soil (Carboniferous Lower Limestone Coal Group, Victoria Park, Glasgow, Scotland).

Palaeosols and Palaeogeography

Just as soils vary from mountain tops to coastal swamps, so do palaeosols give clues to their ancient topographical setting. Many palaeosols within sedimentary sequences show clear relationships with deposits of palaeochannels and levees, so that their depositional subenvironment can be inferred from context. Water tables are close to the ground surface in many sedimentary environments, and palaeosols yield important information on their position relative to ancient water tables. Palaeosols formed below the water table include peats and are grey with chemically reduced minerals such as pyrite and siderite. Burrows of crayfish and other aquatic organisms are locally common in waterlogged soils, but burrows of most rodents and beetles are not. Root traces also do not penetrate deeply into waterlogged soils or palaeosols (Figure 6). Deeply penetrating roots and burrows and red oxidized minerals of iron or aluminium are common in formerly well-drained palaeosols (Figure 3). Palaeosols may also reveal upland sedimentary environments such as alluvial and colluvial fans, glacial moraines, river terraces, and erosional gullies (Figure 7).

Major geological unconformities often mark erosional landscapes of the past. Rocky cliffs and bedrock platforms are found along geological unconformities, but so are upland palaeosols. For example, the hilly erosional landscape of Lewisian Gneiss in northern Scotland had 1 km of relief (Figure 8).

Palaeosols and their Parent Materials

The parent material of a soil or palaeosol is the substance from which it formed and can usually be inferred from the less-weathered lower parts of the profile. The parent material may be precisely known if the palaeosol is on metamorphic or igneous rocks (Figure 8), because pedogenic minerals are easily

Figure 7 A palaeogully in a strongly developed sequence of palaeosols (dark coloured) is filled with alluvium including weakly developed palaeosols (Late Triassic Chinle Formation, Petrified Forest National Park, Arizona, USA). The hill in the foreground is 11 m high. Photograph courtesy of Mary Kraus.

Figure 8 The bleached pink palaeosol formed on gneiss to the right (Sheigra palaeosol) is thicker and more deeply weathered than the light green palaeosol formed on amphibolite to the left (Staca palaeosol). Both palaeosols are overlain by red quartz sandstones of the Torridonian Group (Late Precambrian, near Sheigra, Scotland).

distinquished from igneous and metamorphic minerals. Parent material is more difficult to find in palaeosols that are developed from sedimentary parent materials, especially if sedimentary facies reveal erosional relief (Figure 7). In such settings, the sediment is derived from pre-existing soils, whose degree of weathering can be quite varied. The kinds of soils of sediment and rock also can be very different. If soil were a commercial product, economy would dictate manufacturing it from materials that are already similar in chemical composition and physical characteristics. Soils form more readily from sediments than from rocks. Perhaps the most distinctive of parent materials is volcanic ash, because it may consist of more volcanic glass than minerals. Volcanic glass weathers to noncrystalline amorphous substances such as imogolite, which confer high fertility from loosely bound phosphorous, potassium, and other plant nutrients. Such soils also have low bulk density and good moisture-retaining properties. Such soils around tropical volcanoes support intensive agriculture, despite the hazards of the nearby active volcano, because they are so much more fertile than surrounding soils. Comparable palaeosols are commonly associated with volcanic arcs of the past (Figure 1).

Palaeosols and their Times for Formation

Soils develop their profiles over time, although some soils, such as peats, also accumulate layer-by-layer in the manner of sediments. Each palaeosol within a sedimentary or volcanic sequence represents a short break in sedimentary accumulation, or diastem, whose duration can be calculated from key features of the soil. The peats that become coal seams in the geological record, for example, cannot accumulate at rates of more than 1 mm year ^{1} because the roots will be suffocated by stagnant water. Nor can they accumulate at rates of less than 0.5 mm year ^{1} because aerobic decay will destroy the organic debris as fast as it accumulates. Thus, the durations of coal-bearing palaeosols can be calculated from coal thickness, once compaction is taken into account. Calcareous soils and palaeosols accumulate carbonate at first in wisps and filaments, and later in nodules, which become larger and larger (Figure 4). The size of the nodules thus gives us an idea of the time over which they formed. The development of clayey subsurface horizons is comparable (Figure 3) in that clay becomes more and more abundant over time. The amount of washed-in clay can thus be a guide to the time over which palaeosols formed.

From the times for palaeosol formation and the thickness of rock for successive palaeosols it is possible to calculate rates of sediment accumulation. In the badlands of South Dakota, for example, the clayey lower part of the section accumulated at a slower rate than the ashy and silty upper part of the section (Figure 1). Variations in the rate of sediment accumulation can be used to address a variety of tectonic, volcanic, and sequence stratigraphical problems using palaeosols.

Glossary

Argillan Clay skin, a kind of planar feature in a soil or cutan formed of clay.

Burial decomposition An early diagenetic modification of a palaeosol in which buried organic matter is decayed microbially.

Burial gleization An early diagenetic modification of a palaeosol in which buried organic matter fuels microbial chemical reduction of iron oxides and oxyhydraes to ferrous clays, siderite or pyrite.

Climofunction A mathematical relationship between a soil feature and a measure of climate.

Climosequence A set of soils formed under similar vegetation, topographic setting, parent material and time, but varied climate.

Concretion A seggregation of materials in a soil, harder or more cemented than the matrix, with prominent internal concentric banding, for example iron-manganese concretion.

Cutan A planar feature within a soil formed by enrichment, bleaching, coating or other alteration, for example a clay skin (argillan).

Ferran Ferruginized surface, a kind of planar feature in a soil (cutan) formed by chemical oxidation.

Geosol A mappable land surface of palaeosols, a soil stratigraphic unit in the North American Code of Stratigraphic Nomenclature.

Nodule A segregation of materials in a soil, harder or more cemented than the matrix, with massive internal fabric, for example caliche nodule.

Palaeosol A soil of a landscape of the past: a past surficial region of a planet or similar body altered in place by biological, chemical or physical processes, or a combination of these.

Ped A natural aggregate of soil: stable lumps or clods of soil between roots, burrows, cracks and other planes of weakness.

Pedoderm A mappable land surface of palaeosols, a soil stratigraphic unit in the Australian Code of Stratigraphic Nomenclature.

Pedolith Soil sediment: a seadimentary rock dominated by clasts with the internal microfabrics of soils.

Pedotype A kind of palaeosol: an ancient equivalent of soil series of the United States Soil Conservation Service.

Perched water table Level of water ponded in a soil by an impermeable subsurface layer.

Sepic plasmic fabric Birefringence microfabric: appearance of the fine grained part of a soil or palaeosol in petrographic thin sections viewed under crossed Nicols of wisps or streaks of highly oriented and highly birefringent clay in a less organized dark matrix.

The Sun

K R Lang, Tufts University, Medford, MA, USA

Physical Characteristics of the Sun

Distance to the Sun

The mean distance of the Sun from the Earth sets the scale of our Solar System and enables us to infer, from other observations, the luminosity, radius, effective temperature, and mass of the Sun. This distance is called the astronomical unit, or AU for short, with a value of $1\,\mathrm{AU} = 1.49597870 \times 10^{11}\,\mathrm{m}$. At that distance, light from the Sun takes 499.004 782 s to travel to the Earth. By way of comparison, light from the Sun's nearest stellar neighbour, Proxima Centauri (part of the triple star system Alpha Centauri), takes 4.29 years to reach us.

Absolute Solar Luminosity

The Sun's absolute, or intrinsic, luminosity is designated by the symbol $L_\odot$, where the subscript $\odot$ denotes the Sun. We can infer the Sun's luminosity from satellite measurements of the total amount of solar energy reaching every square centimetre of the Earth every second, obtaining $L_\odot = 3.854 \times 10^{26}$ W, where a power of $1\,\mathrm{W} = 1\,\mathrm{J\,s^{-1}}$.

Radius of the Sun

The Sun's radius, which can be inferred from its distance and angular extent, has a value of $R_\odot = 6.955 \times 10^8\,\mathrm{m}$. That is about 109 times the radius of the Earth.

The Sun's Effective Temperature

We can use the Stefan–Boltzmann law, together with the Sun's size and luminous output, to determine an effective temperature of 5780 K. The temperature of the Sun increases below and above the visible disk (Table 1).

Mass of the Sun

The Sun's gravitational pull holds the solar system together. That is why we call it a solar system: governed by the central Sun with its huge mass. This gravitational attraction keeps the planets in orbit around the Sun, with longer orbital periods at increasing distances from the Sun. And since we know the Earth's orbital period and mean distance from the Sun, we can weigh the Sun from a distance, obtaining its mass $M_\odot = 5.9165 \times 10^{11}\ (\mathrm{AU})^3/P^2 = 1.989 \times 10^{30}\,\mathrm{kg}$, where the constant is equal to $4\pi^2/G$, the universal constant of gravitation is G, the semi-major axis of the Earth's orbit is $1\,\mathrm{AU} = 1.4959787 \times 10^{11}\,\mathrm{m}$, and the orbital period of the Earth is $\mathrm{P} = 1$ year $= 3.1557 \times 10^7\,\mathrm{s}$.

The Sun does not just lie at the heart of our solar system; it dominates it. Some 99.8% of all the matter between the Sun and halfway to the nearest star is contained in the Sun. It is 332 946 times the mass of the Earth. All the objects that orbit the Sun—the planets and their moons, the comets, and the asteroids—add up to just 0.2% of the mass in our solar system.

Composition of the Sun

When the intensity of sunlight is displayed as a function of wavelength, in a spectrum, it exhibits numerous fine dark gaps of missing colours called

Table 1 The Sun's physical properties[a]

Mean distance, AU	1.4959787×10^{11} m
Light travel time from Sun to Earth	499.004782 s
Radius, $R_\odot$	6.955×10^{8} m (109 Earth radii)
Volume	1.412×10^{27} m^3 (1.3 million Earths)
Mass, $M_\odot$	1.989×10^{30} kg (332 946 Earth masses)
Escape velocity at photosphere	617 km s^{-1}
Mean density	1409 kg m^{-3}
Solar constant, $f_\odot$	1366 J s^{-1} m^{-2} 1366 W m^{-2}
Luminosity, $L_\odot$	3.854×10^{26} J s^{-1} 3.854×10^{26} W
Principal chemical constituents	(By number of atoms) (By mass fraction)
	Hydrogen 92.1% X 70.68%
	Helium 7.8% Y 27.43%
	All other 0.1% Z 1.89%
Age	4.566 billion years
Temperature (center)	15.6 million K
Temperature (effective)	5780 K
Temperature (photosphere)	6400 K
Temperature (chromosphere)	6000 to 20 000 K
Temperature (corona)	2 million to 3 million K
Rotation period (equator)	26.8 days
Rotation period (60° latitude)	30.8 days
Magnetic field (sunspots)	0.1 to 0.4 T 1000 to 4000 G
Magnetic field (polar)	0.001 T 10 G

[a]Mass density is given in kilograms per cubic metre (kg m^{-3}); the density of water is 1000 kg m^{-3}. The unit of luminosity is joules per second, power is often expressed in watts, where 1.0 W 1.0 J s^{-1}.

absorption lines. Each chemical element, and only that element, produces a unique set, or pattern, of wavelengths at which the dark absorption lines fall. So these lines can be used to determine the chemical ingredients of the Sun. They indicate that hydrogen is the most abundant element in the visible solar gases. Since the Sun is chemically homogenous, except for its core, a high hydrogen abundance is implied for the entire star, and this was confirmed by subsequent calculations of its luminosity. Hydrogen accounts for 92.1% of the number of atoms in the Sun, and it amounts to 70.68% by mass.

Helium, the second-most abundant element in the Sun, accounts for 7.8% of the number of atoms in the Sun, and it amounts to 27.43% by mass. Helium is so rare on Earth that it was first discovered on the Sun. All of the heavier elements in the Sun amount to only 0.1% of the number of atoms, and just 1.89% by mass.

Rotation of the Sun

The Sun rotates, or spins, around a rotational axis whose top and bottom mark the Sun's north and south poles. Like Earth, the Sun rotates from west to east when viewed from above the north pole, but unlike Earth, different parts of the Sun rotate at different rates. We know from watching sunspots that the visible disk of the Sun rotates faster at the equator than it does at higher latitudes, decreasing in speed evenly towards each pole. Also, because the Earth orbits the Sun, we observe a rotation period that is about a day longer than the true value. The synodic rotation period of the visible solar equator, as observed from Earth, is 26.75 days, while the equatorial region of the visible solar disk is intrinsically spinning about the Sun's axis once every 25.67 days.

Scientists have used sound waves, generated inside the Sun, to show that the differential rotation of the Sun persists to about one-third of the way down inside the Sun, or 220 000 km from the visible disk. Lower down the rotation speed becomes uniform from pole to pole and the rotation rate remains independent of latitude. The Sun's magnetism is probably generated at the interface between the deep interior, which rotates with one speed, and the overlying gas that spins faster in the equatorial middle.

Solar Magnetic Fields

Detailed scrutiny indicates that the visible solar disk often contains dark, ephemeral spots, called sunspots, which can be as large as the Earth. The sunspots appear and disappear, rising out from inside the Sun and moving back into it. Most sunspots remain visible for only a few days; others persist for weeks and even months.

Sunspots contain magnetic fields as strong as 0.3 T, or 3000 G, thousands of times stronger than the Earth's magnetic field. The intense sunspot magnetism chokes off the upward flow of heat and energy from the solar interior, keeping a sunspot thousands of degrees colder than the surrounding gas.

The total number of sunspots visible on the Sun varies over an 11-year cycle. At the maximum in the cycle we may find 100 or more spots on the visible disk of the Sun at one time; at sunspot minimum very few of them are seen, and for periods as long as a month none can be found. Since most forms of solar activity are magnetic in origin, they also follow an 11-year cycle. Thus, the sunspot cycle is also known as the solar cycle of magnetic activity.

Sunspots are usually found in pairs or groups of opposite magnetic polarity. The magnetic field lines emerge from a sunspot of one polarity, loop through the solar atmosphere above it, and enter a neighbouring sunspot of opposite polarity. The highly magnetized realm in, around, and above bipolar sunspot pairs or groups is a disturbed area called an active

region; it consists of sunspots and the magnetic loops that connect them.

Sunspots are usually oriented roughly parallel to the Sun's equator, in the east–west direction of the Sun's rotation. Moreover, sunspot pairs in either the northern or southern hemisphere have the same orientation and polarity alignment, with an exact opposite arrangement in the two hemispheres.

The Outer Solar Atmosphere

The visible photosphere, or sphere of light, is the level of the solar atmosphere from which we get our light and heat, and it is the part that we can see with our eyes. The thin chromosphere and extensive corona lie above the visible sharp edge of the photosphere. They can both be seen during a total solar eclipse, when the Moon blocks the intense light of the photosphere.

Telescopes called coronagraphs allow us to see the corona by using occulting disks to mask the Sun's face and block out the photosphere's glare. Modern solar satellites, such as the *Solar and Heliospheric Observatory* (*SOHO*), use coronagraphs to get clear, edge-on views of the corona.

The solar corona has a temperature of millions of degrees kelvin, hundreds of times hotter than the underlying visible solar disk whose effective temperature is 5780 K. Very hot material—such as that within the corona—emits most of its energy at X-ray wavelengths. Also, the photosphere is too cool to emit intense radiation at these wavelengths, so it appears dark under the hot gas. As a result, the million-degree corona can be seen all across the Sun's face, with high spatial and temporal resolution, in X-rays.

Since X-rays are totally absorbed by the Earth's atmosphere, they must be observed through telescopes in space. This has been done using a soft X-ray telescope on the *Yohkoh* spacecraft (**Figure 1**). *Yohkoh's* soft X-ray images have demonstrated that the corona contains thin, bright, magnetized loops that shape, mold, and constrain the million-degree gas. Wherever the magnetism in these coronal loops is strongest, the coronal gas in them shines brightly at soft X-ray wavelengths.

Not all magnetic fields on the Sun are closed loops. Some of the magnetic fields extend outward, within regions called coronal holes. These extended regions

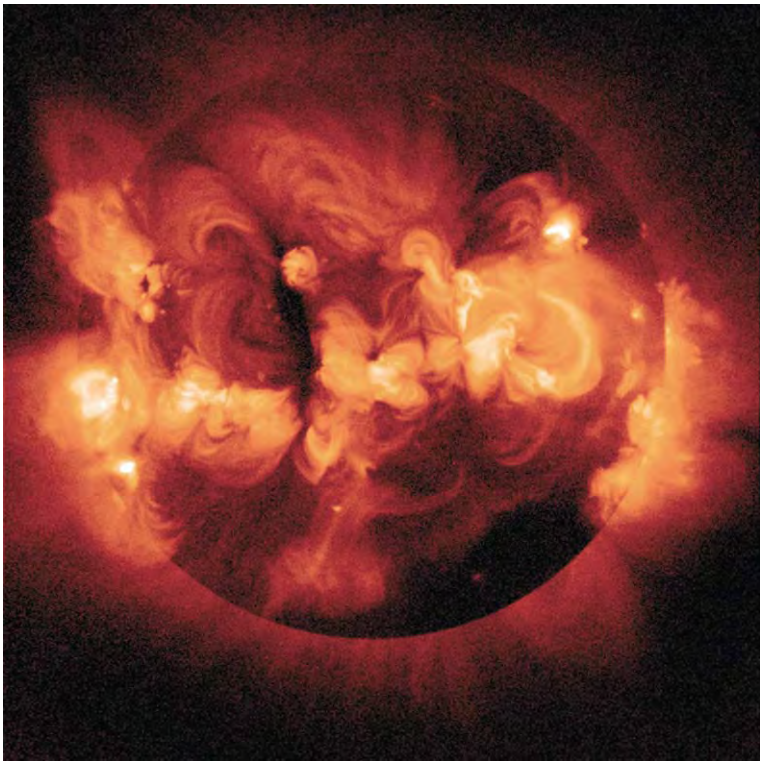

Figure 1 The Sun in X rays. The bright glow seen in this X ray image of the Sun is produced by ionized gases at a temperature of a few million degrees kelvin. It shows magnetic coronal loops which thread the corona and hold the hot gases in place. The brightest features are called active regions and correspond to the sites of the most intense magnetic field strength. This image of the Sun's corona was recorded by the Soft X ray Telescope (SXT) aboard the Japanese *Yohkoh* satellite on 1 February 1992, near the maximum of the 11 year cycle of solar magnetic activity. Courtesy of Gregory L Slater, Gary A Linford, and Lawrence Shing, NASA, ISAS, Lockheed Martin Solar and Astrophysics Laboratory, National Astronomical Observatory of Japan, and University of Tokyo.

have so little hot material in them that they appear as large dark areas seemingly devoid of radiation at X-ray wavelengths. Coronal holes are nearly always present at the Sun's poles, and are sometimes found at lower solar latitudes. The open magnetic fields in coronal holes do not return directly to another place on the Sun, allowing charged particles to escape the Sun's magnetic grasp and flow outwards into surrounding space.

Explosions on the Sun

Solar Flares

Sudden and brief explosions, called solar flares, rip through the atmosphere above sunspots, releasing an incredible amount of energy, amounting to as much as a million, billion, billion (10^{24}) joules in just a few minutes. All of this power is created in a relatively compact explosion, comparable in total area to an Earth-sized sunspot.

For a short time, usually about 10 minutes, a flare is heated to tens of millions of degrees kelvin. The explosion floods the solar system with intense radiation across the full electromagnetic spectrum, from the shortest X-rays to the longest radio waves, and hurls high-energy electrons and protons out into interplanetary space.

Despite the powerful cataclysm, most solar flares are only minor perturbations in the total amount of emitted sunlight. Routine visual observations of solar explosions are only made possible by tuning into the red emission of hydrogen alpha, designated Hα, at a wavelength of 656.3 nm, and rejecting all the other colours of sunlight.

Since solar flares are very hot, they emit the bulk of their energy at X-ray wavelengths, and for a short while, a large flare can outshine the entire Sun in X-rays. The energetic electrons that produce the impulsive, flaring X-ray emission also emit radio waves known as a radio burst to emphasize its brief, energetic, and explosive characteristics. A solar flare can also outshine the entire Sun at radio wavelengths.

There are more flares near the peak of the 11-year cycle of magnetic activity, but this does not mean that sunspots cause solar flares. They are instead energized by the powerful magnetism associated with sunspots. When these magnetic fields become contorted, they can suddenly and explosively release pent-up magnetic energy as a solar flare, with a main energy release in the corona just above sunspots. The energy is apparently released when magnetized coronal loops, driven by motions beneath them, meet to touch each other and connect. If magnetic fields of opposite polarity are pressed together, an instability takes place and the fields partially annihilate each other, releasing energy to power the explosion.

Coronal Mass Ejections

A coronal mass ejection (CME) is a giant magnetic bubble that rapidly expands to rival the Sun in size. Each time a mass ejection rises out of the corona, it carries away up to 50 billion tons (5×10^{13} kg) of coronal material. Its associated shocks also accelerate and propel vast quantities of high-speed particles ahead of them.

CMEs release about as much energy as a solar flare. However, most of the energy of a mass ejection goes into the kinetic energy of the expelled material, whereas a flare's energy is mainly transferred into accelerated particles that emit intense X-ray and radio radiation.

Coronal mass ejections are detected during routine visible-light observations of the corona from spacecraft such the *SOHO*. With a disk in the centre to block out the Sun's glare, the coronagraph is able to show huge pieces of the corona blasted out from the edge of the occulted photosphere (**Figure 2**).

Like sunspots, solar flares, and other forms of solar activity, coronal mass ejections occur with a frequency that varies in step with the 11-year cycle. A few coronal mass ejections balloon out of the corona per day, on average, during activity maximum, and the rate decreases by about an order of magnitude by sunspot minimum.

The triggering mechanism for CMEs seems to be related to large-scale interactions of the magnetic field in the low solar corona. This magnetism is continuously emerging from inside the Sun, and disappearing back into it, driven by the Sun's 11-year cycle of magnetic activity. The release of a coronal mass ejection appears to be one way that the solar atmosphere reconfigures itself in response to these slow magnetic changes.

The Sun's Winds

Basic Properties of the Solar Wind

The tenuous solar atmosphere expands out in all directions, filling interplanetary space with a ceaseless wind that is forever blowing from the Sun. This solar wind is mainly composed of electrons and protons, set free from the Sun's abundant hydrogen atoms, but it also contains heavier ions and magnetic fields. This perpetual solar gale brushes past the planets and engulfs them, carrying the Sun's atmosphere out into interstellar space at the rate of a million tons (10^6 tons $= 10^9$ kg) every second.

The relentless wind has never stopped blowing during the more than three decades that it has been

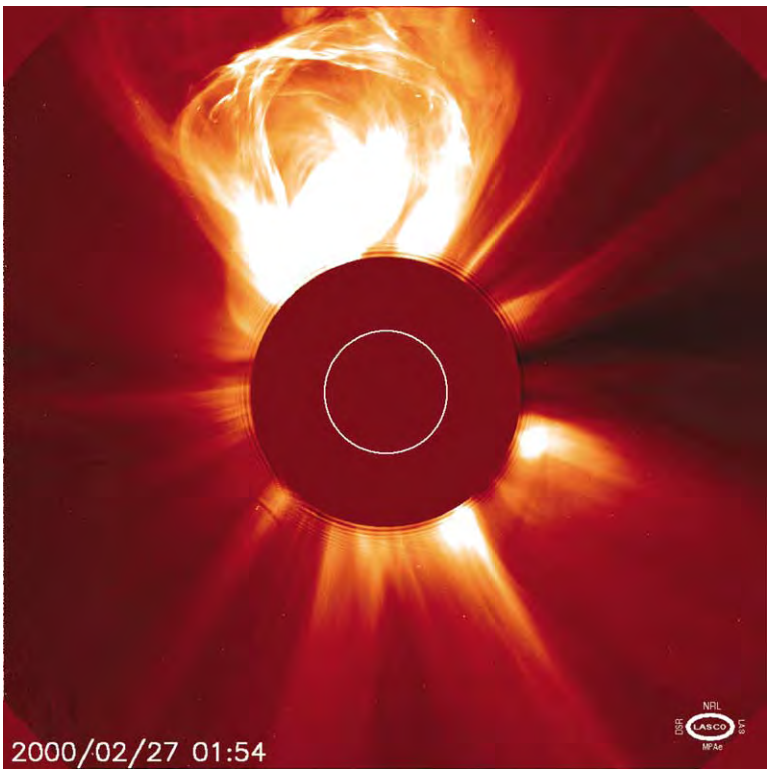

Figure 2 Coronal mass ejection. A huge coronal mass ejection is seen in this coronagraph image, taken on 27 February 2000 with the Large Angle Spectrometric Coronagraph (LASCO) on *the Solar and Heliospheric Observatory* (*SOHO*). The white circle denotes the edge of the photosphere, so this mass ejection is about twice as large as the visible Sun. The black area corresponds to the occulting disk of the coronagraph that blocks intense sunlight and permits the corona to be seen. About one hour before this image was taken, another *SOHO* instrument, the Extreme Ultraviolet Imaging Telescope (EIT), detected a filament eruption lower down near the solar chromosphere. Courtesy of the *SOHO* LASCO consortium. *SOHO* is a project of international cooperation between ESA and NASA.

Table 2 Mean values of solar wind parameters at the Earth's orbit[a]

Parameter	*Mean value*
Particle density, N	$N \approx 10$ million particles m ^{3} (5 million electrons and 5 million protons)
Velocity, V	$V \approx 375\,000$ m s ^{1} and V $\approx 750\,000$ m s ^{1}
Flux, F	$F \approx 10^{12}$ to 10^{13} particles m ^{2} s ^{1}
Temperature, T	T $\approx 120\,000$ K (protons) to 140 000 K (electrons)
Magnetic field strength, H	$H \approx 6 \times 10^{9}$ T 6 nT 6×10^{5} G

[a]These solar wind parameters are at the mean distance of the Earth from the Sun, or at one astronomical unit, 1 AU, where 1 AU 1.496×10^{11} m.

observed with spacecraft. Two winds are always detected—a fast, uniform wind blowing at about 750 km s ^{1} and a variable, gusty slow wind moving at about half that speed.

By the time it reaches the Earth's orbit, the solar wind has been diluted by its expansion into the increasing volume of space to about 5 million electrons and 5 million protons per cubic meter (Table 2).

The charged particles in the solar wind drag the Sun's magnetic fields with them. While one end of the interplanetary magnetic field remains firmly rooted in the photosphere and below, the other end is extended and stretched out by the radial expansion of the solar wind. The Sun's rotation bends this radial pattern into an interplanetary spiral shape within the plane of the Sun's equator. This spiral pattern has been confirmed by tracking the radio emission of high-energy electrons emitted during solar flares (Figure 3), as well as by spacecraft that have directly measured the interplanetary magnetism.

Origin of the Sun's Winds

The million-degree coronal gas creates an outward pressure that tends to oppose the inward pull of the Sun's gravity. At great distances, where the solar gravity weakens, the hot protons and electrons in the corona overcome the Sun's gravity and accelerate away to supersonic speed.

Instruments aboard the *Ulysses* spacecraft conclusively proved that a relatively uniform, fast wind pours out at high latitudes near the solar poles, and

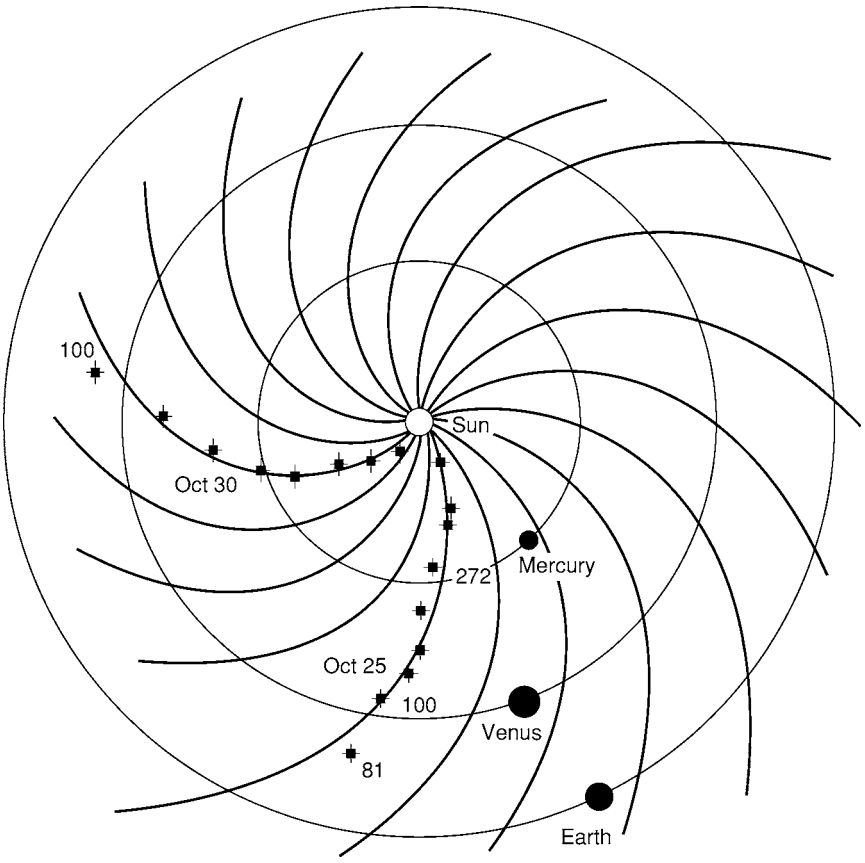

Figure 3 Spiral path of interplanetary electrons. The trajectory of flare electrons in interplanetary space as viewed from above the polar regions using the *Ulysses* spacecraft. As the high speed electrons move out from the Sun, they excite radiation at successively lower plasma frequencies; the numbers denote the observed frequency in kilohertz (kHz). Since the flaring electrons are forced to follow the interplanetary magnetic field, they do not move in a straight line from the Sun to the Earth, but instead move along the spiral pattern of the interplanetary magnetic field, shown by the solid curved lines. The squares and crosses show *Ulysses* radio mea surements of type III radio bursts on 25 October 1994 and 30 October 1994. The approximate locations of the orbits of Mercury, Venus, and the Earth are shown as circles. Courtesy of Michael J Reiner. *Ulysses* is a project of international collaboration between ESA and NASA.

that a capricious, gusty, slow wind emanates from the Sun's equatorial regions at activity minimum.

Comparisons with *Yohkoh* soft X-ray images showed that much, if not all, of the high-speed solar wind flows out of the open magnetic fields in polar coronal holes, at least during the minimum in the 11-year cycle of magnetic activity. In addition, instruments aboard *SOHO* have shown that the strongest high-speed flows gush out of a magnetic network at the bottom of coronal holes near the Sun's poles. Comparisons of *Ulysses* data with coronagraph images pinpointed the equatorial coronal streamers as the birthplace of the slow and sporadic wind during the minimum in the 11-year cycle.

The Heliosphere

A solar gale carries the Sun's rarefied atmosphere past the planets and out to the space between the stars, creating a large cavity in interstellar space called the heliosphere—from the Greek word 'helios' for 'Sun'. Within the heliosphere, physical conditions are dominated, established, maintained, modified, and governed by the magnetic fields and charged particles in the solar wind.

The solar wind's domain extends out to about 150 times the distance between the Earth and Sun, marking the outer boundary of the heliosphere and the edge of our solar system. Out there, the solar wind has become so weakened by expansion that it is no longer dense or powerful enough to repel the ionized matter and magnetic fields coursing between the stars.

The Sun–Earth Connection

Radiation from the Sun

The Sun emits radiation that carries energy through space as waves. Different types of solar radiation differ in their wavelength, although they propagate

at the same speed—299 792 458 m s $^{-1}$, the velocity of light.

Our eyes detect a narrow range of these wavelengths that is collectively called visible radiation. From long to short waves, the colours of visible sunlight correspond to red, orange, yellow, green, blue, and violet. Red light has a wavelength of about 7×10^{-7} m, or 700 nm, and violet waves are about 400 nm long.

Although the most intense radiation from the Sun is emitted at visible wavelengths, it emits less luminous radiation at invisible wavelengths that include the infrared and radio waves, with wavelengths longer than that of red light, and ultraviolet (UV), X-rays, and gamma (γ) rays, which have wavelengths shorter than that of violet light.

Radio waves have wavelengths between 0.001 and 10 m, and they pass easily through the atmosphere, even on cloudy days or in stormy weather. The infrared part of the Sun's spectrum is located between the radiowave region and the red part of the visible region. Atmospheric molecules, such as carbon dioxide and water vapor, absorb infrared radiation from the Sun.

The short-wavelength, ultraviolet radiation from the Sun is sufficiently energetic to tear electrons or atoms off many of the molecular constituents of the Earth's atmosphere, particularly in the stratosphere where ozone is formed.

The X-ray region of the Sun's spectrum extends from a wavelength of one-hundred billionth (10^{-11}) of a meter, which is about the size of an atom, to the short-wavelength side of the ultraviolet. X-ray radiation is so energetic that it is usually described in terms of the energy it carries. The X-ray region lies between 1 and 100 keV (kiloelectron volts) of energy, where 1 keV $= 1.6 \times 10^{-16}$ J. The atmosphere effectively absorbs most of the Sun's ultraviolet radiation and all of its X-rays.

Varying Solar Irradiance of Earth

The total amount of the Sun's life-sustaining energy is called the 'solar constant', and it is defined as the total amount of radiant solar energy per unit time per unit area reaching the top of the Earth's atmosphere at the Earth's mean distance from the Sun. Satellites have been used to accurately measure the solar constant, obtaining a value of $f_{\odot} = 1366.2\ \mathrm{W\,m^{-2}}$, where the power of one watt is equivalent to one joule per second and the uncertainty in this measurement is $\pm 1.0\ \mathrm{W\,m^{-2}}$.

The total power received at any square metre of the Earth's surface, known as the solar insolation, is much less than the solar constant. This is due to the absorption of sunlight in the terrestrial atmosphere, as well as the time of day.

The solar constant is almost always changing, in amounts of up to a few tenths of a per cent and on time-scales from 1 s to 20 years. This inconstant behaviour can be traced to changing magnetic fields in the solar atmosphere, and its variation tracks the 11-year cycle of magnetic activity (Figure 4).

There are enormous changes in the Sun's radiation at the short ultraviolet and X-ray wavelengths that contribute only a tiny fraction of the Sun's total luminosity. The ultraviolet emission doubles from the minimum to maximum of the 11-year cycle, while the X-ray brightness of the corona increases by a factor of 100.

Global Warming and Cooling by the Sun

The brightening and dimming of the Sun dominated our climate for two centuries, from 1600 to 1800. Cooling by hazy emission from volcanoes next played an important role, but the Sun noticeably warmed the climate for another century, from 1870 to 1970. After that, heat-trapping gases apparently took control of our climate. Global warming by the greenhouse effect is probably responsible for this recent, unprecedented rise in temperature. If current emissions of carbon dioxide and other greenhouse gases go unchecked, the average surface temperature of the globe will rise by about 2°C, making the Earth hotter than it has been in millions of years.

The varying Sun may offset some of this warming. Observations of other stars indicate that the Sun luminosity could vary by much more than that observed by satellites so far, producing dramatic changes in the Earth's climate on time-scales of hundreds and thousands of years. Radioactive isotopes found in both tree rings and ice cores indicate that the Sun's activity has fallen to unusually low levels at least three times during the past one thousand years, each drop apparently corresponding to a long, cold spell on Earth of roughly a century in duration.

Further back in time, during the past one million years, our climate has been dominated by the recurrent ice ages, each lasting about 100 000 years. These glaciations begin and end in a relatively short interval of unusual warmth, called an interglacial, lasting 10 000 or 20 000 years, when the glaciers retreat. We now live in such a warm interglacial interval. The rhythmic alteration of glacial and interglacial intervals is related to periodic alterations in the amount and distribution of sunlight received by Earth over tens of thousands of years.

Our Sun-Layered Atmosphere

Our thin atmosphere is pulled close to the Earth by its gravity, and suspended above the ground by

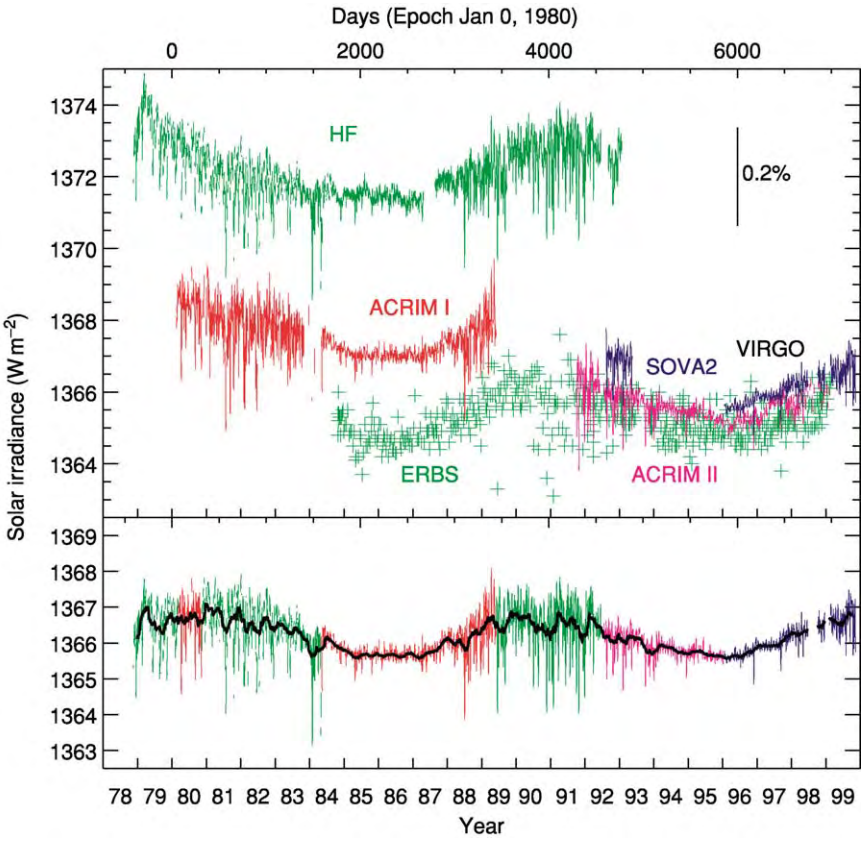

Figure 4 Variations in the solar constant. Observations with very stable and precise detectors on several Earth orbiting satellites show that the Sun's total radiative input to the Earth, termed the solar irradiance, is not a constant, but instead varies over time scales of days and years. Measurements from five independent space based radiometers since 1978 (top) have been combined to produce the composite solar irradiance (bottom) over two decades. They show that the Sun's output fluctuates during each 11 year sunspot cycle, changing by about 0.1% between maximums (1980 and 1990) and minimums (1987 and 1997) in magnetic activity. Temporary dips of up to 0.3% and a few days' duration are due to the presence of large sunspots on the visible hemisphere. The larger number of sunspots near the peak in the 11 year cycle is accompanied by a rise in magnetic activity that creates an increase in luminous output that exceeds the cooling effects of sunspots. Here the total irradiance just outside our atmosphere, called the solar constant, is given in units of watts per square metre, where 1 W 1 J s ^{1}. The capital letters are acronyms for the different radiometres, and offsets among the various datasets are the direct result of uncertainties in their scales. Despite these offsets, each dataset clearly shows varying radiation levels that track the overall 11 year solar activity cycle. Courtesy of Claus Frohlich.

molecular motion. The atmosphere near the ground is compacted to its greatest density and pressure by the weight of the overlying air. At greater heights there is less air pushing down from above, so the compression is less and the density and pressure of the air falls off into the near vacuum of space. The temperature of the air falls and rises in two full cycles at increasing altitudes, and the temperature increases are caused by the Sun's energetic radiation (Figure 5).

The temperature above the ground tends to fall at higher altitudes where the air expands in the lower pressure and becomes cooler. The average air temperature drops below the freezing point of water (273 K) about 1 km above the Earth's surface, and bottoms out at roughly 10 times this height.

The temperature increases at greater heights, within the stratosphere, where the Sun's invisible ultraviolet radiation warms the gas and helps make ozone. This ozone layer protects us by absorbing most of the ultraviolet and keeping its destructive rays from reaching the ground, where it can cause eye cataracts and skin cancer.

Due to the Sun's variable ultraviolet radiation, the total global amount of ozone becomes enhanced, depleted, and enhanced again from 1 to 2% every 11 years, modulating the protective ozone layer at a level comparable to human-induced ozone depletion by chemicals wafting up from the ground. Monitoring of the expected recovery of the ozone layer from outlawed, man-made chemicals will therefore require careful watch over how the Sun is changing the layer from above.

The temperature declines rapidly with increasing height just above the stratosphere, reaching the lowest levels in the entire atmosphere, but the temperature

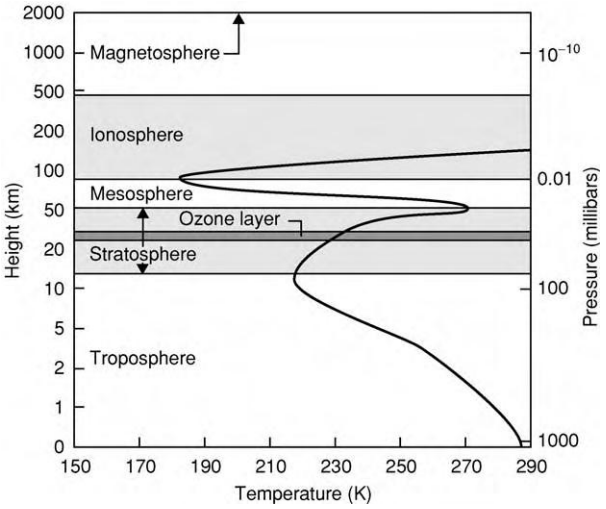

Figure 5 Sun layered atmosphere. The pressure of our atmosphere (right scale) decreases with altitude (left scale). This is because fewer particles are able to overcome the Earth's gravitational pull and reach higher altitudes. The temperature (bottom scale) also decreases steadily with height in the ground hugging troposphere, but the temperature increases in two higher regions heated by the Sun. They are the stratosphere, with its critical ozone layer, and the ionosphere. The stratosphere is mainly heated by ultraviolet radiation from the Sun, and the ionosphere is created and modulated by the Sun's X ray and extreme ultraviolet radiation.

rises again within the ionosphere, reaching temperatures that are hotter than the ground. The ionosphere is created and heated by absorbing the extreme ultraviolet and X-ray portions of the Sun's energy. This radiation tears electrons off the atoms and molecules in the upper atmosphere, thereby creating ions and free electrons not attached to atoms.

At a given height in the ionosphere, the temperature, the density of free electrons, and the density of neutral, unionized atoms all increase and decrease in synchronism with solar activity over its 11-year cycle.

The Earth's Magnetosphere

Invisible magnetic fields, produced by currents in the Earth's molten core, emerge out of the Earth's south geographic polar regions, loop through nearby space, and re-enter at the north polar regions. The surface equatorial field strength is 0.000031 T, or 31 000 nT, and the field strength decreases at greater distances from the Earth.

Yet, the Earth's magnetism is strong enough to deflect the Sun's wind away from the Earth, forming the magnetosphere (Figure 6). The magnetosphere of the Earth, or any other planet, is that region surrounding the planet in which its magnetic field dominates the motions of energetic charged particles such as electrons, protons, and other ions. It is also the volume of space from which the main thrust of the solar wind is excluded.

The solar wind pushes the terrestrial magnetic field towards the Earth on the dayside that faces the Sun, compressing the outer magnetic boundary and forming a bow shock at about 10 times the Earth's radius. Also the Sun's wind drags and stretches the Earth's magnetic field out into a long magnetotail on the night side of our planet. The magnetic field points roughly towards the Earth in the northern half of the tail and away in the southern. The field strength drops to nearly zero at the centre of the tail where the opposite magnetic orientations lie next to each other and currents can flow.

Some of the energetic particles outside the magnetosphere do manage to penetrate it, especially in the magnetotail. When the solar and terrestrial magnetic fields touch each other in the magnetotail, it can catapult the outer part of the tail downstream and propel the inner part back towards Earth.

The inner magnetosphere is always filled with electrons and protons, trapped within two torus-shaped belts that encircle the Earth's equator but do not touch it. These regions are often called the inner and outer Van Allen radiation belts, named after James A Van Allen (1914–) who discovered them in 1958. The inner belt is about 1.5 Earth radii from planet centre, and the outer belt is located at about 4.5 Earth radii, where the Earth's radius is 6378 km.

Intense Geomagnetic Storms

Significant variations in the Earth's magnetic field, lasting seconds to days, are known as geomagnetic storms. The great, sporadic geomagnetic storms, which shake the Earth's magnetic field to its very foundations, can produce magnetic fluctuations as large as 1.6% at mid-terrestrial latitudes, or 500 nT, compared with the Earth's equatorial field strength of 31 000 nT.

Solar wind disturbances driven by exceptionally fast coronal mass ejections produce the most intense geomagnetic storms. The Earth intercepts about 70 coronal mass ejections per year when solar activity is at its peak, and less than 10 will have the punch needed to produce large, geomagnetic storms. These mass ejections plow through the solar wind, driving a huge shock wave far ahead of them. When directed at the Earth, these shocks ram into the terrestrial magnetic field and trigger the initial phase, or sudden commencement, of an intense geomagnetic storm a few days after the mass ejection leaves the Sun.

Strong interplanetary magnetic fields are also generated by fast coronal mass ejections (*see* **Magnetostratigraphy**). It is their intense magnetism and high speed that account for the main phase of a powerful

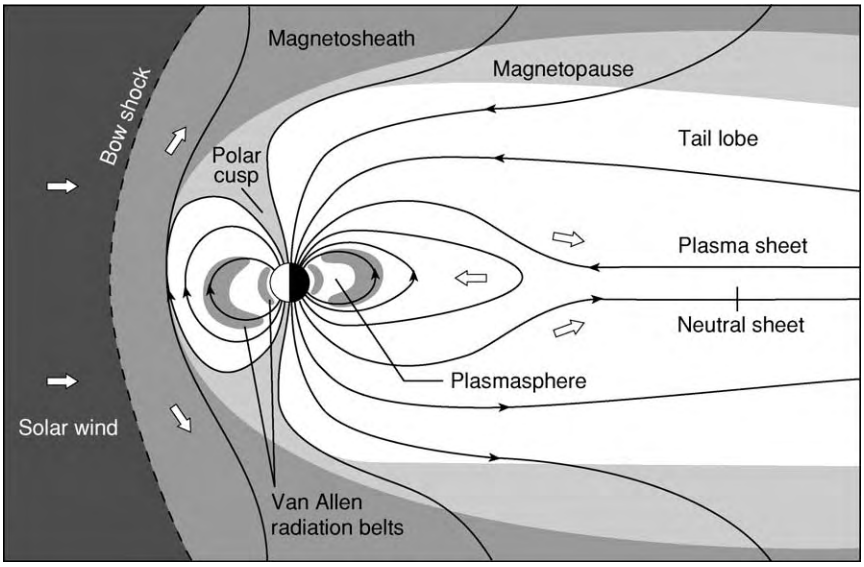

Figure 6 Magnetosphere. The Earth's magnetic field carves out a hollow in the solar wind, creating a protective cavity, called the magnetosphere. A bow shock forms at about 10 Earth radii on the sunlit side of our planet. Its location is highly variable since it is pushed in and out by the gusty solar wind. The magnetopause marks the outer boundary of the magnetosphere, at the place where the solar wind takes control of the motions of charged particles. The solar wind is deflected around the Earth, pulling the terrestrial magnetic field into a long magnetotail on the night side. Plasma in the solar wind is deflected at the bow shock (left), flows along the magnetopause into the magnetic tail (right), and is then injected back towards the Earth and Sun within the plasma sheet (centre). The Earth, its auroras, atmosphere, and ionosphere and the two Van Allen radiation belts all lie within this magnetic cocoon.

geomagnetic storm, provided that the magnetic alignment is right. The Earth's field is generally directed northwards in the outer dayside magnetosphere, so a fast coronal mass ejection is more likely to merge and connect with the terrestrial field if it points in the opposite southward direction.

Moderate Geomagnetic Activity

Moderate mid-latitude magnetic fluctuations of about 0.1%, or tens of nanoTesla, last a few hours, and they are most noticeable near the minimum of the 11-year solar activity cycle. They have a 27-day repetition period, corresponding to the rotation period of the Sun at low solar latitudes when viewed from the moving Earth.

The recurrent activity is linked to long-lived, high-speed streams in the solar wind that emanate from coronal holes. When this fast wind overtakes the slow-speed, equatorial one, the two wind components interact, producing shock waves and intense magnetic fields that rotate with the Sun, and periodically sweep past the Earth, producing moderate geomagnetic activity every 27 days.

The Auroras

The northern or southern lights, named the 'aurora borealis' and 'aurora australis' in Latin, are one of the most magnificent and earliest-known examples of solar–terrestrial interaction. They illuminate the cold, dark Arctic and Antarctic skies with curtains of green and red light that flicker across the night sky far above the highest clouds.

Spacecraft look down on the auroras from high above, showing an oval centred at each magnetic pole (Figure 7). An observer on the ground sees only a small, changing piece of the aurora oval.

The reason that auroras are usually located near the polar regions is that the Earth's magnetic fields guide energetic electrons there. The high-speed electrons move down along the Earth's magnetic field lines into the upper polar atmosphere, colliding with oxygen and nitrogen. The pumped-up atoms or molecules fluoresce, giving up the energy acquired from the electrons and emitting a burst of light.

The electrons that cause the auroras come from the Earth's magnetic tail and are also energized locally within the magnetosphere. The rare, bright, auroras seen at low terrestrial latitudes only become visible during very intense geomagnetic storms.

Space Weather

Down here on the ground, we are shielded from the direct onslaught of solar explosions and the solar wind by the Earth's atmosphere and magnetic fields, but out in deep space there is no protection. Energetic charged particles hurled out from intense solar flares

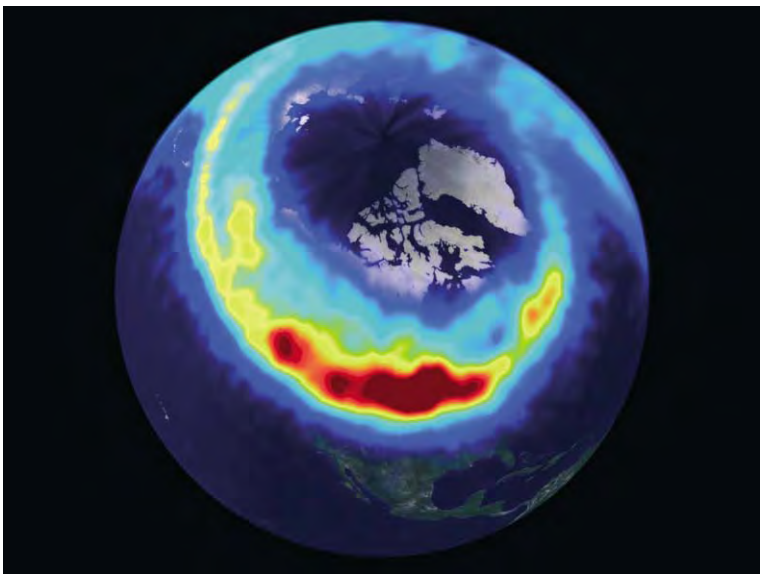

Figure 7 The auroral oval. The *POLAR* spacecraft looks down on an aurora from high above the Earth's north polar region on 22 October 1999, showing the northern lights in their entirety. The glowing oval, imaged in ultraviolet light, is 4500 km across. The most intense aurora activity appears in bright red or yellow. It is typically produced by magnetic reconnection events in the Earth's magnetotail, on the night side of the Earth. Courtesy of the Visible Imaging System, University of Iowa and NASA.

can seriously damage satellites, including their solar cells and electronic components, and even kill an unprotected astronaut.

The high-speed protons and electrons follow a narrow, curved path once they leave the Sun, guided by the spiral structure of the interplanetary magnetic field, so they must be emitted from active regions near the west limb and the solar equator to be magnetically connected with the Earth. Solar flares emitted from other places on the Sun are not likely to hit Earth, but they could be headed towards interplanetary spacecraft, the Moon, Mars, or other planets. The most energetic flare particles can travel from the Sun to the Earth in just 8 minutes, moving at nearly the velocity of light.

Coronal mass ejections move straight out of the Sun, energizing particles over large regions in interplanetary space. Mass ejections are most likely to hit the Earth if they originate near the centre of the solar disk, as viewed from the Earth, and are sent directly towards the planet. They take about 4 days to travel from the Sun to the Earth, moving at a typical speed of about 400 km s $^{-1}$.

The strong blast of X-rays and ultraviolet radiation from a solar flare alters the Earth's atmosphere, transforming the ionosphere, which reflects radio waves to distant locations on Earth. During moderately intense flares, radio communications can be silenced over the Earth's entire sunlit hemisphere, disrupting contact with airplanes flying over oceans or remote countries.

The enhanced ultraviolet and X-ray radiation from solar flares also heats the atmosphere and causes it to expand, and similar or greater effects are caused by coronal mass ejections that produce major geomagnetic storms. The expansion of the terrestrial atmosphere brings higher densities to a given altitude, increasing the drag exerted on a satellite, pulling it to a lower altitude, and causing a premature and fatal spiral towards the Earth.

When a coronal mass ejection slams into the Earth, the force of impact can push the bow shock, at the dayside of the magnetosphere, down to half its usual distance of about 10 times the Earth's radius, compressing the magnetosphere below the orbits of geosynchronous satellites and exposing them to the damaging effects of the full brunt of the gusty solar wind.

During an intense geomagnetic storm, associated with a colliding coronal mass ejection, strong electric currents flow in the ionosphere. They induce potential differences in the ground below them, and produce strong currents in any long conductor such as a power line. These currents can blow circuit breakers, overheat and melt the windings of transformers, and cause massive failures of electrical distribution systems. A coronal mass ejection can thereby plunge major urban centres, like New York City or Montreal, into complete darkness, causing social chaos and threatening safety.

Our technological society has become so vulnerable to the potential devastation of these storms in space that national centres employ space weather

forecasters to continuously monitor the Sun from ground and space to warn of threatening solar activity.

Asteroids, Comets and Space Dust

P Moore, Selsey, UK

Introduction

Asteroids and comets must be regarded as minor members of the Solar System. Compared with planets they are of very low mass, and they have even been referred to as cosmic debris. The asteroids, dwarf worlds most of which are well below 1000 km in diameter, are found mainly between the orbits of Mars and Jupiter, though some stray from this 'main belt'; comets have been described as 'dirty snowballs', and though they may become very conspicuous in the sky they are very insubstantial. This article reviews the asteroids and comets, together with the large amount of thinly-spread material lying in the Solar System.

Distribution of the Asteroids

The Solar System is divided into two well-defined parts. There are four relatively small, rocky planets: Mercury, Venus, the Earth, and Mars. Then come the four giants: Jupiter, Saturn, Uranus, and Neptune. Between the orbits of Mars and Jupiter thousands of asteroids, otherwise known as minor planets, make up what is known as the main belt (Figure 1). Of the main belt asteroids, only one (Ceres) is as much as 900 km in diameter, and only one (Vesta) is ever visible with the naked eye. Some of the larger main belt asteroids are listed in Table 1.

Some small asteroids can leave the main belt, and swing closer to the Sun; they may even approach the Earth, and collision cannot be ruled out (it may even be that the impact of an asteroid, some 65 million years ago in Mexico, caused a climatic change and mass extinction, which included the dinosaurs). All of these Near Earth Approach (NEA) asteroids are very small indeed. There are asteroids known as Trojans which share the orbits of major planets; others have very eccentric orbits which take them into the far reaches of the Solar System, and recently it has been found that there are asteroid-sized bodies near and

well beyond the orbits of Neptune and Pluto. These make up what is known as the Kuiper Belt.

Discovery

A mathematical relationship, known as Bode's Law, led astronomers to believe that there should be another planet moving between the orbits of Mars and Jupiter. From 1800, a systematic search was carried out by a group of observers who called themselves the 'Celestial Police', and on 1 January 1801, the first asteroid, Ceres, was discovered by G Piazzi (who was not then a member of the group, though he joined later). Three more small bodies were found during the next few years: Pallas, Juno, and Vesta. It was not until 1845 that the next asteroid, Astræa, was found; others followed, and by now many thousands are known. When a new asteroid is discovered, it is given a temporary designation and then, when its orbit has been reliably worked out, a number. At first mythological names were used, but the supply of these names soon ran out; today the discoverer is entitled to suggest a name, which is then ratified by the International Astronomical Union.

Origin and Orbits

It is no longer thought that the asteroids are fragments of a large planet which broke up. It seems that no planet of appreciable size could form in this part of the Solar System, because of the disruptive influence of Jupiter. The asteroids in the main belt are not evenly distributed; Jupiter's gravitational pull tends to produce groups or 'families', made up of numbers of asteroids moving at around the same distance from the Sun (**Figure 2**). A family is named after one of its most prominent members, and does seem to be due to the disruption of a larger body, The Flora family has at least 400 members. There are also gaps in the main belt (the Kirkwood Gaps) which are almost empty, because of regular gravitational interactions with Jupiter. For instance, there is a gap at a distance of 375 million km from the Sun, where an asteroid would complete three orbits for every one orbit of Jupiter (**Figure 3**).

Types of Asteroids

Asteroids are divided into various types, according to their physical and surface characteristics. The main types are listed in **Table 2** (**Figure 4**). There is certainly a link between comets and small asteroids; thus a tailed comet discovered in 1951 (Wilson-Harrington) was lost for years before being recovered in 1979 in the guise of an asteroid. It was given a number (4015) and now shows no sign of cometary activity.

Asteroid Surfaces and Composition

Details on some asteroids have been recorded. 3 Vesta has been imaged by the Hubble Space Telescope, and

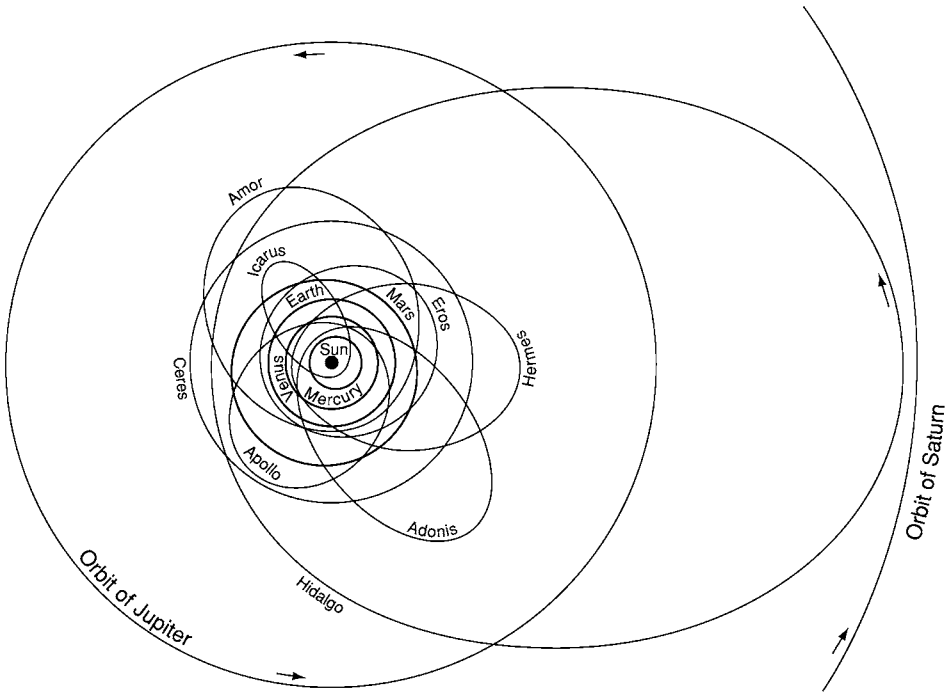

Figure 2 Orbits of some asteroids.

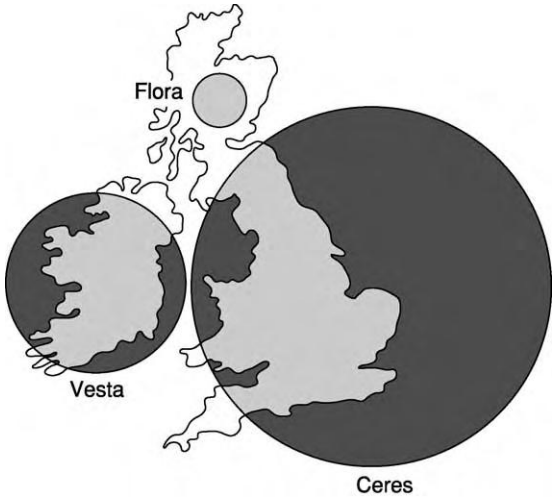

Figure 3 Sizes of same asteroids compared with British Isles Diameters: Ceres 970 km Vesta 288 × 230, Flora 204.

Table 2 Types of asteroids

C (Carbonaceous)	Most numerous, increasing in number from 10% at 2.2 a.u. up to 80% at 3 a.u. Low albedo; spectra resembles carbonaceous chondrites
S (Silicaceous)	Most numerous in the inner part of the main zone. Generally reddish, spectra resemble those of chondrites
M (Metallic)	Moderate albedoes; may be the metal rich cores of larger parent bodies
E (Enstatite)	Relatively rare, high albedos; enstatite ($MgSiO_3$), is a major constituent
D	Low albedo; reddish; surfaces are 90% clays, with magnetite and carbon rich substances
A	Almost pure olivine
P	Dark and reddish; not unlike Type B.
V	Igneous rock surfaces, very rare; 4 Vesta is the only large example
U	Asteroids which are regarded as unclassifiable

is geologically of great interest; there are two distinct hemispheres, covered with different types of solidified lava, and there is one huge impact crater. Some asteroids have been imaged from passing space-craft; 253 Mathilde (Figure 5) is very dark and irregular, and has been described as 'a heap of rubble', while 243 Ida is cratered and is accompanied by a tiny satellite, Dactyl. 216 Kleopatra has two lobes of similar size, and looks remarkably like a dog's bone!

Asteroids closer-in than the Main Belt

These are of various types. Details are given in Table 3. All are small, usually only a few kilometres across, and are irregular in shape. The first to be discovered (in 1898) was 433 Eros; it is an Amor asteroid, so that its orbit crosses that of Mars but not that of the Earth. It can approach Earth at a distance of 23 million km. On 12 February 2001,

Figure 4 511 Davida, a Main Belt asteroid 320 km in diameter. This sequence of images was taken at the WM Keck Observatory on 28 December 2002, The rotation period is just over one hour; here Davida is seen from above its north pole as it spins counter clockwise.

Figure 5 Asteroid 253 Mathilde, imaged by NEAR space craft on 27 June 1997, from a range of 2400 km. There are large craters. The asteroid is very dark, with an average albedo of 4%. Mathil de's diameter is 50 × 50 × 70 km, rotation period 418 hours.

the space-craft NEAR-Shoemaker made a controlled landing on it; Eros proved to be a very primitive body, (Figure 2) and very ancient. Craters were plentiful, as well as rocks and boulders of all kinds, and superficial 'landslides' in the surface material were recognized.

Some small asteroids pass between the Earth and the Moon, and collision cannot be ruled out, and there are more potentially hazardous asteroids (PHAs) than used to be thought.

Asteroids Beyond the Main Belt

The Trojan asteroids move in the same orbit as Jupiter, though they keep either well ahead of or well behind the Giant Planet and are in no danger of being engulfed. Mars has several Trojans, and Neptune one. No true Earth Trojans are known, though 3753 Cruithne has almost the same orbital period and describes a curious sort of 'horseshoe' path with respect to the Earth. There are also asteroids, such as 944 Hidalgo and 5335 Damocles, with very eccentric orbits, very like those of comets. For example, Damocles has a period of 40.9 years; its orbit crosses those of Mars, Jupiter, Saturn, and Uranus, but is in no danger of collision as its orbital inclination is 61°. It is no more than 15 km in diameter.

Table 3 Asteroids closer in than the Main Belt

Apohele type	Orbit entirely within that of the Earth, only one example is known, the tiny 2003 CR20
Aten type	Average distance from the Sun less than 1 a.u., though they may cross the Earth's orbit. All very small
Apollo type	Orbits cross that of the Earth; average distance from the Sun over 1 a.u.
Amor class	Orbits cross that of Mars, but not that of the Earth

The 'Centaur' asteroids remain well beyond the Main Belt; the first to be found (in 1977) was 2060 Chiron, which moves mainly between the orbits of Saturn and Uranus, in a period of 50 years. It shows traces of a coma at times, but seems much too large to be classed as a comet, even though it has been given a cometary number.

The Kuiper Belt

Many asteroidal bodies have been found near and beyond the orbits of Neptune and Pluto; the existence of such a belt was suggested by GP Kuiper (and earlier, less positively, by K. Edgeworth). Some are larger than any Main Belt asteroids; 50 000 Quaoar has a diameter of about 250 km, more than half that of Pluto. Other large Kuiper Belt objects are 28 978 Ixion (1200 km), 20 000 Varuna (900 km), and 38 093 Rhadamanthus (320 km). There are also asteroid-sized bodies which recede to immense distances from the Sun, and have orbital periods of hundreds of years. There are excellent reasons for suggesting that Pluto should be regarded as merely an exceptionally large Kuiper Belt object rather than as a bonafide planet. The Kuiper belt also includes some comets.

Comets

Comets are the most erratic members of the Solar System. They were once regarded as unlucky, and descriptions of them go back for thousands of years. Certainly a brilliant comet may look really spectacular, but by planetary standards all comets are of very low mass. They are true members of the Solar System, but in general their orbits are very eccentric, and their movements are quite unlike those of the planets.

Nature of Comets

The only fairly substantial part of a comet is the nucleus, made up of rocky fragments held together by frozen ices such as H_2O methane, carbon dioxide,

and ammonia. When a comet is warmed as it approaches perihelion the rise in temperature leads to evaporation, so that the comet develops a head or coma, often with a tail or tails. Cometary tails always point away from the Sun, and are of two main types ion and dust tails. A gas or ion tail is due to particles being repelled by the solar wind, while with a dust tail the particles are driven out by the pressure of sunlight; this means that when a comet is moving outward, after perihelion, it travels tail-first. However, not all comets develop tails of any kind, and even a large comet will lose its tail when it has receded into the far part of the Solar System.

Nomenclature

Traditionally, a comet is named after its discoverer or discoverers; thus the brilliant comet seen in 1995 and 1996 was known as Hale-Bopp, since it was found independently by two American observers, Alan Hale and Tom Bopp. Occasionally the comet is known by the name of the mathematician who first computed its orbit, as with Comets Halley and Encke. There is also an official numbering system which relates to the date of discovery.

Orbits

Many comets have short periods – for example 3.3 years for Comet Encke. These short-period comets can be predicted, and some can be followed all round their orbits. Many have their aphelia near the distance of the orbit of Jupiter, making up what is termed Jupiter's comet family. Most of them are faint, and few attain naked-eye visibility. The only reasonably bright comet with a period of less than 100 years is Halley's (76 years), which last returned to perihelion in 1986–1987.

Long-period comets recede to great distances, and since their periods amount to many centuries they cannot be predicted, Hale-Bopp (Figure 6) will be back in about 2350 years, but for the next return of Comet Hyakutake, which was bright for a few weeks in 1996, we must wait for around 14 000 years. These orbits are almost parabolic, and indeed some comets are thrown into parabolic orbits after passing perihelion, so that they will never return. Arend-Rolànd, the bright comet of April 1957, is one example of this.

Figure 6 Comet Hale Bopp, 1997. Note the straight ion tail, and the curved dust tail. This was the most spectacular comet for many years.

Origin of Comets

It seems that short-period comets come from the Kuiper Belt. In general, their orbits are not highly inclined to the ecliptic, though some, notably Halley's Comet, have retrograde motion. Comets of much longer period are thought to come from the Oort Cloud, a huge spherical cloud of debris surrounding the Sun at a distance of over one light-year; its existence was suggested in 1950 by the Dutch astronomer JH Oort. It is, of course, unobservable from Earth. If an Oort Cloud comet is perturbed for any reason, it may swing in towards the Sun; it may then be perturbed into a short-period orbit, it may fall into the Sun and be destroyed, or it may simply return to the Oort Cloud. The orbital inclinations may be very high, and many long-period comets have retrograde motion.

It may be that the Oort Cloud comets were formed closer to the Sun than the Kuiper Belt objects. Low-mass objects formed near the giant planets would have been ejected by gravitational encounters. While Kuiper Belt objects, formed further out, were not so affected. Details of some notable comets are given in Table 4 (*see* **Solar System:** Meteorites).

Comets and Meteors

As a comet moves, it leaves a 'dusty trail', and if the Earth passes through such a trail we see a meteor shower. In many cases the parent comets are identifiable, for example the Orionid meteors, seen every October, come from Halley's Comet, while the August Perseids come from Comet Swift–Tuttle.

Some comets have been seen to disintegrate; thus Biela's Comet, which had a period of 6.6 years, broke in two during its return in 1846, and has not been seen since 1852, though for many years meteors appeared from the position where the comet ought to have been. Other periodical comets have been lost because their orbits have been so violently perturbed by planetary encounters. One comet, Shoemaker-Levy 9, in captured orbit around Jupiter, was destroyed in 1994 when it impacted Jupiter.

Halley's Comet

Named for Edmond Halley, who observed it in 1682 and was the first to realize that it was periodical

I orbital inclination, degrees.
M absolute magnitude (the magnitude which the comet would have if seen from a distance of 1 a.u. from the Sun and 1 a.u. from the Earth.)
P period, years.

(Figure 7). It was probably record by the Chinese as early as 1059 BC, and since 240 BC it has been seen at every return; it came to perihelion in 1066, and is shown in the famous Bayeux Tapestry. During the 1986 return several space–craft were sent to it, and one of these, Giotto, passed within 605 km of the nucleus. The nucleus was shaped rather like a peanut, and measured 15 × 8 × 8 km. Over 60 000 million comets of this mass would be needed to equal the Earth. The nucleus was dark-coated, and made up largely of water ice; dust-jets were active, though only from a small area on the sunward wide (Figure 8). The comet is now too faint to be detected, though it should be recovered before the next perihelion passage, due in 2061.

Figure 7 Halley's Comet, March 1986, (Photo by Tom Polaks with a 100 mm lens at f/2.8.) The faint globular cluster M75 is also shown. From the most left of the three conspicuous stars left and above Halley's head, go to the fainter star above and left. This star forms a fainter, nearly rectangular triangle with the other stars above and left of it. On the line connecting with the far left edge a star like spot anneals; this is M75.

Great Comets

Really brilliant comets were seen fairly frequently during the nineteenth century, but were less common in the twentieth century (Figure 9). The brightest comet of near-modern times was probably that of 1843, which cast shadows and was visible in broad daylight. The last two really spectacular comets were those of 1910 – the Daylight Comet, seen shortly before Halley's – and 1965 (Ikeya–Seki), which faded quickly. Its period has been given as 880 years. Some Great comets are listed in Table 5.

Comet Hale-Bopp was not so brilliant as these, but was exceptionally beautiful, and was visible with the naked eye for over a year, from July 1996 to October 1997. It was enormous by cometary standards, with a 40 km nucleus, but unfortunately it did not come close to the Earth. There were both ion and dust tails, plus a third inconspicuous tail made up of

sodium. It was last at perihelion about 4200 years ago, but planetary perturbations mean that it should return in about 2350 years, though of course all periods of this kind of length cannot be given accurately. Its orbital inclination is 89°, so that its path lies at almost a right angle to that of the Earth. During its period of visibility there were marked changes in the tails, and a spiral structure developed in the coma. Comet Ikeya-Zhang of 2002 was much less striking – it became no brighter than the fourth magnitude – but is notable because it was found to be a return of the comet of 1661, and is therefore the longest-period comet to have been seen at more than one apparition. It will be back once more in 2343.

Life in Comets?

The 'panspermia' theory was due to the Swedish scientist Svants Arrhenius, whose work won him the Nobel Prize for Chemistry in 1903. Arrhenius believed that life on Earth was brought here in a meteorite, but the theory never became popular, because it seemed to raise more problems that it solved. The same sort of theme has been followed up much more recently by Sir Fred Hoyle and C Wickramasinghe,

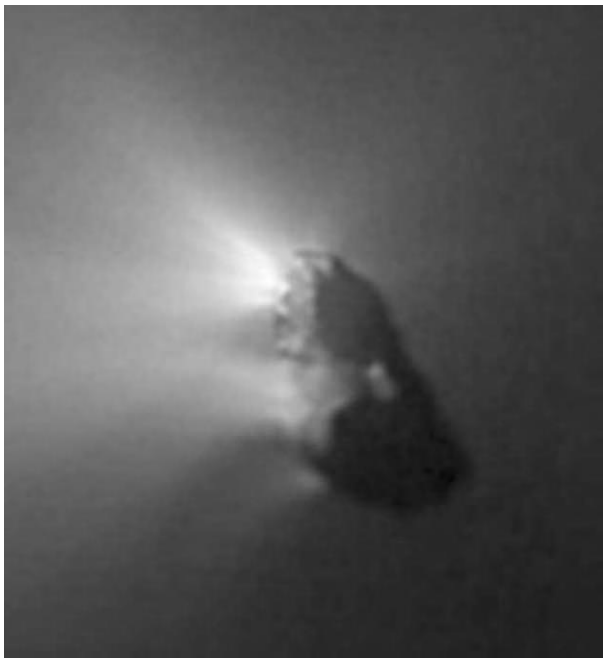

Figure 8 Head of Halley's Comet, imaged from the Giotto space craft. The dark coating and the active dust jets are well seen. (Photograph from the HMC [Halley Multi colour Camera]), Giotto passed 605 km from the nucleus on the night of, 13 14 March 1986.

Figure 9 Comet Hyakitake, C/1996 B2. This beautiful comet was conspicuous object briefly in April May 1996; it was obvi ously greenish, and had a long tail. It was in fact a small comet, but made a fairly close approach to the Earth. It will next come to perihelion in 14 000 years! time, look out for it then.

Table 5 Some Great Comets

Year	*Name*	
1744	de Chéseaux	Multi tailed comet; max. magnitude 7
1811	Flaugergues	Mag. 0; 24 degree ion tail. Period 3096 years
1843	Great Comet	Mag. 6. Sun grazer. Period 517 years
1858	Donati	Mag, 1. Most beautiful of all comets, with ion and dust tails. Period 1951 years
1882	Great Comet	Reached mag. 4. Period 760 years
1910	Daylight Comet	Magnitude 4. Immensely long period
1927	Skjellerup Maristany	Magnitude 6; 35 degree tail
1947	Southern Comet	Magnitude 5, 25 degree tail
1965	Ikeya Seki	Magnitude 10; seen very near the Sun
1976	West	Magnitude 2. Multiple dust tail
1996	Hyakutake	Briefly reaches magnitude Q. Very long tail. The green comet
1997	Hale Bopp	Magnitude 0.5; naked eye object for over a year

Figure 10 The Zodiacal Light. A typical display, photographed on 19 November 1998 over the Qinghai Radio Observatory near Delinghom Qinghai, Central China. (M Langbroek).

who claimed that comets can actually deposit harmful bacteria in the Earth's upper atmosphere, causing epidemics. Again there has been little support.

Space Dust

There is a great quantity of 'dust' in the Solar System, particularly near the main plane. It is the cause of the Zodiacal Light, (Figure 10) which may be seen as a cone of light extending upwards from the horizon for a fairly brief period either after sunset or before sunrise. Since it extends along the ecliptic, it is best seen when the ecliptic is nearly vertical to the horizon, in February to March and again in September–October. Cometary debris is a major contributary factor. It was first correctly explained by the Italian astronomer, GS Cassini, in 1683.

Another glow due to cosmic dust is the Gegenschein, seen as a faint patch exactly opposite to the Sun in the sky. It is extremely elusive, and is visible only under near-ideal conditions. The best opportunities occur when the anti-Sun position is well away from the Milky Way, from February to April and from September to November. Generally it is oval in shape, measuring about 10° by 22°, so that its maximum diameter is 40 times that of the full moon.

The Zodiacal Band is a very dim, parallel-sided band of radiance which may extend to either side of the Gegenschein, or prolonged from the apex of the Zodiacal Light Cone to join the Zodiacal Light with the Gegenschein. It also is due to sunlight being reflected from interplanetary particles near the main plane of the Solar System.

Meteorites

G J H McCall, Cirencester, Gloucester, UK

Introduction

Meteorites are bodies of metal or stony material mixed with metal which fall to Earth in sporadic and random arrival events, characterized by entry of a fireball or bolide streaking, often with punctuated explosive bursts, through the sky on their frictional passage through the Earth's atmosphere (Figure 1). The history of the gradual scientific acceptance of the reality of such events is followed by a brief description of the classification of various types of meteorite; the four age and time interval measurements significant for any meteorite; and the known or likely provenance in the bodies of the Solar System of the various types are then considered. After a brief mention of impact cratering and tektites, and also 'fossil' meteorites enclosed in ancient rocks, an account is given of the revolution in 'Meteoritics' (essentially an extension of geology, geochemistry, metallurgy, and physics into the realms of astronomy and planetology) during the latter half of the twentieth century. This is a result of space exploration and the recognition of hitherto unknown optimum collection regions (icebound Antarctica; the Nullarbor Plain, Australia; and other desert regions). Examples of some extensions of research into meteoritics in modern state-of-the-art science are listed.

Figure 1 A painting by P.V. Medvedev of the fireball accompanying the Sikhot Alin fall of 1949 (reproduced from McCall 1973).

Historical: the Fall of Stones and Metal from the Sky

Records of shooting stars, bright objects seen to dart across the night sky, go back to Egyptian papyrus writings of *ca*. 2000 BC and records of actual meteorites falling to Earth out of the sky go back almost as far – the fall of a black stone in the form of a cone, circular below and ending in an apex above, was reported in Phrygia about 652 BC, the familiar image of a stony meteorite such as the Middlesborough Meteorite (Figure 2) coming to us from the distant past. The Parian chronicle records falls of stones in Crete in 1478 BC and in 1168 BC of iron. In 618 BC, a fall of stones is reported to have broken

Figure 2 The Middlesborough, England, stone (fell 1881) showing the dark fusion crust and anterior surface in flight, the apex of the cone being in the direction of flight and the radiating flutings being produced by atmospheric ablation (from McCall 1973).

several chariots and killed ten men, a unique fatality. The sacred stone built into the Kaaba at Mecca is reported to have been long known prior to Islam and to have fallen from the sky. Such falls were given a religious significance, and officers of the Geological Survey in India had to go hot-foot to the site of a fall or the mass was either enshrined or broken into pieces to release evil spirits. American Indians confused later scientists by transporting masses long distances and burying them in cysts. Particularly pleasing is the custom in mediaeval France of chaining meteorites up to prevent them departing as swiftly as they arrived or from wandering at night. The earliest material from a fall preserved in western Europe is believed to be at Ensisheim, Alsace, stored in the local church since it fell in AD 1462.

Despite all these early records (and there are many more, in particular from Russia and China), scientists were slow to accept the process of rocky or metal material falling from the sky. Though there are records of the finds of irons and the falls of stones much earlier and the problem had been solved – Diogenes of Apollonia wrote "meteors are invisible stars that fall to Earth and die out, like the fiery, stony star that fall to Earth near the Egos Potamos River (in 465 BC): and natives in northern Argentina had led the conquistadors to buried masses of exotic iron, of supposed celestial origin in 1576 – scientific acceptance was widely achieved only in the last years of the eighteenth century Age of Enlightenment and the earliest years of the nineteenth century, with natives leading the explorer Pallas in Siberia to a buried stony-iron mass reputedly fallen from the sky; also falls were followed by material recovery at Wold Cottage, near Scarborough, Yorkshire and L/Aigle France.

The fall at Albareto, Italy, in 1766, had been well described by the Abbé Dominico Troili, but dismissed as the product of a subterranean explosion which hurled it high in the sky from a vent in the Earth. The stone which fell at Lucé, France in 1768, the first to be chemically analysed, was dismissed as neither from thunder, nor fallen from the sky, but as a piece of pyritiferous sandstone by a panel of august scientists! So it was the Pallas stony-iron meteorite (700 kg, 'Krasnojarsk'), the subject, together with the Otumpa iron from South America, of a book published by E.F.F. Chladni in Riga in 1794, which really established the scientific reality of meteorite falls. Both were exotic, being found far from any known volcanic province, and by a process of elimination, he reached a single possible answer and further connected them with the phenomenon of fireball meteors. Russian scientific circles were distant from western Europe, and the English were really convinced only by the fall of a stone at Wold Cottage near Scarborough in 1795. This came into the possession of Joseph Banks, who recognized the similarity of the black fusion crust to the Siena fall material of 1794 in his possession. Edward Howard studied both and the presentation of his findings to the Royal Society in 1802–1803 convinced sceptics in England. Presentation to the Institut de France convinced several important scientists, but resistance to the idea was not finally overcome in that country until 3000 stones showered down on L'Aigle, Normandy and were described by Biot. Chladni's work then received belated international acknowledgement, but decades would elapse before the connection with fireballs was completely established and a century before the origin of most of them through impacts between asteroids would be established.

Classification

The classification of meteorites has developed over the years and some new types and revisions of the system have inevitably arisen in the last half of the twentieth century with the prolific collection from optimum Antarctic and desert regions; despite this, the system remains workable though some revision might in time be necessary.

There are three principal classes:

Irons (**Figures 3, 4**)
Stony-irons (**Figure 5**)
Stones (**Figure 2**)

The latter are subdivided into (i) Chondrites, which display rounded bodies (chondrules) (**Figures 6, 7**),

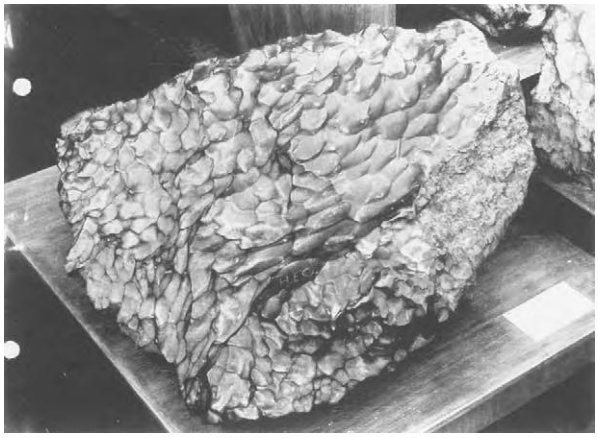

Figure 3 The Haig, Western Australia, iron (find 1951, 480 kg, III AB) with typical hackly markings on the surface.

Figure 4 Cut and etched surface of the Mount Edith iron, Western Australia (find 1913, 160 kg, III AB) showing the Widmanstatten pattern and dark troilite (sulphide) nodules.

Figure 5 Cut surface of the Brenham, Kansas, pallasite stony iron (find 1962, 22 and 9 kg), showing nickel iron (light grey) and olivine (dark) (from McCall 1973).

believed to be relics of a very early accretionary stage in the formation of the asteroidal parent bodies (the chondrules may be wholly obliterated by recrystallization); and (ii) Achondrites, without chondrules, having textures resembling those of terrestrial igneous rocks (Figure 12). The classification used worldwide, as at 2003, is shown in Table 1a and 1b and the statistics of meteorite falls and finds in Table 2.

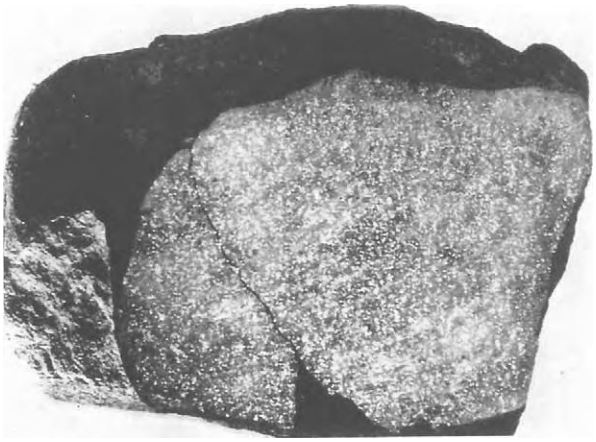

Figure 6 The Cocklebiddy, Western Australia, ordinary chondrite (fall 1949, 0.794 kg), cut face showing specks of light grey nickel iron disseminated in a dark grey silicate matrix: the rounded chondrules are microscopic and thus not visible (from McCall 1973).

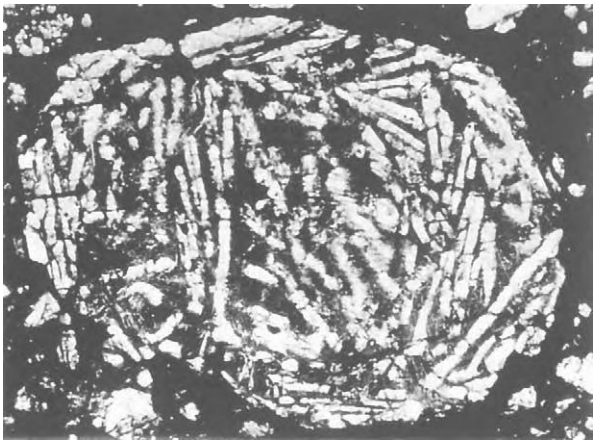

Figure 7 View in a microscope thin section across a chondrule (2 mm diameter) showing elongated olivine crystals and dark glass, within the rounded chondrule, which is set in an aggregate of olivine, pyroxene, and feldspar grains, opaque nickel iron, sulphide and products of secondary weathering (Mulga South ordinary chondrite, Western Australia (from McCall 1973)).

Meteorites within Meteorites

Many meteorites are brecciated, probably mainly due to shock processes through collision with other meteorites in space, but some also carry other meteorite types as fragments within them. Chondrites may occur as fragments within dissimilar host chondrites. Even more spectacular are shocked eucrite achondrite bodies within the Mount Padbury stony iron (mesosiderite) and enstatite and carbonaceous and ordinary chondrite bodies within the Bencubbin stony iron meteorite, both found in Western Australia.

Table 1a Undifferentiated meteorites

Class	*Symbol*	*Example*
Carbonaceous chondrites	CI	Orgueil
	CM	Murchison
	CO	Ornans
	CV	Allende
	CK	Karounda
	CR	Renazzo
	CH	ALH 85085
Rumurutiites	R	Rumuruti
Kakangari type chondrites	K	Kakangari
Ordinary chondrites	LL	Saint Mesmin
	L	L'Aigle
	H	Wiluna
Enstatite chondrites	EL	Eagle
	EH	Saint Sauveur

Carbonaceous chondrites: characterized by sparse to abundant chondrules set in a dark, friable matrix of carbon rich compounds, phyllosilicates, mafic silicates, Ni Fe metal, and glass. The letter symbols separate groups based on different mineralogy, relative abundance of different lithophile and siderophile elements, relative abundance and size of chondrules, and oxygen isotope signatures. Numerical suffixes 3, 2, and 1 denote progressive aqueous alteration and 3, 4, 5, and 6 progressive thermal alteration.
Rumurutiites: a new rare group of chondrites.
Kakangari type chondrites: a small group of chondrites now separately defined.
Ordinary chondrites: chondrules are embedded in a finely crystalline matrix of mafic minerals, pyroxene, and olivine, together with NI Fe metal and glass. Some are recystallised thermally and lose the definition of chondrules and the glass. The H, L, and LL groups differ in the magnesian/iron ratio in the ferromagnesian silicate minerals. The number suffixes 3 7 denote degree of thermal alteration (loss of original texture and recystallization).
Enstatite chondrites: these are chondrites with the Mg rich pyroxene enstatite. The EL and EH groups have different relative abundances of silicates and metals. The numerical suffixes above (3 6) may be applied.

Table 1b Differentiated meteorites*

Class	*Symbol*	*Example*
Irons	I AB	Campo del Cielo
	I C	
	II AB	Sikhot Alin
	II C	
	II D	
	II E	
	II F	
	III AB	Cape York
	III CD	
	III E	
	III F	
	IV A	Gibeon
	IV B	
Stony irons	Mesosiderites	Mount Padbury
	Pallasites	Krasnojarsk
Stones (Achondrites)	Eucrites	Camel Donga
	Diogenites	Johnstown
	Howardites	Kapoeta
	Angrites	Angra dos Rios
	Ureilites	Novo Urei
	Aubrites	Aubres
	SNC Meteorites (Mars sourced?)	
	Shergottites	Shergotty
	Naklites	Nakhla
	Chassignite (Orthopyroxenite)	Chassigny ALH 84001
	Basaltic and anorthositic achondrites (Lunar sourced)	ALH 85085
Primitive achondrites*	Brachinites	Brachina
	Winonaites	Winona

*The primitive achondrites have igneous textures with no chondrules, but their mineralogy and bulk chemistry shows little difference from ordinary chondrites. They are supposed to have undergone igneous processes but with no fractional crystallization, but partial melting and segregation of the phases to varying degrees.
The irons were formerly separated into *octahedrites* (kamacite plus taenite; on etching yield criss crossing Windmanstatten patterns) (**Figure 4**): *hexahedrites* (mostly kamacite, yield only narrow thin Neumann lines on etching) and *ataxites* (no etch pattern). The Symbol classification above which replaced this metallurgical classification is still being modified and I AB and III CD have recently been grouped as I AB III CD. These symbols reflect the differences in chemistry (nickel, gold, iridium content, etc.).
The eucrites have basaltic textures.
Many meteorites defy classification and are listed as unclassified. For example, the Bencubbin (find, Australia) meteorite appears to be a stony iron but is in fact a mixture of four types, an iron, an enstatite achondrite, and two chondrites, one carbonaceous. It would seem to be the result of more than one collision, the first mixing occurring very early in its history (*ca.* 4500 Ma) and causing heating and melting.

Age

There are four periods of time that are significant in the history of any meteorite:

Terrestrial age: the time spent on Earth since fall. Obviously, the material from an observed fall has an immediately known terrestrial age. Cosmic-ray induced isotopes are used to obtain this age from such finds. We know from observed fall meteorites how much of these isotopes are in a meteorite when it arrives. A meteorite found later will have less isotopes because the Earth's atmosphere protected it after arrival, and unstable products of cosmic radiation, such as ^{14}C will decay, so that the difference between the normal content on arrival and that

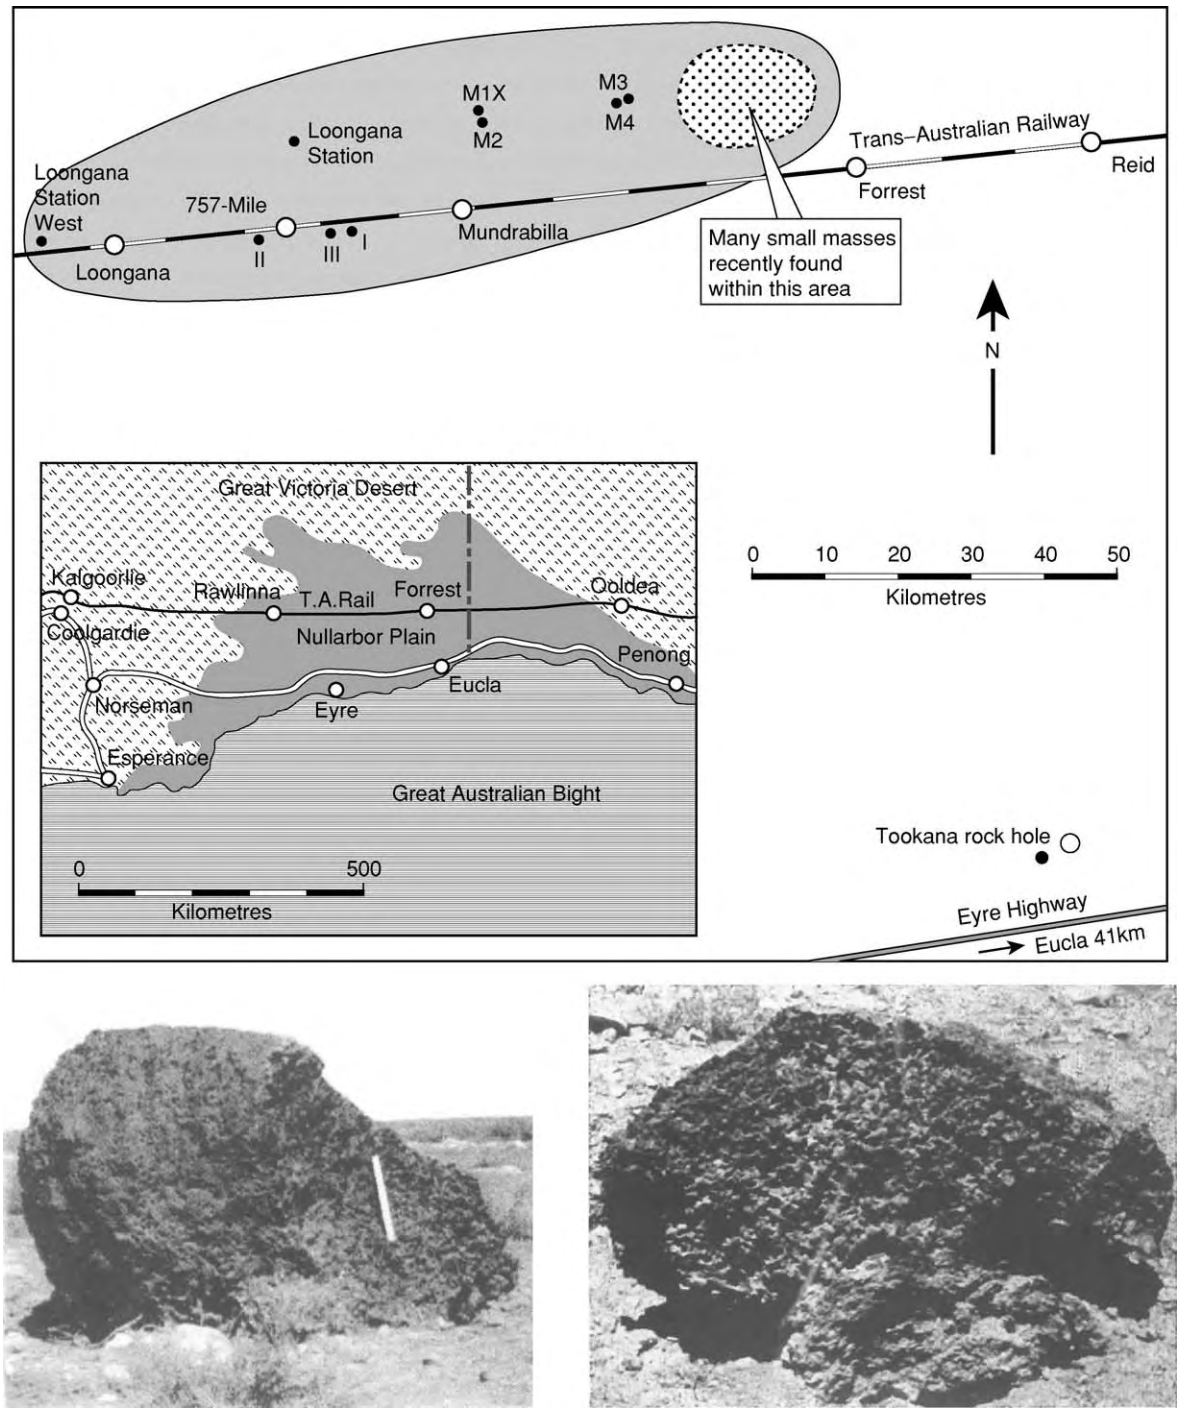

Figure 8 The distribution of the Mundrabilla irons on the Nullarbor Plain, Western Australia (rediscovered 1964 onwards) showing the typical dispersion ellipse. Below left: the M1 mass (est. 11 tonnes), as found, showing the space capsule shape with striations on anterior surface in atmosphere descent: also the curved face where the M2 mass separated. Below right, the M2 mass (est. 5 tonnes), showing the 10 cm pad of iron shale below, the product of a million years weathering by surface agents since fall (from McCall 1999, reproduced with permission of Palgrave Macmillan).

Table 2 The total of known meteorites up to the end of 1999

Class	*Fall*	*Find*	*Total*
Stones	940	20574	21514
Stony irons	12	104	116
Irons	48	817	865
Unknown	5	7	12
Total	1005	21502	22507

(After MM Grady (2002)).

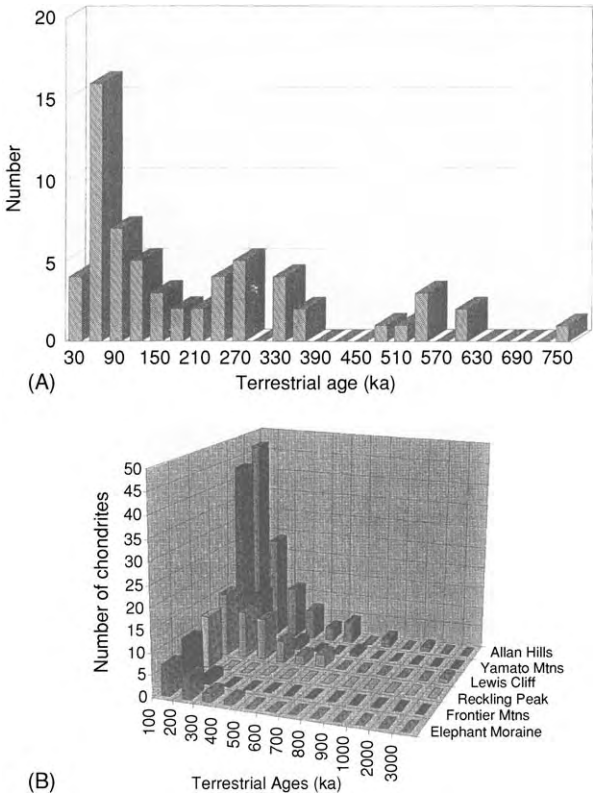

Figure 9 (A) Terrestrial age distribution for meteorites from the Allan Hills main icefield, Antarctica. (B) Terrestrial age distribu tion for 280 Antarctic meteorites sorted by stranding site. (A) from AJT Jull, S Cloudt, and E Cielaszyk; and (B) from ME Zolensky, in Grady *et al.* (1998). Published with the permission of the Geological Society Publishing House, Bath.

measured after the find can be used to determine the terrestrial age. As meteorites decay through natural weathering processes, these ages are usually values of tens of thousands of years, but in arid regions such as the Nullarbor Plain they are likely to be more, even a million years in the case of the large Mundrabilla iron (Figure 8); and in the Antarctic the ages taper off about 300 000 years though a very few have ages of one to three million years (Figure 9).

Cosmic ray exposure age: the time spent as a metre-scale meteoroid orbiting the Sun. Cosmic rays react with some atoms in iron or stony meteoroids and the quantity of gases formed depends on the chemical nature of the meteoroid and the duration of exposure to cosmic rays in space. The most usual measurements are of the quantity of neon gas resulting from this cosmic ray exposure. The evidence suggests that few stony meteorites survive in space without further collisional destruction and pulverisation for more than 40 million years, but iron meteorites are more robust, surviving up to 1000 million years.

Formation age: the age between the last high temperature episode in the parent body and the present. In the case of basaltic achondrites, this represents the time of crystallization from the liquid in a magma: chondrites, which have slightly greater formation ages, did not melt but were hot and recrystallised as solids soon after formation. The method involves the normal radioactive 'clocks' used by geologists, such as uranium-lead, the amount of lead produced by radioactive decay being an indicator of formation age. Values for chondrites are near to 4550 million years; some parent bodies were then heated and melted with fractional crystallization during the next 100 million years.

Formation interval: the time of the formation of the elements in stars (where almost all the elements except H and He were formed) and their incorporation in the parent body. This is done by measurement of the decay products of plutonium, an element which, because of its short half life, does not occur naturally. Plutonium was formed in a star about 150 million years before the formation of the asteroidal parent bodies of meteorites, but other elements were formed at different times.

Provenance

Asteroidal

Meteorites are nowadays accepted as fragments of strays from the asteroid belt between Mars and Jupiter. Prior to the mechanism being established of producing (due to collisions) eccentric elongated orbits for asteroids – replacing their quasi-circular orbits beyond Mars – the nucleii of comets, impoverished in volatiles by repeated passage round the Sun, were long favoured as their source, but petrological and mineralogical evidence is against this. The Farmington fall in Kansas in 1890 seems to have heralded the firm establishment of asteroidal source. Sixty reports of visual observations of this fireball, at 12.50 pm on

a midsummer day and reportedly rivalling the Sun, were selected by scientists who deduced an orbit indicating that the parent asteroid was 1862 Apollo, Hermes, or 1865 Cerberus. Direct observation of fireballs by astronomers of the Sikhot-Alin, Siberia, 1949 and Pribram, Czechoslovakia, 1959 fireballs again strongly supported asteroidal sources and there have been many further supporting observations since (Figure 10). In recent years there have been numerous attempts to use optical and spectrographic methods to equate the reflectance and chemistry of asteroids with different classes of meteorites, but results seem to be inconclusive, possibly because of the operation of little understood space-weathering processes which affect the regolith surface of asteroids. Even a direct exploration mission to Eros in 2000–2001 (Figure 11) yielded no correlation and it must be borne in mind that there must be asteroids of classes never sampled by meteorites falling on the Earth. Several thousand asteroids are now known and it is estimated that there may be as many as 10 000 out there.

Even in these small parent bodies, though some did not reach 100°C, others heated to more than 1200°C, the temperature needed to form a basaltic-textured eucrite. The heat sources in these small bodies are not known for certain, but a source in extreme early heating of the Sun or internal short-lived radioactive isotopes such as ^{26}Al is favoured.

Martian Achondrites?

Some meteorites apparently do not originate from asteroids. The 'SNC' group of achondrites (Shergottites, Nakhlites, Chassignite) (Figures 12 and 13)

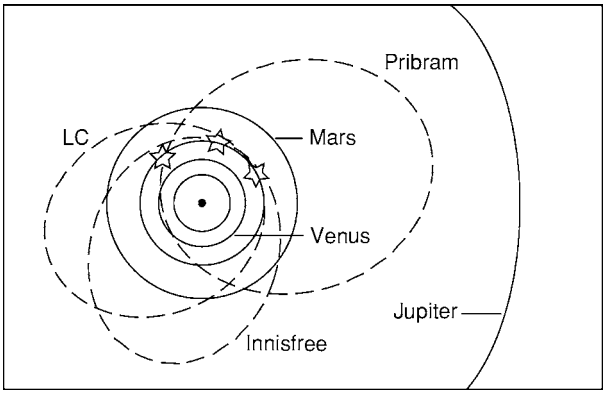

Figure 10 Orbits crossing that of the Earth derived photographically from the falls of the Pribram (Czechsoslovakia), Innisfree (Canada), and Lost City (USA) meteorites. (New figure, after Hutchison and Graham (1992).)

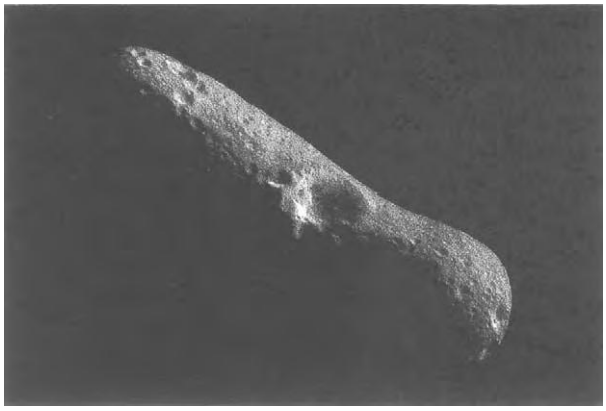

Figure 11 Asteroid 433 Eros (NEAR Shoemaker multispectral NASA image). The large crater, Psyche, has a diameter of 5.3 km.

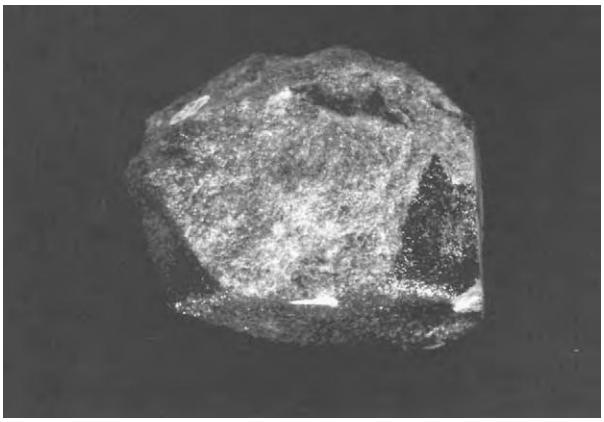

Figure 12 The Nakhla achondrite (fell 1911, Egypt, one of 40 stones, totalling 40 kg); one of the SNC (?Mars sourced) meteorites (from McCall 1999, reproduced with permission of Palgrave Macmillan).

Figure 13 Thin section view of the microtexture of the Nakhla meteorite, a typical achondritic texture resembling that of terrestrial igneous rocks, formed by diopside pyroxene, olivine, and a few plagioclase crystals (×10) (from McCall 1999, reproduced with permission of Palgrave Macmillan).

were first thought to come from Mars because of the presence of oxidised iron and hydrated minerals. Later in the twentieth century, entrapped gases in these meteorites were found to be similar to the Martian atmosphere sampled by Viking missions. The ages of formation of these meteorites (see below) are not those of the asteroidal meteorites (*ca*. 4550 Ma), but fall into two groups – Nakhlites 180 and Shergottites 1300 Ma (equivalent to Earth's Jurassic and mid-Proterozoic). The widely accepted source of these meteorites is Mars – the source must surely be a planet, and the mechanism the spalling off the surface by large impacts (there are theoretical objections to volcanic ejection). However there are problems: the trapped atmosphere should be the planet's atmosphere 180 and 1300 Ma ago, not the present atmosphere, and atmosphere's change with time: also, why are the 26 SNC meteorites recovered to date all a limited range of familiar igneous rocks – Mars is a very diverse surfaced planet? A hypothetical geological history of Mars has been built up by scientists on the basis of these 26 meteorites, an edifice which direct exploration may surely demolish?

The joker in the pack is the famous ALH 84001 from Antarctica, a unique orthopyroxenite, which has a formation age similar to the asteroidal meteorites and contains the famous putative microfossils, the evidence about which seems now to favour inorganic rather than organic origin.

Lunar Achondrites

Lunar achondrite meteorites (Figure 14) so completely match lunar surface rock samples obtained by Apollo and Luna missions that there is no doubt as to their provenance. First found in Antarctica, they have been later recognized in an existing collection from Western Australia and also new finds in the Libyan desert. Volcanic ejection can be ruled out; isotopic evidence suggests that all were spalled off by geologically quite recent and relatively minor impacts on the surface of the Moon, but here there is a glaring unresolved problem. There is widespread scientific acceptance of a major impact bombardment of the Moon 3.9 Ma ago, forming innumerable and immense craters: this must have hurled vast volumes of rock out into space, sampling deep below the regolith and surficial breccia (which is all that has yet been directly sampled), there is no trace of this material in the varied log of meteorites. Where has it gone?

Cratering and Tektites

Meteorites normally land with little effect on the ground – even the 11 tonne Mundrabilla iron left no dent in the limestone surface – but multiple showers may produce small, simple craters (the 1947 Sikhot-Alin shower produced 106 associated with nickel-iron fragments). Larger masses have, in the quite recent geological past, produced kilometre-scale simple craters associated with nickel-iron (e.g., Canyon Diablo, Arizona; Wolfe Creek, Western Australia) and about 170 larger simple craters and more complex ring structures in the geological record are attributed to impact explosion processes involving larger masses, even asteroids. The largest, at 180 km diameter (Chicxulub, Yucatan, Mexico) has been associated with the Cretaceous-Tertiary boundary extinction of life (*see* **Impact Structures**). Only geochemical traces of the impactor have been discovered at such sites. Tektite showers were associated with a very small minority of such structures, but tektites are not meteorites, but are glassy objects melted from the impacted surface rocks, and spread over strewn fields at long distances from the impact sites (*see* **Tektites**).

Figure 14 Lunar sourced achondrite meteorite, ALH 81005 from Antarctica, discovered in 1981, after the first such discovery in 1979 by Japanese scientists in the Yamato Mountains. The structure is that of the lunar regolith breccias and a large white fragment of highlands anorthosite is visible. The cube has sides of 1 cm length (from McCall 1999, reproduced with permission of Palgrave Macmillan).

Fossil Meteorites

The only recorded case of a meteorite being recorded in ancient rocks relates to limestone strata at a quarry near Goteborg, Sweden, where there are 12 horizons crowded with ordinary chondrite meteorites, which must have been derived from rains of stones 480 Ma ago, in the Ordovician, the stones falling onto the limey mud bottom of shallow sea. Meteorites do not fall repeatedly at the same place because of the Earth's rotation and this repetition is astonishing, as it implies repeated globally spread rains of meteorites over a period of about 1.75 million years.

The Twentieth-Century Revolution in Meteoritics

Up to the orbital flight of Sputnik heralding the space age in 1957, the study of meteorites was a quiet museum occupation. The scientific interest in meteorites then exploded because of what they might tell us about planets, satellites, and asteroids.

By coincidence, the year of Apollo XI, 1969, saw a Japanese party find nine meteorites on an area of bare ice in the Yamato Mountains. Antarctica. This 5×10 km area subsequently yielded 1000 meteorites. Blue ice areas and moraines in Antarctica have now yielded approximately 30 000 specimens representing some 20 000 falls. Two principle factors produce the optimum conditions for recovery: weathering is virtually nil in the arid climatic conditions and low temperatures prevailing, and the 'conveyor belt' situation on the ice sheet, snow falling and being buried and compacted to ice together with any meteorites on the surface, the snow moves coastwards and where nunataks (rocky peaks) obstruct its passage, the entrained and buried meteorites are excavated by wind action which removes the ice above (Figures 15 and 16).

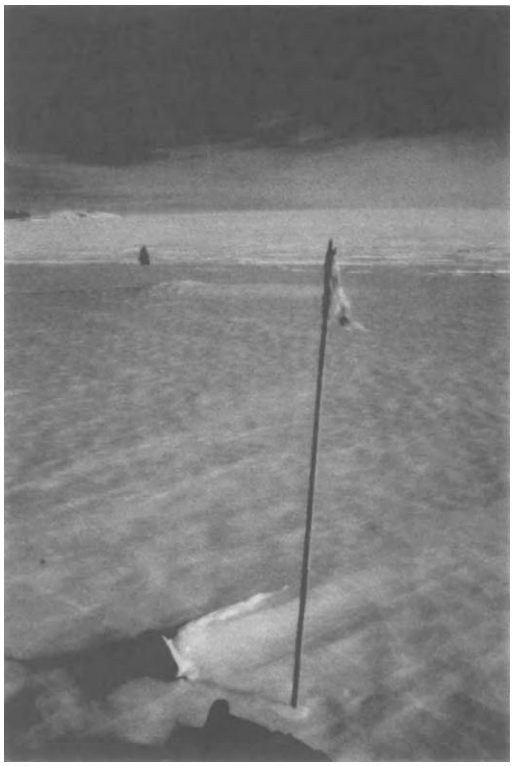

Figure 15 A meteorite as found on blue ice, its position flagged, Antarctica (from McCall 1999, reproduced with permission of Palgrave Macmillan).

By coincidence again, in the 1960s, rabbit trappers kept bringing in meteorite finds strewing the limestone surface of the arid Nullarbor Plain in Western Australia, and the writer of this entry, then working at the Western Australian Museum, wrote prophetically, "that the Nullarbor Plain must be littered with meteorites of all types". This was indeed so and systematic collection has so far yielded about 300 individual meteorites including two shower groups of more than 500 meteorite masses. Other desert areas of the world were then searched and Libya, Algeria, Morocco, and Oman have yielded several hundred finds, while desert areas in Roosevelt County, New Mexico have also proved productive. Neither Antarctica nor the desert areas are 'worked out' and many more finds will undoubtedly be made in the next years of this century. There are some desert areas in Asia, including the Gobi, that are not even searched so far, but a reconnaissance in the Gobi proved disappointing.

State-of-the-Art Research

Meteoritics is a major area of scientific research nowadays and as many as 500 scientists may attend the yearly meetings of the Meteoritical Society. Research topics are extremely varied and besides such related topics as impact processes; tektites; planetary, lunar, satellite, cometary, and asteroid exploration, topics bearing directly on meteorites may include:

- Ca-Al rich inclusions (CAIs) in meteorites, believed to be survivals from the accretion of the Solar System
- Isotope fractionation in pre-solar graphite in carbonaceous chondrites
- Isotope studies of chondrules and CAIs
- Modelling conditions for the launch-window of ?Martian meteorites
- Aqueous alteration of carbonaceous chondrites
- Presolar nano-diamonds in meteorites
- Xenon isotopes in nano-diamonds
- Trapped gases in ordinary chondrites
- Trace elements trapped in lunar meteorites

This random sample illustrates the diversity of research: the revolution in meteoritics described above has produced enough subject material to keep science busy for many decades, if not centuries, and more keeps coming in. The important point to remember that meteorites come in free of charge – they have been called the poor man's 'space probe'. Even the cost of searching after major bolide events, searching Antarctica and systematic searching of the

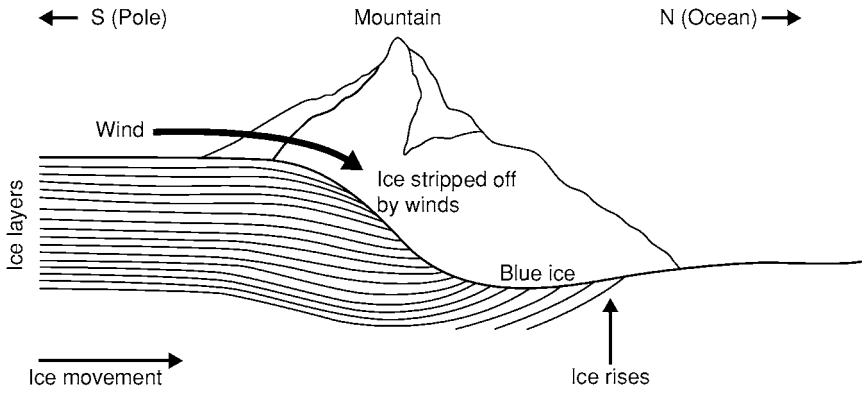

Figure 16 Diagram showing how ice, moving very slowly towards the coastal ice front, is arrested by a rock nunatak, is stripped by wind action while stationary, to reveal entrained meteorites (new figure, after Hutchison and Graham 1992).

Nullarbor are infinitesimal when compared with the costs involved in direct space exploration.

Mercury

G J H McCall, Cirencester, Gloucester, UK

Historical

Mercury, the closest planet to the Sun, was something of a mystery to ancient watchers of the sky, being visible to the naked eye only low down on the horizon close to sunset or sunrise – it is never seen more than 28° of arc from the Sun and is never seen against a dark sky. It was also some time before 'morning Mercury' and 'evening Mercury' where identified as the same planet. Nothing was known of its physical appearance until the advent of telescopes. Its phases and the blunting of its 'horns' (an optical effect) were then recognized (Figure 1). Johann Schroter (1745–1815) and W F Denning (1848–1931) claimed to have detected light and dark configurations, but their sketches bear no resemblance to the real surface as revealed by Mariner 10 in 1974. Denning also claimed to have detected a 25 h rotation period, now known to be erroneous. In 1953 A Dollfus recorded the presence of a tenuous atmosphere, which was later confirmed by Mariner 10, although it is even more tenuous than he supposed. The largest telescope cannot show Mercury as well as the Moon can be seen with the naked eye. Thus, accurate representation of a large part of its surface had to await Mariner 10, which reached a distance of 470 miles from the planet and transmitted images with a resolution of approximately 100 m showing a surface remarkably like that of the Moon, predominantly cratered with scarps, ridges, and plains.

'Vulcan': An Inner Neighbour Planet?

In 1958, Le Verrier received a report that a French amateur astronomer had discovered an innermost planet, closer to the Sun than Mercury. He had earlier found the movements of Mercury to suggest that such a planet existed, but in fact the anomalous movements have since been explained, and it is certain that 'Vulcan', the putative inner planet, does not exist, although some asteroids may pass closer to the Sun than Mercury on their orbits oblique to the ecliptic.

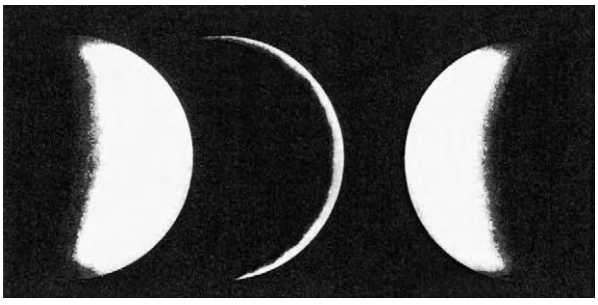

Figure 1 Phases of Mercury showing the optical effect of blunted 'horns'. Reproduced from Cross CA and Moore P (1977) *The Atlas of Mercury.* London: Mitchell Beazley Publications.

Statistics

Mercury is situated within the Solar System 57 850 000 km from the Sun. Its orbital eccentricity is 0.206, as determined by Antoniadi (1870–1943), the largest eccentricity of any planet except Pluto. It is, unlike Venus, brightest when gibbous. The equatorial diameter is 4880 km, intermediate between those of the Moon and Mars, more or less equal to that of Jupiter's satellite Callisto, and less than those of Ganymede (Jupiter) and Titan (Saturn). The escape velocity is 4.3 km s ^{1}, meaning that very little atmosphere is likely to be retained. Its density is surprising, at 5.4 g cm ^{3}; this high value compared with the Moon requires that a heavy iron-rich core takes up a higher relative proportion of the globe than in the case of the Earth. The mass of Mercury is 0.055 times that of the Earth, and its volume is 0.056 times that of the Earth. Its orbital period of 87.969 Earth days is not, as in the case of the Moon, synchronous with its rotation around its axis, which takes 58.65 Earth days. On Mercury there is no area of permanent daylight or night and no twilight zone. It has no satellite. There is a suggestion in the literature that it may have once been a satellite of Venus – the diameter ratio is not unlike that of the Earth and Moon.

Mariner 10 Mission

Technical Summary

All we know in any detail of Mercury is derived from the remarkable Mariner 10 mission, which visited both Venus and Mercury in 1974 on a gravity-assist trajectory. The mission lasted 17 months, and the same instruments were used throughout to obtain information about Earth, Moon, Venus, and Mercury – an advantage in making comparisons. There were two daylight-side encounters with Mercury as well as a night-side encounter, for orbital-change reasons, which allowed measurement of the night-surface temperature, the atmosphere, and the magnetic field. During 17 days of encounter only 17 h were spent

close enough to obtain high-resolution images: 647 pictures were taken during the first daytime encounter and 300 during the second. The peculiar relation between the rotation period and the orbital period of Mercury meant that the same hemisphere was studied during both encounters. The sun rises and sets once during a Mercury day, which is two Mercury years long. During a Mercury day the planet rotates three times with respect to the stars.

Results

Mariner 10 imaged 40% of the lunar-like landscape, covering virtually a complete hemisphere. Despite the startling similarity, the high density of Mercury means that similarity to the Moon is only skin deep. In the 1970s the Moon was considered to supply a 'paradigm' for the understanding of other planets, but the high density and geochemical properties (volatiles, refractory minerals, FeO content in the crust) of Mercury revealed by Mariner 10 suggested that Mercury is the end member of an inner–outer progression of planets, whereas Mercury is anomalous. Of course, if the suggestion that Mercury is a displaced satellite of Venus is correct, then both the Moon and Mercury are anomalous. Only further missions to Mercury will answer this question.

The surface revealed by Mariner 10 has all the features of the Moon, except that it lacks extensive dark smooth plains (e.g. Imbrium) but there are quite substantial areas of lighter smooth-plain terrain, and the circular Caloris Planita feature (the largest single feature so far recognized at 1300 km in diameter) is of comparable extent to some maria and does show resemblance to lunar maria (Figure 2). The smooth-plain material does appear to have lapped over, obscured, and infilled large as on the Moon craters (Figure 3), which were formed in an older, rougher surface formation, analogous to the lunar highlands, although probably not of the same composition.

Craters dominate the entire mapped surface, and, as on the Moon, when one crater interferes with another the smaller crater is usually the intruder. Beethoven, the largest crater on Mercury, has a diameter of 625 km. Tolstoj (Figure 4), at 400 km, is about the same size as Mare Crisium on the Moon and is larger than any lunar crater. Some craters are double or have distorted circular outlines – Bach (225 km in diameter) shows both these features (Figure 5). Other craters have double walls. There are crater-sized rings outlined by annular grooves in otherwise flat plains. There are even circlets of small craters. There are prominent rayed craters like those of the Moon, which are apparently late-introduced features (e.g. Copley, Kuiper, Snori, Mena): Copley (Figure 6) is clearly later than the smooth plains; Mena (Figure 7) displays two anomalous features – one sector totally lacks rays and the rays are both curved in places and do not all emanate from a shared point focus, a characteristic seen at other rayed craters. These features are more consistent with rays being due to deposits along fracture lines than being ejection rays. Central peaks are common and may be single central peaks or off-centre single and clustered peaks.

There are few 'Montes' on Mercury, the only such feature recorded so far being the edge of Caloris Planita. Linear scarps called 'Rupes' are, however, widespread. The albedo is different from that of the Moon – on the Moon iron-rich plain basalts and light feldspathic highland anorthosites make for a dark–light contrast, whereas the surface rocks of Mercury are all relatively light coloured because of their

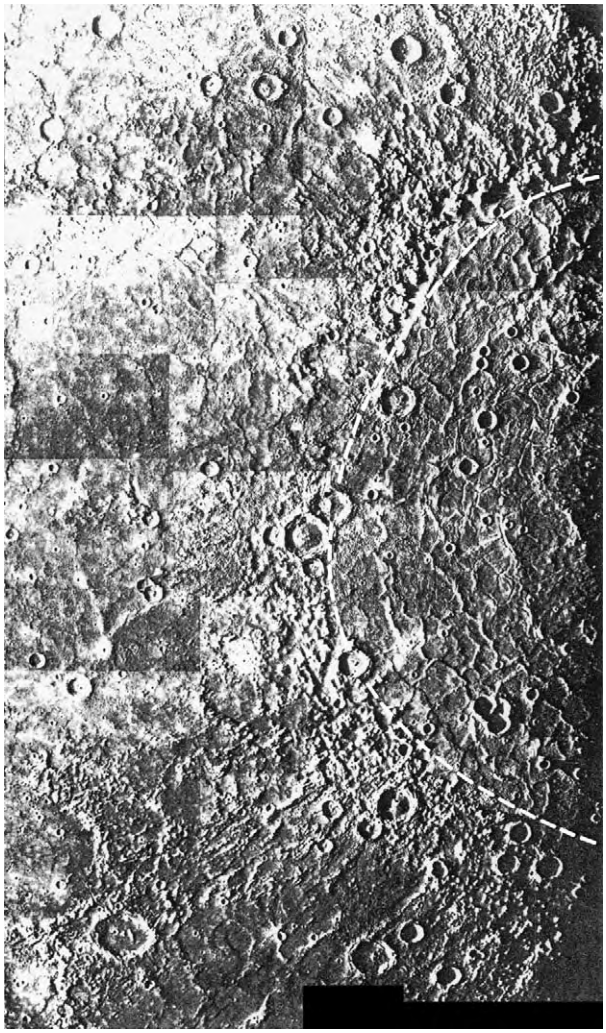

Figure 2 Caloris Planitia (dashed line) showing the concentric ridge pattern. The basin has a diameter of 1300 km. Mountain blocks at the margin rise to 1 2 km above the surrounding terrain and the peripheral linear ridge terrain extends to 100 km from the outer edge. Photograph from NASA image bank.

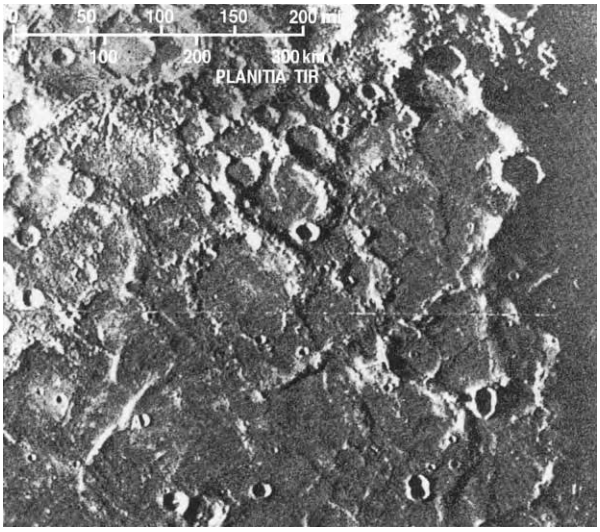

Figure 3 Part of Tir Planitia, on Mercury, showing the flooding of older large craters by smooth plain material.

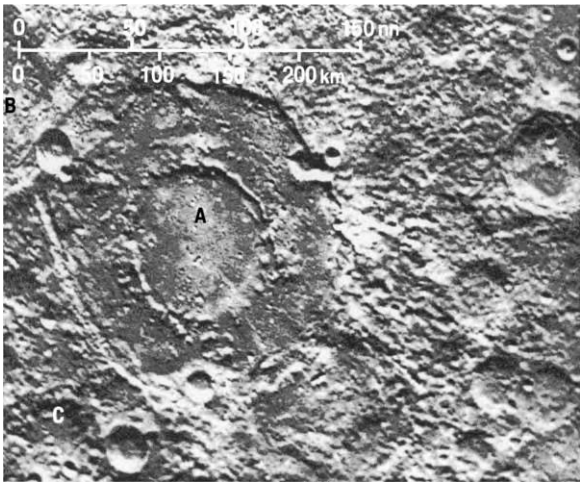

Figure 5 Bach, a double ring crater with plain material in its floor; the shape of the outer ring is subpolygonal and one side has a wall formed by an almost straight groove.

Figure 4 The large crater Tolstoj (outlined by the dashed line), which is comparable in size to the lunar Mare Crisium.

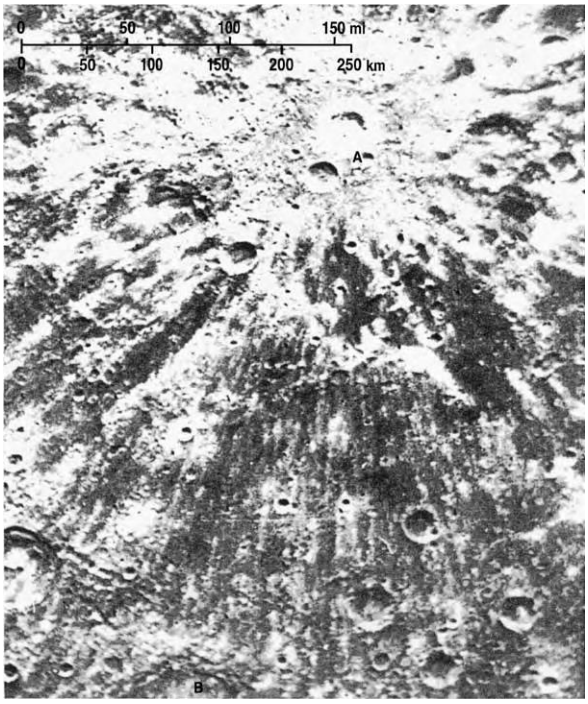

Figure 6 The rayed crater Copley, which is clearly younger than the smooth plain material. The rays extend out into the south east sector for 400 km. Note the irregularity and curved trace of the rays and the fact that rays overprint smooth plain terrain.

iron-poor nature (Figure 8). At the Mercury conference in Chicago in 2001 there was a consensus that the FeO percentage in the rocks of Mercury averages around 3%. This is consistent with models in which the planet was assembled from planetesmals that were formed near the planet's current position. The magmas of Mercury may be similar in composition to the aubrites (enstatite achondrite meteorites), though these are demonstrably from their isotopic character asteroidal, not Mercurian, in provenance.

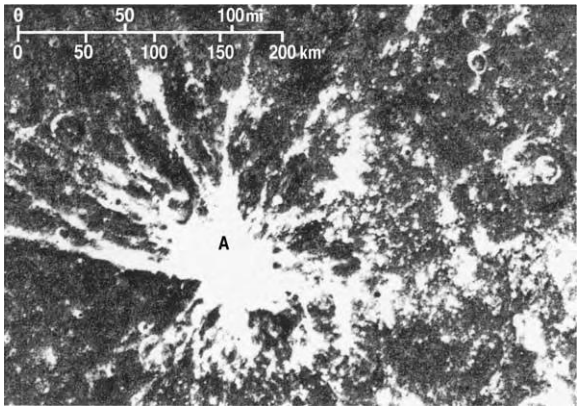

Figure 7 The rayed crater Mena, the rays of which neither emanate from a single focal point nor are straight; they extend outwards for more than 250 km. Photograph from NASA image bank.

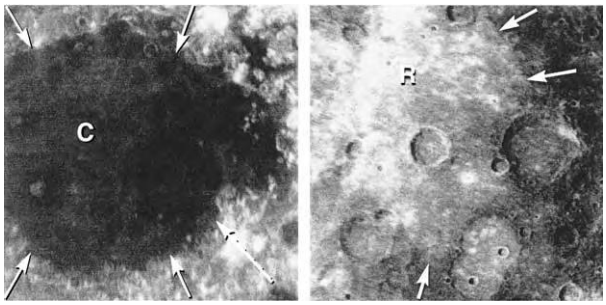

Figure 8 The contrast between the dark floored Mare Crisium on the Moon and the similar smooth Rudaki plains of Mercury; both have embaying boundaries (arrowed). Both images were taken by Mariner 10 and are reproduced from Robinson MS and Taylor GJ (2001) Ferrous oxide in Mercury's crust and mantle. *Meteoritics and Planetary Science* 36: 842 847. © 2001 by the Meteoritical Society.

There are lobate scarps on the surface that may be due to shrinkage (thermal models predict 4–6% shrinkage), and these have been suggested to be the result of thrust faulting.

One entire side of Mercury remains to be seen, and this may be either similar to or very different from the cratered known surface.

The magnetic field was the biggest surprise revealed by Mariner 10. Though only amounting to 1% of the strength of our own planet's field, it is enough to indicate the existence of a core dynamo. Only the strength of the dipole component is at present known, but a solid inner core and liquid outer core are required by the present evidence. Convection in the outer core becomes more complex as the inner core grows. Thermal models suggest that the inner core of Mercury, if it exists, cannot be pure metal, and a non-metal such as sulphur is required to lower the crystallization temperature and density.

Volcanism on Mercury?

The impact-cratering paradigm is part and parcel of NASA's exploration and interpretation philosophy. For example, a presentation by Potts and others in 2002 made the assumption that the overall cratering results from 'bombardment time'. It remains possible, however, that many supposed impact craters, especially simple craters and some very complex structures, on surfaces of space bodies may have been too summarily dismissed as due to impact. Past volcanism is manifest on Mars, the Moon, and Venus, and there is active volcanism on Io. The widespread plains material on the surface of Mercury, as revealed by Mariner 10, though not as extensive as the larger lunar Maria, could be the result of primary volcanic flows or lobate crater ejecta. Study of the theoretical possibilities by Milkovich and others, published in 2002, indicates that widespread volcanism or no volcanism whatever or something in between are all possible. No volcanic features can be identified in the Mariner 10 images, although at the same image resolution few, if any, volcanic features would be identified on the Moon without the prior knowledge obtained by Apollo on-the-ground examination. High-resolution low-sun-angle images from Mariner 10 do show what appear to be flow fronts on Mercury; these could be volcanic lava flow fronts or ejecta flows. It seems likely that Mercury may show the same 'freezing' of the surfaces of lava flows as seen on the Moon, with lava of a basaltic (*sensu lato*) or a peculiar Mercurian petrological character preserving a plains surface among the craters and flooding some craters that were formed in the early history of the planet, perhaps around 4 Ga ago, with, as in the case of the Moon, very little having happened since then except for minor-scale impacts. This is, however, no more than informed speculation – Milkovich and others are correct in concluding that a clear assessment of the role of volcanism and whether it is primary or secondary (impact generated) must wait for better data.

Nevertheless, there are many features in the Mariner 10 database that appear to be incompatible with impact origin – for instance, the sprinkling of an area about 400 km across centred on the crater Zeami with a myriad of small craters, all virtually the same size. These have been dismissed as 'secondaries', but this explanation appears facile. The scalloped walls of the largest crater, Beethoven (Figure 9), are anomalous in an impact crater, and it lies in the centre of a cluster of similarly scalloped-walled craters that include double and triple rings. Unfortunately,

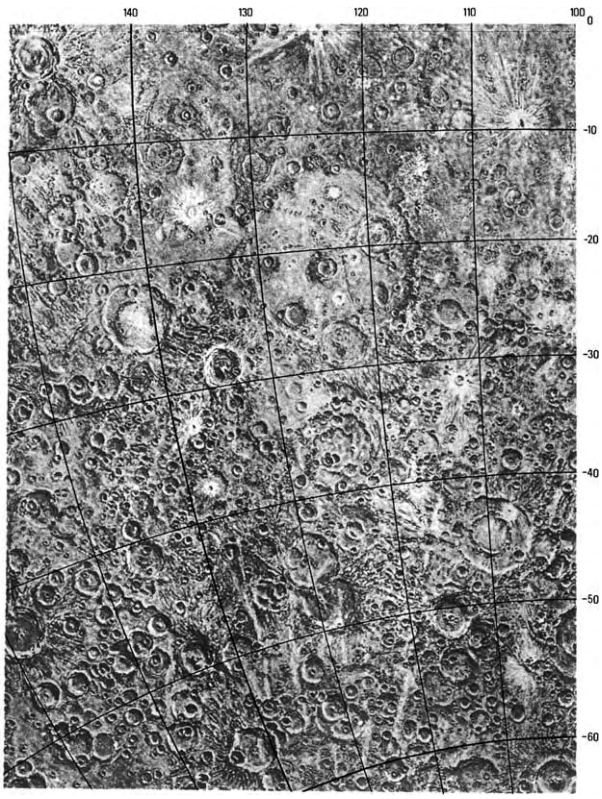

Figure 9 The area around Beethoven, the largest Mercurian crater, showing its scalloped walls and its position within a cluster of scalloped walled craters including doubles and triples. Photograph from NASA image bank.

rigorous analysis of cratering features appears to have lapsed amongst planetologists, with the convenient assumption that impact craters can be secondarily modified in every conceivable way – and so all can be dismissed as products of the 'Great Bombardment'.

It must be concluded at the post-Mariner 10 state of knowledge that Mercury probably has had no volcanic activity, like the Moon, for nearly 4 Ga, but that the heavily cratered 'lunar-like' terrain cannot, as yet, be entirely dismissed as impact generated, and volcanism (either primary and endogenous or secondary, exogenous, and impact-generated) may have contributed significantly to the early formation of the crater dominated surface of Mercury. Future Mercury-directed missions will hopefully resolve this problem.

The success of Mariner 10

Mariner 10 told us just enough for us to realize how interesting it would be to plan return missions, more technically equipped and specifically designed, and building on Mariner 10, to answer outstanding questions, but Mercury remained the elusive planet until 2001 when the two new 'Messenger' and 'Bepi Colombo' missions were proposed.

The Future: 'Messenger' and 'Bepi Colombo'

It requires considerable energy to put a spacecraft into orbit around the innermost planet. NASA's 'Messenger' will use multiple gravity-assist encounters when it is launched in 2004 to reach Mercury in 2009. The European Space Agency and Japan Institute of Space and Astronomical Science's 'Bepi Colombo', to be launched in 2009 and arrive in 2012, will use propulsion technology, which is costlier and riskier but reduces the transit time from 5 years to 2.5 years. Messenger will study the nature of the surface, geochemistry, the Space environment, and ranging. Bepi Combo's remit is not fully worked out but will include geochemistry. It will deploy two orbiters and a lander. Thus, the nature of the unexplored side of the planet at least will be revealed when the orbiters send back the data.

The thermal environment provides the biggest challenge, with the Sun being more than 11 times as intense as on Earth and temperatures reaching up to 400°C on the sunlit side. The high temperature causes stress in equipment and may inhibit full uptake of geochemical data. The collection of mineralogical data is similarly inhibited by the blocking out of some infrared bands. Bepi Colombo will carry an actively cooled infrared spectrometer to counter this. Use of conventional solid-state detectors is impossible without power-hungry active cooling. Solar panels decay under such high temperatures. Despite these constraints, both missions will use photon (gamma, X-ray, optical) and neutron spectrometers to provide impressive geochemical information.

These two missions will research the magnetic field and its implications for the core configuration. Experiments will determine whether there is an inner core, decoupled from the rest of the planet. These experiments are important in understanding the geophysical properties of the planet and its volatile inventory, sulphur being a volatile element.

Space weathering by micro-impacts is likely to be greatly enhanced on Mercury compared with the Moon because of the flux of incoming particles close to the Sun (*ca.* X 20% has been suggested) but, because of the magnetic field, this effect may be limited to an equatorial belt. Mercury has a long comet-like sodium tail, which is probably caused by particle sputtering.

Ground-based radar observations suggest that there may be water-ice in the polar regions – high

radar reflectivity suggests ice, possibly mantled by dust. There is similar evidence from craters where the surface is in 'shadow' from direct solar heating. Thermal models, however, predict that ice would not be stable there. The two missions will investigate this problem.

The tenuous atmosphere will also be the subject of investigation. Ground-based spectroscopy has detected a high sodium to potassium ratio. This is the case in the Moon's exosphere, and there it is related to the ratio found in the returned lunar-surface rocks. However, the Mercurian ratio is very large and shows diurnal variations; it appears to be related to the magnetic field rather than to the surface rocks.

Data return to Earth will also be constrained, because Mercury and the Sun interfere with radio transmission during part of the duty cycle. Antenna design is critical and constrained by weight limits and the fact that pointing antennae will tend to fail owing to the thermal cycling. Two fixed-phase array antennae on Messenger will limit the data return rate, and the same constraints will affect Bepi Colombo's planetary orbiters.

The two missions will overlap in their remits. Unfortunately, there seems to be little scope for short-term adjustment of the remit of the later Bepi Colombo mission on the basis of Messenger findings as the launch of the former in 2009 will coincide with the duty of the latter.

The orbits of both missions will, of necessity, be highly eccentric, and periapsis for Messenger will be over the north pole, so the southern hemisphere will be less well mapped. Thus, it would be ideal if Bepi Colombo had its periapsis at the south pole.

Conclusion

The idea that Mercury is a displaced satellite of Venus, though perhaps unlikely for astronomical reasons, must, unlike the 'Vulcan' concept, be taken seriously, in view of the surficial similarity to our Moon. If true, it would relegate the popular but criticized 'big planet collision' model for the origin of our Moon to the outer limits of credibility, for two such collisions of like dimensions are beyond the realms of probability.

The surface rocks of Mercury have been likened to the aubrite meteorites (enstatite achondrites) in their low FeO content (though we know from isotopic evidence that these achondrites do not come from Mercury). If the surface of Mercury was moulded by a giant bombardment as is widely supposed for the surface of the Moon, then the vast amount of internal rock material ejected into Space must be somewhere. Like the ejecta from the Moon's supposed Great Bombardment, this is as yet unrecognized among Space bodies. Because the Mercury ejecta was sent out closer to the Sun, total spiralling into the Sun is more conceivable as a reason for this absence, but it is still to be expected that some of it would have formed breccias by collision with asteroids. Once we know more about the nature of Mercurian rocks it will be possible to search for such foreign material in asteroidally sourced brecciated meteorites.

The renewed interest in Mercury is welcome, for the astonishing resemblence of its surface to that of the Moon revealed by Mariner 10 does suggest that when we know more about Mercury we will be able to extend this knowledge to the prime conundrum of the Earth–Moon system, and we may have to reject out of hand models for the Earth–Moon system that are at present widely supported (as we had to throw out the concept of lunar tektites after the Apollo and Lunar missions). Geologists would value more than anything a Luna-style retrieval and return of a rock sample from Mercury, but, alas, it appears that the technical obstacles are overwhelming. Yet there seem to be no limits to the ingenuity of Man. One thing is certain, there will never be a 'one step for mankind' on Mercury, such are the physical constraints.

Venus

M A Ivanov, Russian Academy of Sciences, Moscow, Russia
J W Head, Brown University, Providence, RI, USA

Introduction

Venus, similar to Earth in many ways, also shows many differences and provides insight into different paths of evolution that can be taken by Earth-like planets. The atmosphere of Venus is predominantly carbon dioxide; surface temperatures exceed the melting point of lead and surface pressures are almost 100 times that of Earth's atmosphere. The crater retention age of the surface of Venus is very young geologically, similar to that of the Earth; however, plate tectonics does not seem to be recycling the crust and lithosphere at present. The surface is dominated by regional volcanic activity and vertical crustal accretion, and regional tectonism appears to have been much more pervasive in the earliest part of the preserved stratigraphic record, dating from less than a billion years ago. The characteristics and distribution of superposed impact craters suggest that a major resurfacing event, perhaps catastrophic in nature, occurred on Venus in its relatively recent geological history. Venus may thus be characterized by relatively recent episodic heat loss, rather than the more monotonic loss thought to be typical of the other Earth-like planets. Despite the fact that the majority of the preserved geological record on Venus dates from the last ~20% of its history, Venus may provide insight into processes, such as the formation of continents, that operated in the first half of Earth history.

Venus is the second largest terrestrial planet by size after Earth, and in major characteristics is close to our planet: The radius of Venus is 6051.8 km (0.95 of Earth's radius), its mass is 4.87×10^{27} g (0.81 of Earth's mass), bulk density is 5.24 g cm ^{3} (0.95 of Earth's density), and surface gravity is 8.87 m s ^{2} (0.91 of Earth's gravity). For decades, Venus was considered as a 'twin' planet to Earth. Current knowledge of Venus geology is derived from several interplanetary missions, including landers and orbiters, as well as Earth-based observations. In the mid-1970s, the former Soviet Union conducted a series of successful landings; the Soviet landers transmitted panoramas of the surface of Venus, in addition to data on the near-surface environment, on surface rocks, and the chemistry of the atmosphere. The Pioneer Venus was the first American orbiter of Venus; launched by the United States in 1978, the Pioneer Venus collected data on global topography and gravity. The fundamental findings of this mission were that the global Venus hypsogram, in contrast to that of Earth, is characterized by one peak corresponding to the mean planetary radius (MPR), about 6051 km (**Figure 1A**), and that the gravity and topography of Venus are highly correlated. Three major topographic provinces characterize the surface of Venus (**Figure 1B**): lowlands (below MPR, ~11% of the surface), midlands (0–2 km above MPR, ~80% of the surface), and highlands (>2 km above MPR, ~9% of the surface). The spatial resolution of the Pioneer Venus imaging radar was too low to describe morphology of the surface in detail.

The systematic photogeological study of Venus began when high-resolution radar images were collected by the Soviet Venera-15/16 orbiters and by Earth-based radar observations from Arecibo Observatory. At a resolution of ~1–2 km, Venera-15/16 mapped the surface in the northern hemisphere above ~30° N; images from the Arecibo telescope covered a large area between 65° S–65° N and 270° E–30° E. In the early 1990s, the United States Magellan orbiter provided almost complete coverage (~97% of the surface) of Venus, providing high-resolution images (100–200 m) and medium-resolution altimetry

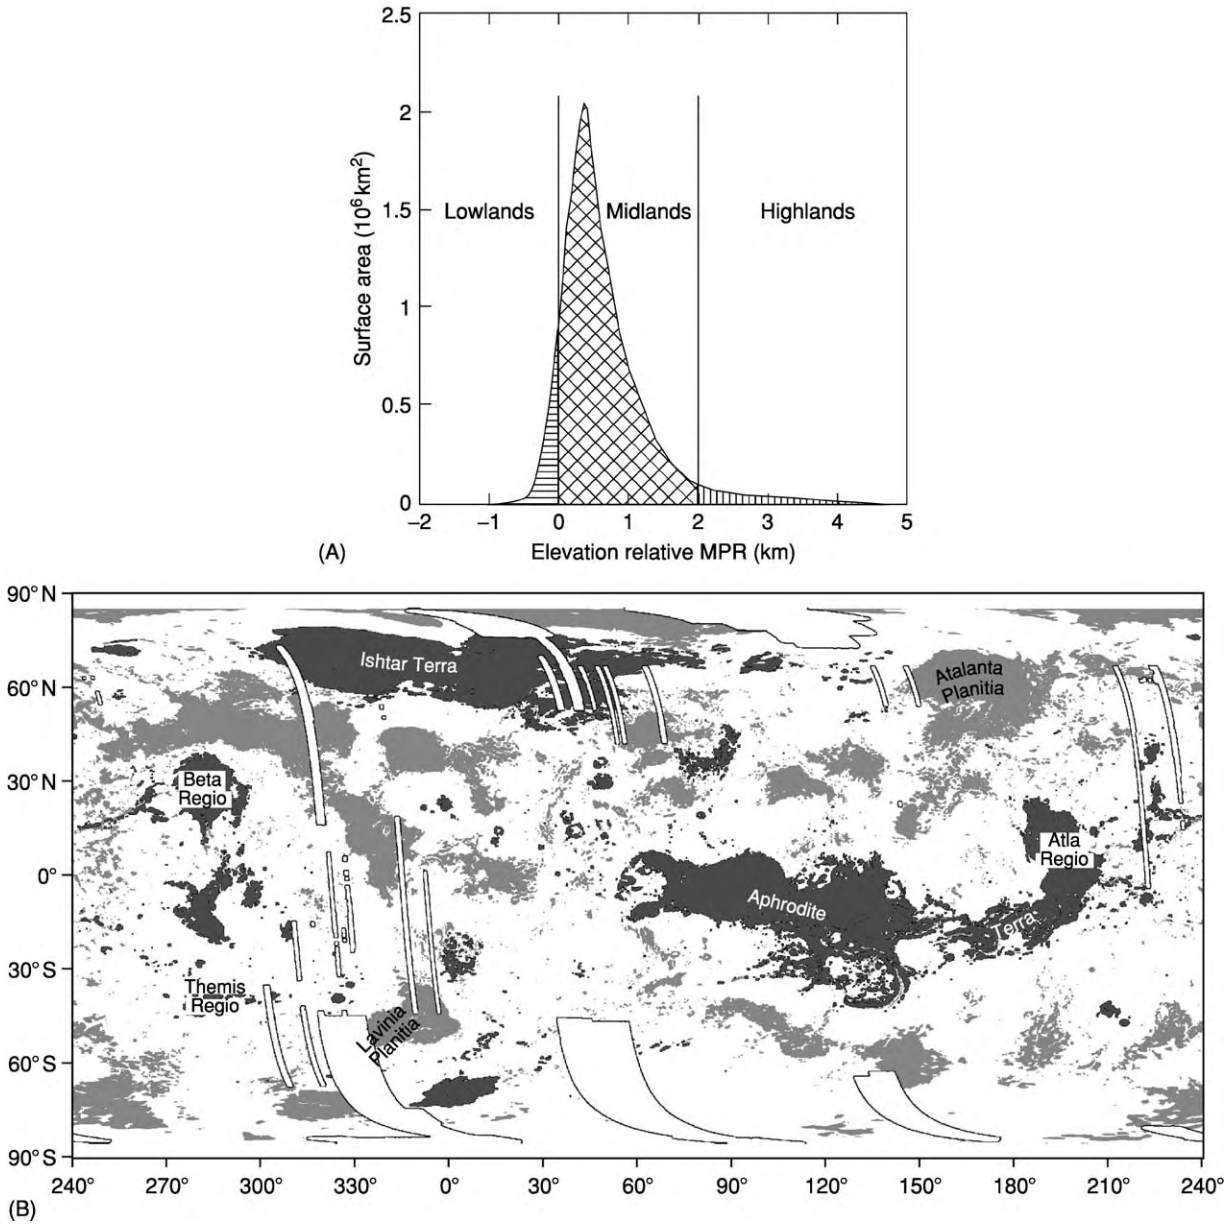

Figure 1 Characteristics of the global altimetry of Venus. (A). The Venus hypsogram (the fraction of surface area vs. elevation) has one peak, implying the absence of the surface elevation dichotomy that characterizes the distribution of the surface elevation on Earth (high standing continents and low lying ocean floor). The mean planetary radius (MPR) of Venus is 6051.84 km. (B) The map in simple cylindrical projection, showing the areal distribution of the three major topographic provinces of Venus. Lowlands (light grey, below 0 km), midlands (white, 0 2 km), and highlands (dark grey, above 2 km). The majority of the surface is within the midlands.

(~20-km footprint). Magellan also collected data on the Venus gravity field.

Surface Conditions and Rock Composition

In contrast to Earth, a very dense atmosphere (the pressure at the surface is ~95 bar) consisting primarily of CO_2 (Table 1) blankets Venus. The relative role of three major contributors to the atmosphere, primordial nebular material, volcanic outgassing, and influx of volatiles by comets, in the formation of the present atmosphere is an open question. Although the current atmosphere is very dry, a minute quantity of water is still detectable. An important feature of water in the Venusian atmosphere is that the deuterium/hydrogen (D/H) ratio is 150 ± 30 times higher than is found in terrestrial water. If water on Earth represents a sample of primitive water on Venus, the Venusian D/H ratio suggests that, depending on the

escape flux of hydrogen and deuterium, originally Venus had 260 to 7700 times the current amount of water. Such an amount is equivalent to a global layer of water 4 to 115 m deep.

The dense and dry atmosphere on Venus results in a strong greenhouse effect that governs the conditions on the surface, leading to very high near-surface temperatures (~740 K) and equalizing the temperatures over the planet. Important consequences are the absence of both free water and water erosion, along with significantly reduced wind activity. Thus, the principal factors resurfacing Venus are volcanism and tectonics. Volcanism is the main mechanism driving the growth of the Venusian crust. The chemical compositions of the surface rocks have been measured at seven landing sites (Tables 2 and 3). The rock chemistry correlates with the compositions of terrestrial basalts, suggesting that volcanism on Venus is mostly basaltic.

Surface Population of Impact Craters

A study of the spatial density and distribution of impact craters is the principal means of understanding the age of the surface and the history of resurfacing of planetary bodies. There are 968 impact craters on the Venusian surface, making the mean crater density ~2 craters per 10^6 km^2. This value implies that the surface of Venus is relatively young; depending on the models of the flux of projectiles crossing the orbit of Venus, the surface is estimated to be from 300 to 750 My old.

A discovery of fundamental importance is that Venus lacks the densely cratered terrain characterizing significant portions of the surface of the Moon, Mars, and Mercury (Figure 2). Thus, Venus does not display the surface age dichotomy typical of the smaller terrestrial planets. Detailed study of the spatial distribution of surface craters, either by Monte Carlo simulations or by near-neighbor analyses, has shown that the distribution of impact craters is very close to a completely spatially random distribution (Figure 2). Another important characteristic of impact craters on Venus is their state of preservation. A global survey of craters has revealed that a majority appear to be morphologically pristine (Figure 3A), with only a small percentage either embayed by volcanic flows (about 2.5%; Figure 3B) or deformed tectonically (about 12%; Figure 3C). The small total number of impact craters on Venus, their predominantly pristine morphology, and their almost completely random spatial distribution may be explained by two alternative end-member models. In the first model, the catastrophic resurfacing model, the craters on Venus are considered to belong to a production population, with the planet now in the stage of accumulation of craters. This model proposes that the observable geological history of Venus (the last ~10–15% of the total history) began after a major planet-wide and relatively short 'catastrophic' episode of resurfacing that reset the crater record. The present crater population is thought to be accumulating since that time, in an environment of sluggish endogenous activity. Alternatively, the equilibrium-resurfacing model proposes that the actual crater population is in equilibrium with the current volcanic and tectonic activity that occurs within small areas ~400 km across. These two models imply fundamentally different histories and modes of geology on Venus. In the catastrophic model, the geological history is considered to be episodic, whereas the equilibrium-resurfacing model implies a steady-state (more Earth-like) history.

Table 1 Composition of the atmosphere of Venus

Atmosphere component	*Elevation above the surface (km)*		*Content*
	From	*To*	
CO_2	1.5	63	97 ± 4 vol. %
N_2	1.5	63	1.35 4.5 vol. %

Major Surface Tectonic, Volcanic, and Volcano-Tectonic Features

Image and altimetry data reveal a rich array of volcanic and tectonic features on Venus, implying a complex geological history. In the practical absence of erosion on Venus, the features shaping its surface are well preserved and directly portray the volcanic and tectonic processes that have formed them. The most important terrains, tectonic structures, and volcanic material units making up the surface of Venus are listed in Table 4.

Major Tectonic Features

Tessera terrain The tessera terrain (Figure 4) is among the most deformed regions on Venus. Tesserae are defined as radar-bright, topographically elevated, equidimensional or elongated areas that are complexly deformed by at least two sets of coupled contractional (ridges) and extensional (grooves) tectonic structures. Tesserae cover ~8% of the surface of Venus; the size of individual tessera occurrences varies from a few hundred kilometres up to several thousand kilometres. The largest tesserae occur on the surface of major plateau-shaped highlands of Venus (Figure 1B). The smaller tesserae are within the midlands and only a few small fragments of a tessera occur on the floor of large lowland basins. Tessera terrain is concentrated in the equatorial zone and at high northern latitudes; there is a distinct paucity of tessera terrain south of about 30° S (Figure 5), where the vast low-lying plains dominate the surface of Venus. The elevated regions where the major rift zones are associated with coronae and large volcanoes represent another type of territory where

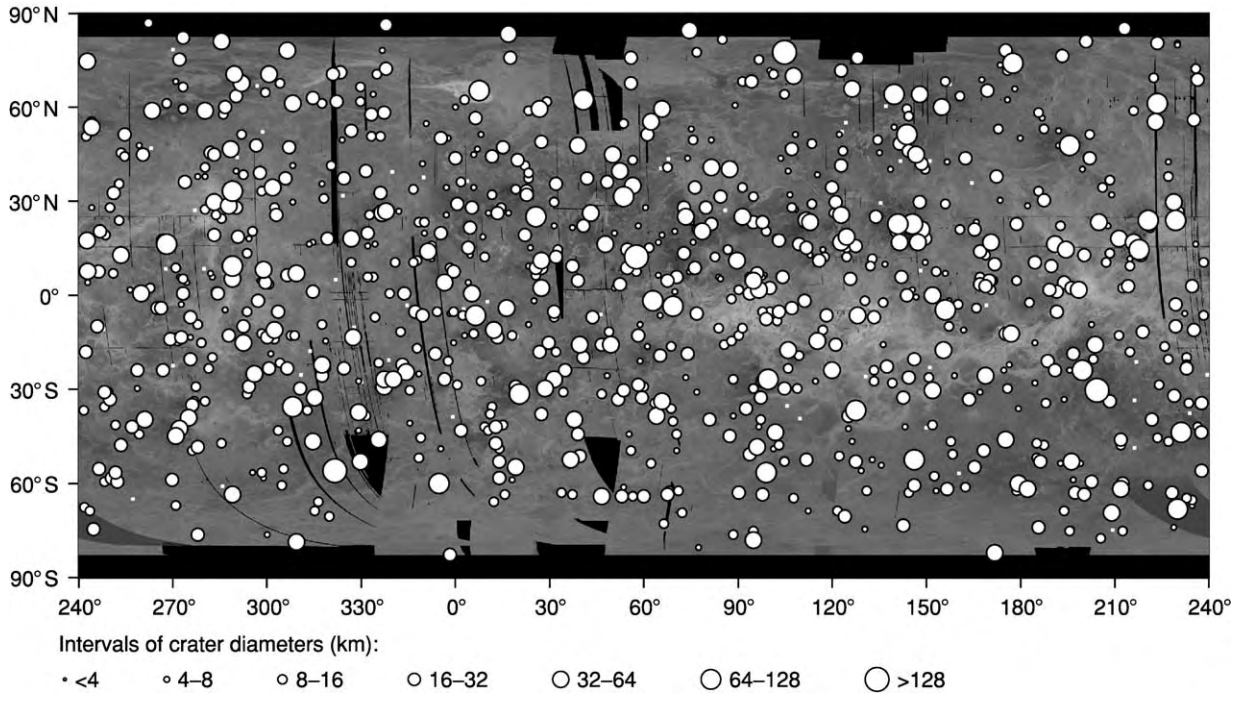

Figure 2 The spatial distribution of impact craters (white dots) on the surface of Venus is very close to a spatially random distribution. There is no evidence for the bimodal distribution of crater density characterizing the surface of Mercury, Moon, and Mars, where the heavily cratered terrains are in contact with lightly cratered plains. Crater size on Venus corresponds to the different intervals of diameters indicated at the bottom of the map. The map is in simple cylindrical projection.

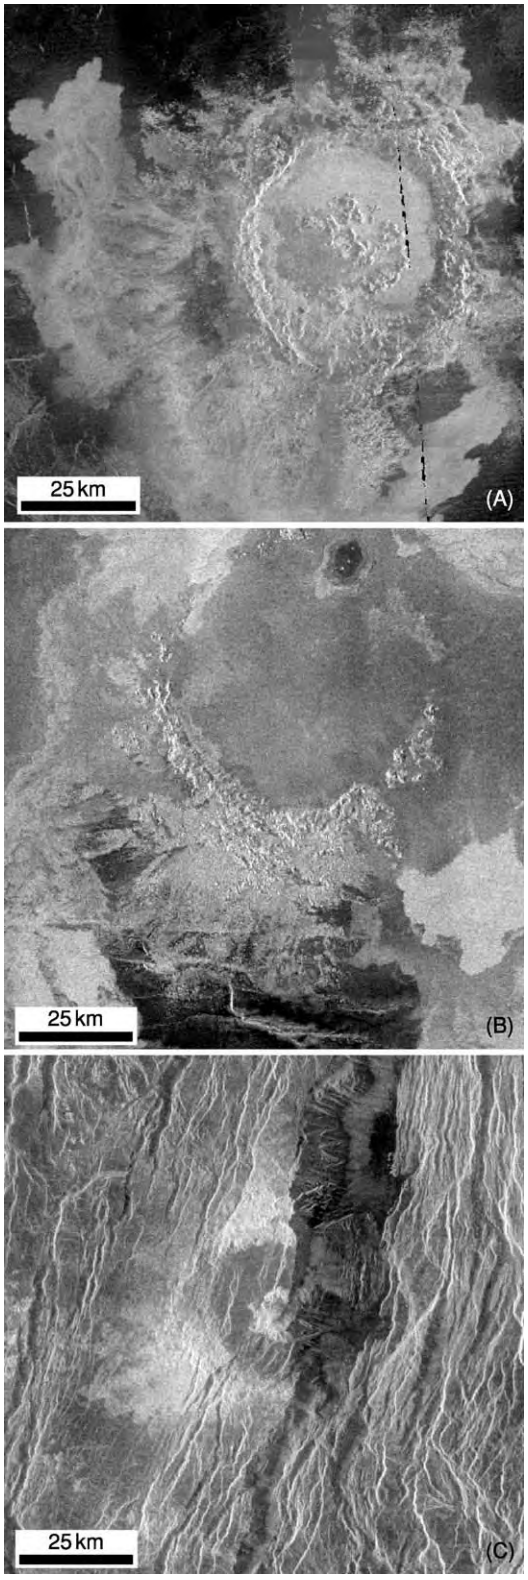

Figure 3 Morphology of impact craters on Venus. (A) Impact crater Caldwell (23.6° N, 112.4° E, 51 km) is characterized by a pristine morphology, a radar bright floor, and extensive outflows (south and west of the crater) superposed on surrounding plains. Fragment of C1 MIDR.30N117; illumination is from the right. (B) Impact crater Gautier (26.3° N, 42.8° E, 59.3 km) is heavily embayed by volcanic flows; only the southern half of the crater rim is visible. Dark material at the bottom of the image is regional wrinkle ridged plains on which ejecta from the crater are superposed. Younger lobate plains embay both the crater materials and the regional plains. Fragment of C1 MIDR.30N045; illumination is from the left. (C) Impact crater Balch (29.9° N, 282.9° E, 40 km) is severely deformed by tectonic structures of the Devana Chasma rift zone in Beta Regio. Only the western half of the crater is visible (center of the image); the eastern half is almost completely destroyed. A small fragment of the easternmost part of the rim is visible among individual graben of the rift zone. The position of the eastern rim suggests horizontal extension across the rift. Fragment of C1 MIDR.30N279; illumination is from the left.

tessera terrain is rare or absent. The surrounding plains embay practically all tessera massifs, meaning that the tessera is the oldest recognizable unit on Venus.

Densely fractured areas On the surface of Venus small areas are heavily dissected by numerous subparallel, densely packed, narrow and short lineaments (Figure 6). The lineaments that are wide enough to be imaged appear as fractures and imply a tectonic environment of extension during their formation. The dense fractures typically deform low-relief areas with an overall smooth surface, suggesting that these were initially lava plains. Densely lineated plains predominantly occur within midlands and there are almost no outcrops of the unit within vast areas of regional plains in lowland basins. The densely fractured areas and lineated plains occupy a small percentage of the Venusian surface and typically form small (tens of kilometres across) equidimensional, elongated, and arc-like occurrences (Figure 7) that sometimes form rims of coronae and corona-like features. Where the plains and tesserae are in contact, there is evidence for embayment of the tesserae by the material of densely lineated plains (Figure 8), suggesting that the plains are younger. Other plains units embay occurrences of densely lineated plains, which means that this unit represents one of the oldest terrains on Venus.

Ridge belts and ridged and grooved plains In some areas on Venus there are distinct belts consisting of swarms of contractional ridges (Figure 9). The linear and curvilinear ridges, 10–15 km wide and several tens of kilometres long, have smooth surfaces, rounded hinges, and appear to be symmetrical in cross-section. The ridge belts and individual ridges deform ridged and grooved plains and gradually merge with the surface of these plains, suggesting that they are tectonic facies of the same material unit. The ridged and grooved plains and ridge belts comprise less than 5% of the surface of Venus and

Table 4 Classification of the major features and terrains on Venus

Feature/terrain	Shape of occurrences	Dimensions	Areal distribution	Topographic characteristics		Associated tectonics	Associated volcanism
				Background	Relief		
Regional tectonic features							
Tessera	Equidimensional, elongated, irregular shape	A few 100s up to ~1000s of km across	Megaclusters, arcs; mostly in northern hemisphere	Midlands and highlands; rare in lowlands	Major regions are a few km high	Crisscrossing ridges and grooves	No evidence
Areas of dense fractures	Equidimensional, elongated, arc like	10s to a few 100s of km across	Dispersed patches; clusters in places	Midlands; rare in lowlands	Little relief	Dense narrow and short fractures	No evidence for contemporaneous volcanism
Ridge belts	Compact, elongated belts	100s to 1000s of km long, 10s of km wide	Major area is in a fan shaped area in the northern hemisphere	Midlands and lowlands; rare in highlands	Rises, several 100s of m	Linear ridges a few km wide and tens of km long	Associated with specific volcanic plains
Fracture belts	Belts and arc and star like occurrences	100s to 1000s of km long, 10s of km wide	Belts, swarms in both hemispheres	Midlands to lowlands	Rises (100s of m high) in places; central valley	Dense fractures and graben up to 100s of km long	In places, evidence for contemporane ous volcanism
Rift zones	Elongated zones	1000s of km long, 100s of km wide	Equatorial zone, Beta Atla Themis regiones	Highlands to midlands	Deep (a few km) depressions	Fractures and graben	Volcanic plains in places
Regional volcanic plains							
Densely lineated plains	Equidimensional, elongated, arc like	10s to a few 100s of km across	Dispersed patches; clusters in places	Midlands; rare in lowlands	Low relief	Dense narrow and short fractures	Plains volcanism, no discernible sources
Ridged and grooved plains	Elongated, belt like, equidimensional	100s (up to 1000s) of km long, 10s of km wide	Major area is in a fan shaped area in the northern hemisphere	Midlands to lowlands	Low relief	Deformed by ridges of ridge belts	Plains volcanism, no discernible sources
Shield plains	Equidimensional patches	10s to 100s of km across	Dispersed patches; clusters in places	Midlands; rare in lowlands	Low relief	Moderately deformed by wrinkle ridges	Plains volcanism with abundant small edifices
Wrinkle ridged plains (regional plains)	Vast extensions	Up to 1000s of km across	Equidimensional and elongated regional lowlands	Lowlands and midlands	N/A	Moderately deformed by wrinkle ridges	Plains volcanism, no discernible sources
Lobate plains	Equidimensional and elongated	100s of km across	Patchy regional distribution	Highlands; rarely in midlands	N/A	In places, cut by rift structures	Plains volcanism through distinct sources
Regional volcano-tectonic features							
Lakshmi Planum	Circular highland plateau	A few 1000s of km across	Unique feature in the northern hemisphere	Midlands	Several km high	Highest mountain ranges outside	Abundant volcanism inside
Coronae and arachnoids	Circular, equidimensional	100s to 1000s of km across; average is ~300 km	Chains, clusters, isolated features	Midlands; some are in highlands	Relief varies from local lows to local highs	Annulus of fractures; ridges are subordinate	Lava flows and lava fields
Novae	Star like, equidimensional	10s to 100s of km across; average is ~200 km	Isolated occurrences	Midlands; some are in highlands	Predominantly, topographic highs (100s of m)	Radial pattern of fractures and graben	Individual lava flows
Large shield volcanoes	Equidimensional	100s of km across	Isolated occurrences	Midlands to highlands	Several km high	In places, rift related graben	Abundant lava flows on flanks

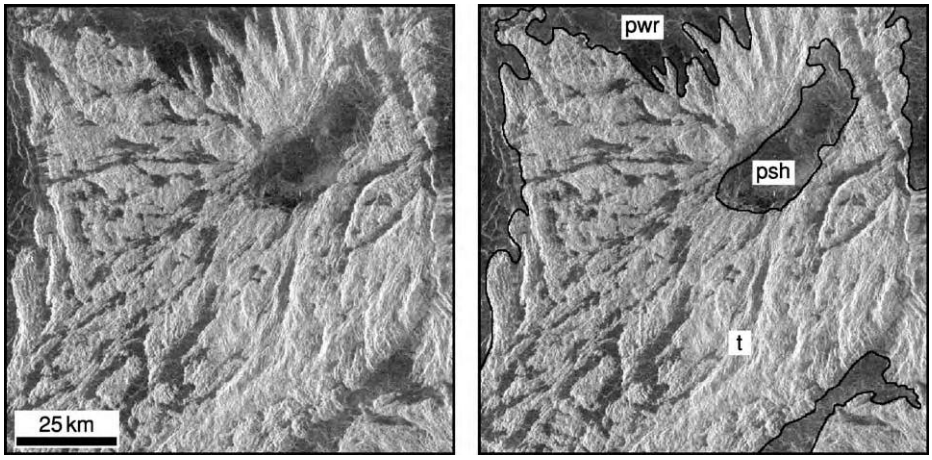

Figure 4 The surface of a tessera terrain (t) is deformed by several sets of tectonic features that completely obscure the morphological nature of the pre existing terrain. The tessera is embayed by all plains units on Venus. The units in this example are shield plains (psh) and wrinkle ridged plains (pwr). Fragment of C1 MIDR.30N009; illumination is from the left.

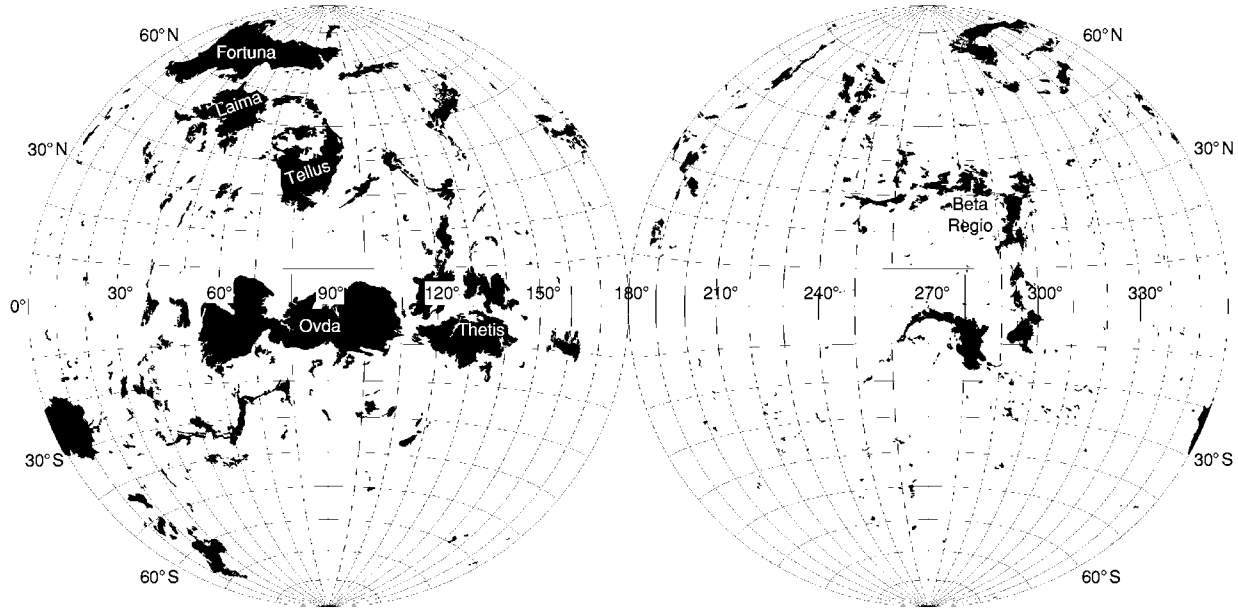

Figure 5 Map showing the global distribution of all occurrences of tessera terrains on Venus. The equatorial zone (Ovda and Thetis regiones) and high northern latitudes (Fortuna, Laima, and Tellus tesserae) have a higher density of tessera massifs. The hemisphere centred at about 230° E is dominated by major rift zones and large volcanoes and shows the clear scarcity of tesserae. The paucity of tesserae is also noticeable south of about 30° S. The map is in Lambert equal area projection.

occur predominantly in midlands, but in some cases are found on the floor of lowlands (e.g., Lavinia and Atalanta planitiae) (Figure 10). The most prominent zone of ridge belts extends for thousands of kilometres in the northern hemisphere, where individual belts are several hundreds of kilometres long and tens of kilometres wide (Figure 11). The plains embay tesserae and densely lineated plains, suggesting the younger age of both emplacement and deformation (Figure 12A and B).

Groove belts Groove belts are swarms of curvilinear lineaments that are usually wide enough to be resolved as fractures and graben (Figure 13), manifesting the tectonic environment of extension across long (hundreds of kilometres) and broad (up to a few hundred kilometres) zones. Individual structures of the belts can reach several tens of kilometres in length and are up to 1–2 km wide. The belts occupy a small percentage of the surface and in places form prominent zones thousands of kilometres long (Figure 10).

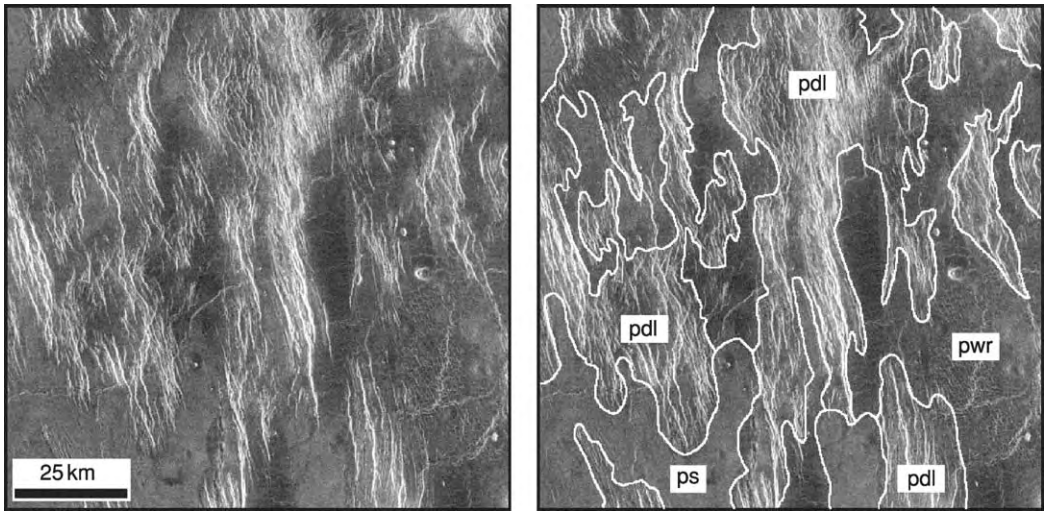

Figure 6 Areas of dense fracturing. Typically, small occurrences of these densely lineated plains (pdl) are heavily deformed by numerous narrow and densely packed lineaments (very narrow fractures). Fragments of densely lineated plains are embayed by varieties of lava plains, such as smooth plains (ps) and regional wrinkle ridged plains (pwr). Fragment of C1 MIDR.30N027; illumination is from the left.

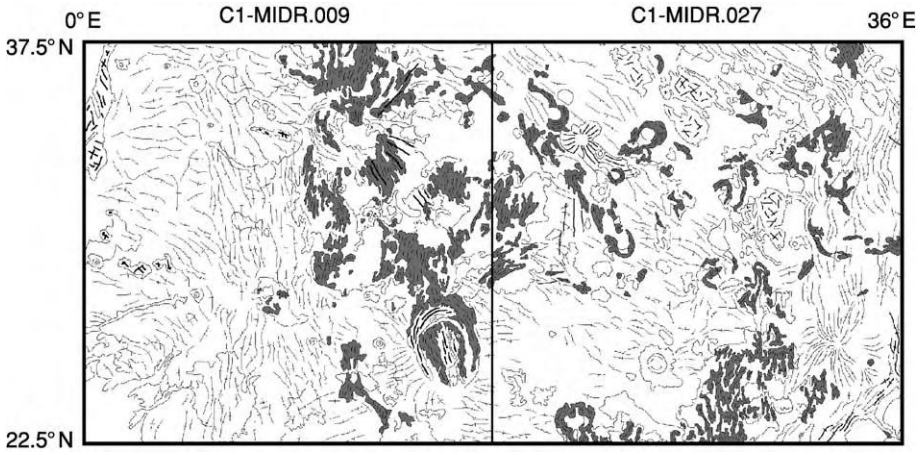

Figure 7 An example of the spatial distribution of densely lineated plains. Small fragments of densely lineated plains (dark grey) occur in clusters and as isolated patches within regional plains. In places, fragments of densely lineated plains occur within and near coronae and corona like features (north and south east of C1 MIDR.30N009).

Within the belts, the fractures are often anastomosing and sometimes form elliptical and circular coronae and corona-like features (Figure 14). Where groove belts are in contact with other units, they cut tesserae, densely lineated plains, and ridge belts, but are mostly embayed by younger plains such as shield plains and regional wrinkle-ridged plains (Figure 15).

Rift zones The most spectacular deformational belts on Venus are zones a few hundred kilometres wide and up to thousands of kilometres long, consisting of fractures and wide graben that can reach hundreds of kilometres in length and tens of kilometres in width (Figure 16). These features imply that the zones were formed by tensional stresses and in many aspects they resemble continental rifts on Earth. Topographically, the rift zones on Venus are troughs up to several kilometres deep that usually occur within regionally elevated areas. Preferentially, the rifts occur in a giant triangle-like area thousands of kilometres across, between Beta, Atla, and Themis regiones (the BAT province; Figure 17), where relatively young volcanic and tectonic activity on Venus is concentrated. The rift zones tend to occur with large dome-shaped rises; they are in close spatial association with lava plains and individual large lava flows, which appear to be

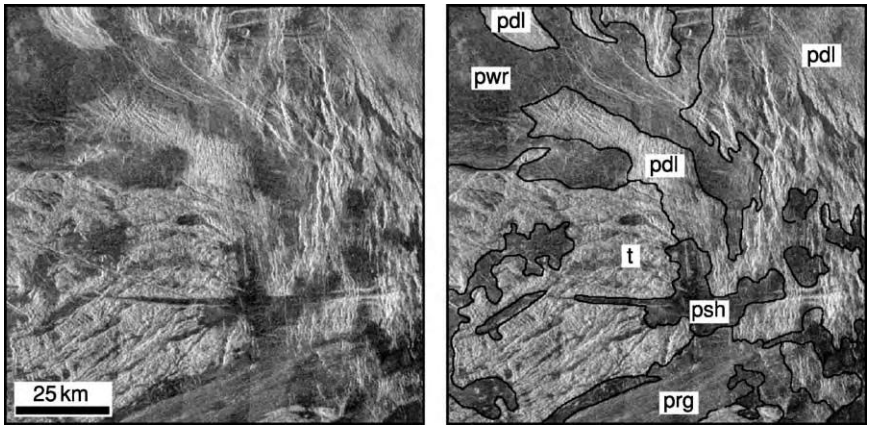

Figure 8 The relationships between tesserae (t) and densely lineated plains (pdl). A tessera has multiple sets of tectonic structures and a pdl is dissected by one set of narrow parallel lineaments. The complex pattern of deformation of tesserae is confined within its occurrences and does not penetrate into fragments of densely lineated plains. The pdl type structures deform tessera massifs (centre of the image). The younger shield plains (psh), wrinkle ridged plains (pwr), and ridged and grooved plains (prg) embay both tesserae and densely lineated plains. Fragment of C1 MIDR.30N125; illumination is from the left.

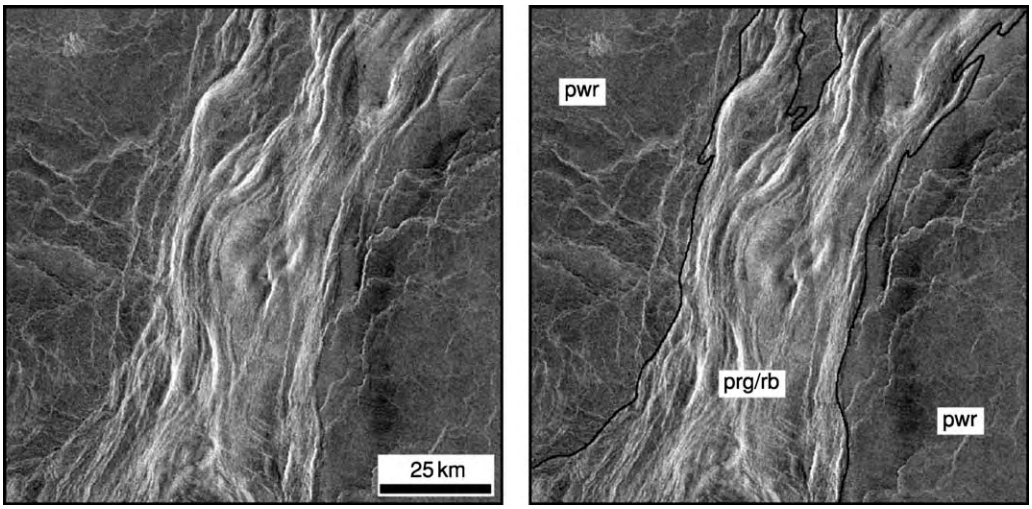

Figure 9 This typical ridge belt (rb) represents a small fragment of a larger elongated occurrence of ridged and grooved plains (prg). The curvilinear ridges typical of ridge belts are broader and less sinuous than wrinkle ridges within regional plains (pwr) are. Regional plains embay the ridge belt, implying that the belt was formed by contractional deformation of the material of ridged and grooved plains before emplacement of regional plains. Fragment of C1 MIDR.30N153; illumination is from the left.

the youngest volcanic features on Venus, and there is evidence for partly contemporaneous formation of the rifts and young volcanic plains.

Regional Plains on Venus

Due to conditions on Venus, volcanism is the prime factor contributing to growth of the crust on the planet, and extensive lava plains make up the vast majority of the surface. Several distinct units form extensive regional plains that are moderately deformed by tectonic structures.

Shield plains Shield plains are characterized by numerous small (up to 10 km across) shield- and cone-like features that are interpreted to be volcanic edifices (Figure 18). The surface of the plains is morphologically smooth but is sometimes deformed by wrinkle ridges. Shield plains cover about 10–15% of the surface of Venus and typically occur as small equidimensional areas several tens of kilometres across. Less frequently, occurrences of the plains are larger and can reach a few hundred kilometres (Figure 19A and B). The overall relief of the plains

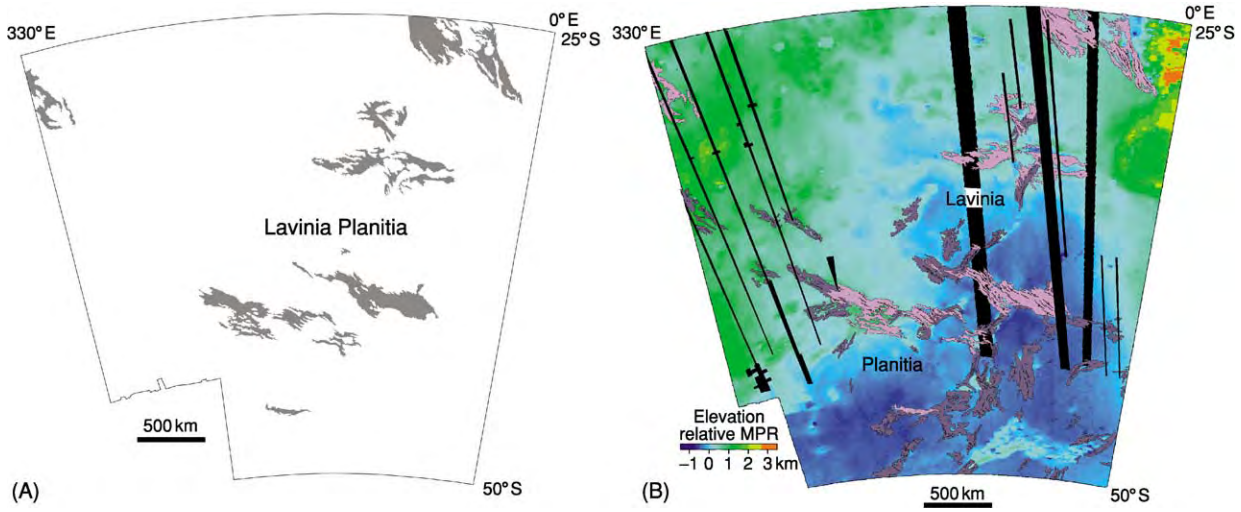

Figure 10 (A) An example of the spatial distribution of groove belts. Groove belts (dark grey) make major deformational belts on the floor of Lavinia Planitia. Individual occurrences of the belts can reach a 1000 km in length and several hundred kilometres in width. The map is in Lambert conformal projection. (B). An example of the spatial distribution of major deformational belts within the lowland of Lavinia Planitia. Occurrences of ridge belts (dark purple) are oriented in a north eastern direction. Groove belts (pink) are orthogonal to the strike of ridge belts. Both types of belts are concentrated within the deepest portion of Lavinia Planitia and the ridge belts are parallel to the elongation of the floor of the lowland. Colours show distribution of elevation relative to mean planetary radius (MPR; 6051 km). Black strips are data gaps. The map is in Lambert conformal projection.

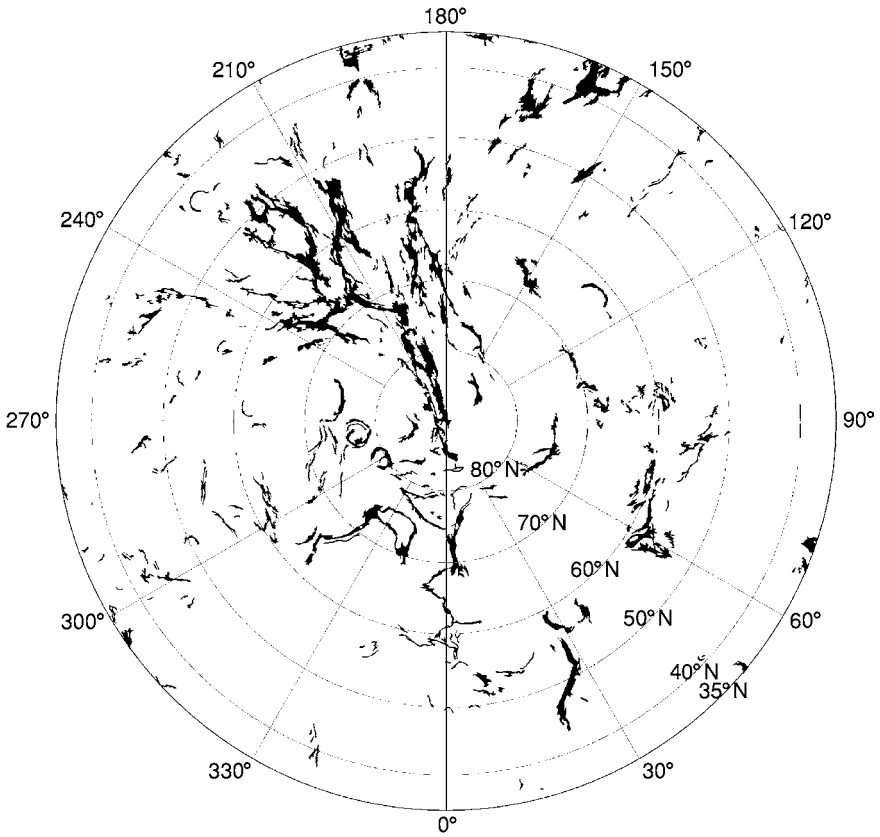

Figure 11 Distribution of ridged and grooved plains and ridge belts (black areas) in the northern hemisphere of Venus above 35° N. The most important occurrence of ridge belts is fan shaped and centred at about 210° E. The map is in polar stereographic projection.

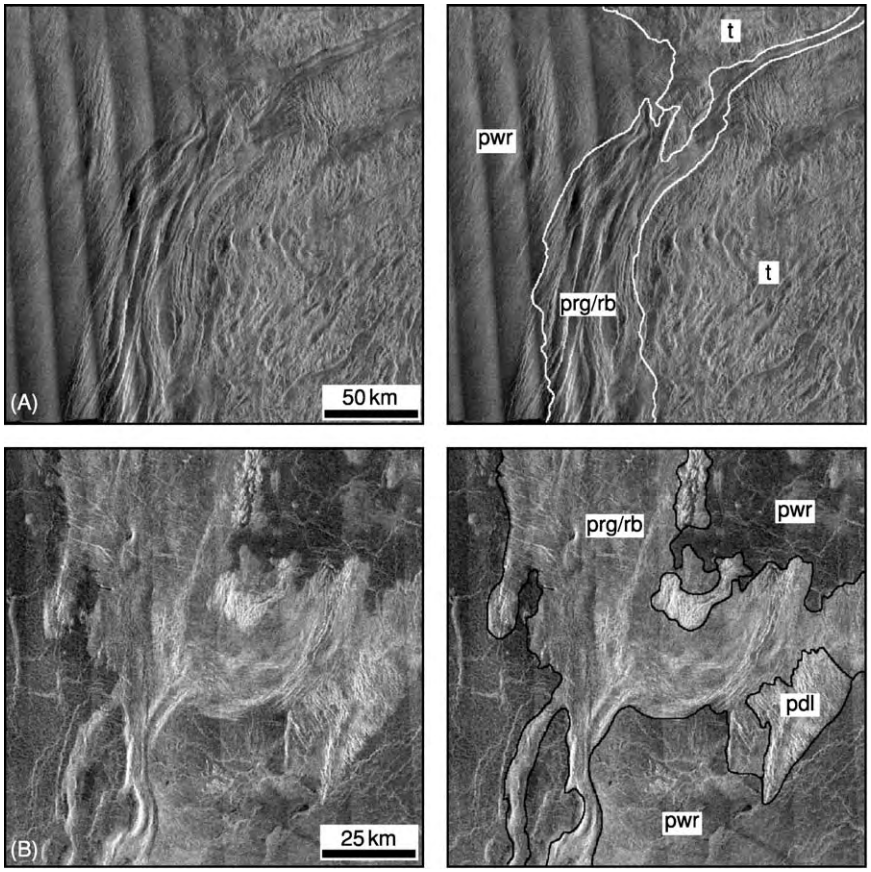

Figure 12 The relationships of ridge belts and ridged and grooved plains with other units. (A) Occurrences of ridged and grooved plains deformed into ridge belts (prg/rb) run along the edge of extensive tessera regions (t). The complex pattern of deformation within a tessera is confined within its massifs and appears to be cut by the system of ridges of the ridge belt. The surface of the regional plains (pwr) is moderately deformed, and plains material embays ridges of the belt. Fragment of C1 MIDR.00N112; illumination is from the right. (B) Material of the ridges and grooved plains, which is deformed in places into ridge belts (prg/rb), embays small fragments of densely lineated plains (pdl). Regional wrinkle ridged plains (pwr) broadly embay both prg/rb and pdl. Fragment of C1 MIDR.30N153; illumination is from the left.

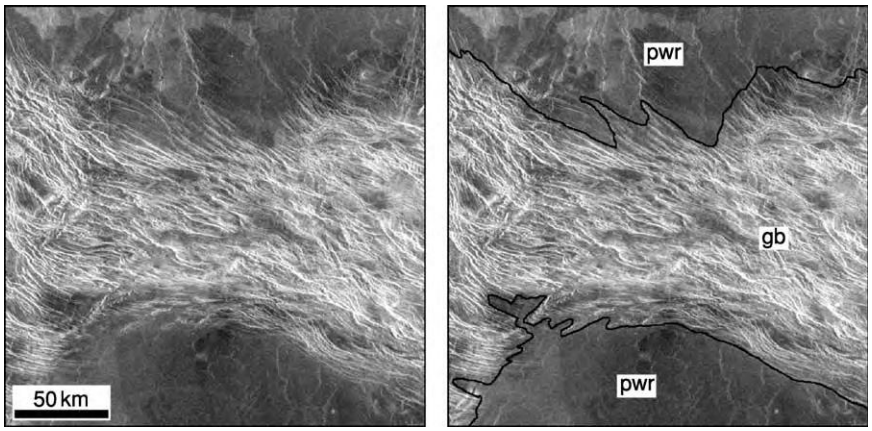

Figure 13 Typical groove belt consists of numerous linear and curvilinear fractures and graben that almost completely destroy pre existing materials (pwr, wrinkle ridged plains; gb, groove belt). Fragment of C1 MIDR.45S350; illumination is from the left.

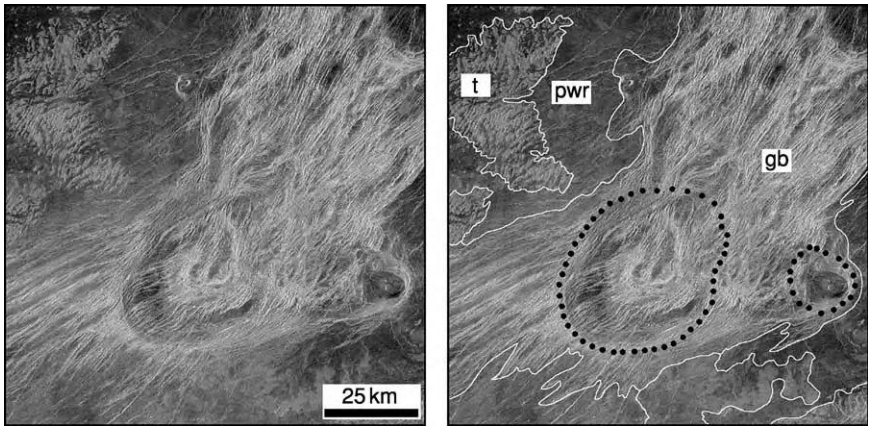

Figure 14 A fragment of a groove belt (gb), the structures of which outline coronae and corona like features (dotted lines in the right image). t, tessera; pwr, wrinkle ridged plains. Fragment of C1 MIDR.30N261; illumination is from the left.

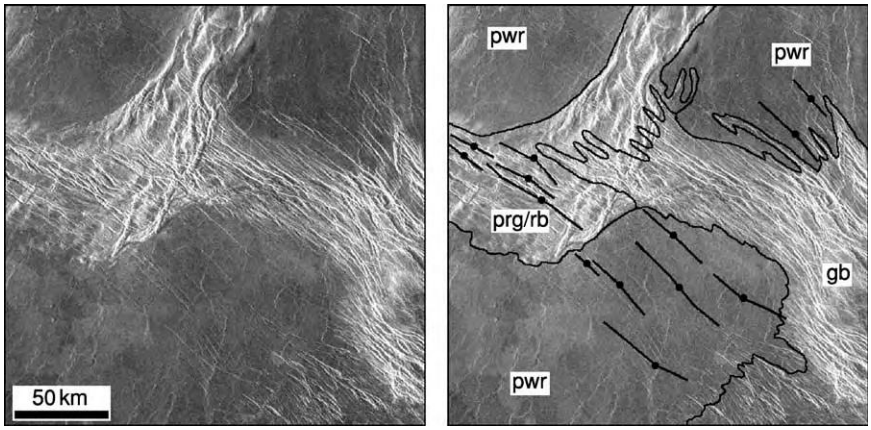

Figure 15 Relationships between groove belts (gb) and ridge belts (rb) typically show that fractures and graben of groove belts cut structures of ridge belts. Material of regional wrinkle ridged plains (pwr) embays both types of deformational belts. prg, ridged and grooved plains. Fragment of C1 MIDR.45S350; illumination is from the left.

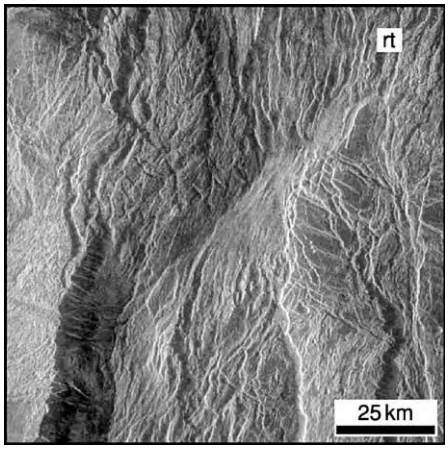

Figure 16 A portion of the Devana Chasma rift zone (rt) that cuts through the central portion of Beta Regio. The rift zone consists of a great number of fractures and graben, between which remnants of pre existing terrains are visible. Fragment of C1 MIDR.30N279; illumination is from the left.

appears to be hilly due to abundant shield features; occurrences of shield plains tend to be slightly higher compared to the surrounding regional plains. Although shield plains occur at different elevations, they preferentially occupy regional slopes away from old elevated terrains such as tesserae or ridge belts. The plains embay older, heavily tectonized units (Figure 20A) but are predominantly embayed by regional wrinkle-ridged plains (Figure 20B).

Regional wrinkle-ridged plains Regional wrinkle-ridged plains have morphologically smooth surfaces that are moderately deformed by numerous low, narrow, and sinuous wrinkle ridges (Figure 21). Wrinkle-ridged plains make up ~50–55% of the surface, appear as a regional background (with other units and structures being either older or younger), and can be traced almost continuously around the planet. The surface of the plains usually has a

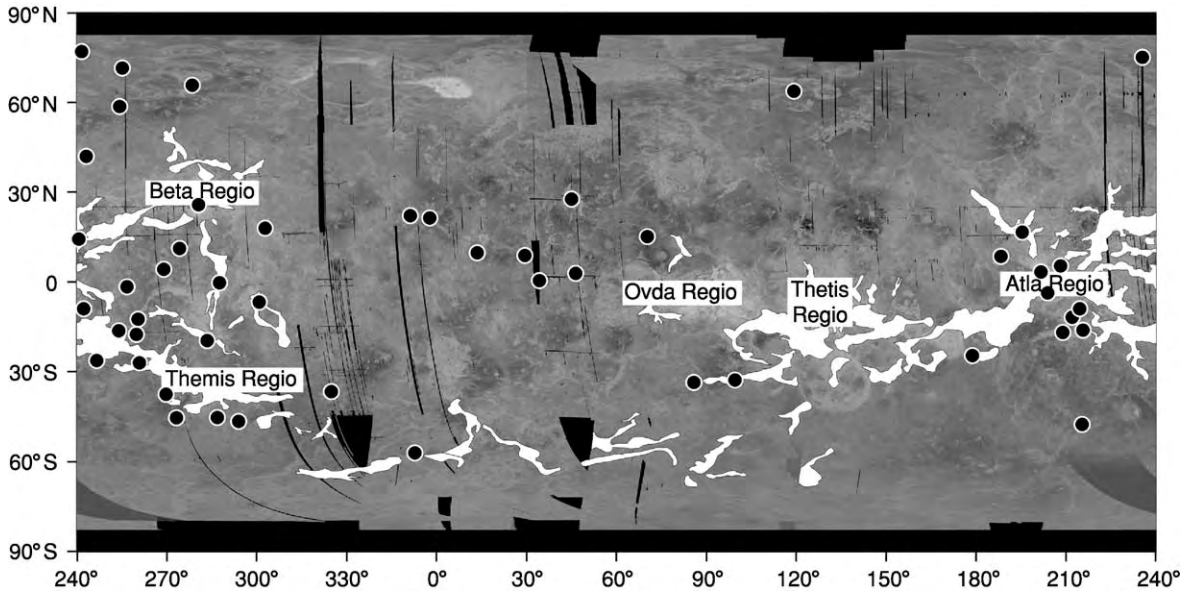

Figure 17 The global distribution of major rift zones (white) on Venus. The main concentration of rifts is within a giant triangle shaped area between Beta, Atla, and Themis regiones. The photobase is a low resolution synthetic aperture radar image of the Venus globe in simple cylindrical projection.

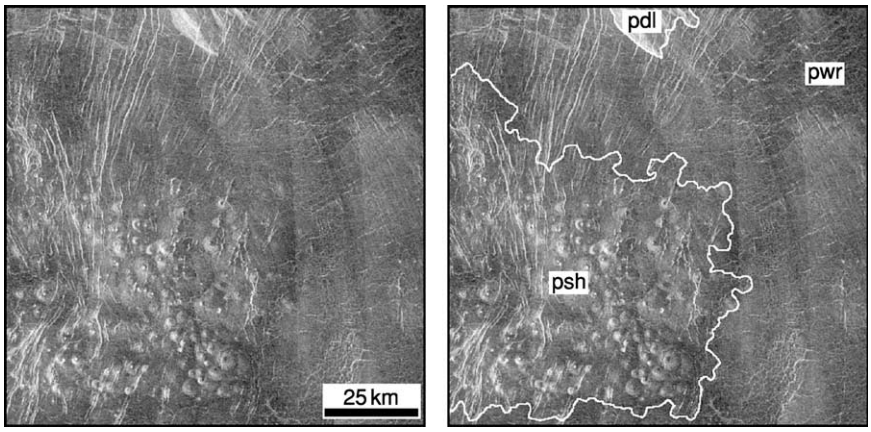

Figure 18 The surface of shield plains (psh) is characterized by a large number of small shield like features interpreted as volcanic edifices. Many of the shields have a bright dot in the centre; this is interpreted as a central pit (crater). The occurrence of shield plains is visible in the central part of Boala Corona. pdl, Densely lineated plains; pwr, wrinkle ridged plains. Fragment of C1 MIDR.30N135; illumination is from the left.

relatively low and uniform radar albedo with no visible flowlike features, which precludes identification of the sources of the plains material. A specific characteristic of the plains is the presence of long and narrow channels on their surface. The longest channel, Baltis Vallis, is about 7000 km long (Figures 21 and 22). In some places, the radar albedo of regional plains is distinctly higher and plains occur as relatively bright areas hundreds of kilometres across. These areas often surround distinct volcanic centers, such as large volcanoes and some coronae, and they form a distal apron of volcanic materials around them. Although in many cases there is evidence for embayment of the darker plains by the material of the brighter ones (Figure 23), the same family of wrinkle ridges appears to deform both varieties of regional plains (Figure 23). Regional plains cover the surface of large equidimensional basins (Figure 1) and make up the majority of midlands, but are noticeably less abundant within either plateau-shaped or dome-shaped highlands such as Ovda or Beta regiones.

Large volcanoes and lobate plains The large volcanoes are equidimensional mountains several hundred

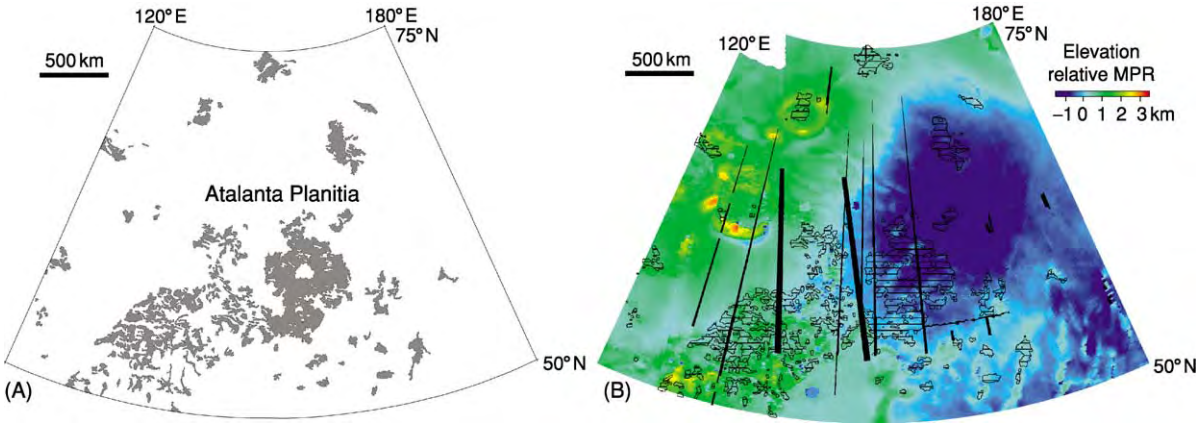

Figure 19 (A) The spatial distribution of shield plains (dark grey) within Atalanta Planitia. Fragments of the plains vary in size from several tens of kilometres up to a few hundred kilometres and occur in clusters and as individual patches. The map is in Lambert conformal projection. (B) The spatial distribution of shield plains (ruled pattern) within the Atalanta Planitia basin. Fragments of the plains vary in size from several tens of kilometres up to a few hundred kilometres and occur mostly on the regional slope of the Atalanta lowland, where groups of older units such as tesserae and densely lineated plains collectively form local highs. Colours show distribution of elevation relative to mean planetary radius (MPR; 6051 km). Black strips are data gaps. The map is in Lambert conformal projection.

kilometres across and a few kilometres high. Sometimes, a broad caldera-like feature is present at the summit of the volcano; in these cases, numerous radar-bright and dark flow-like features interpreted as lava flows always cover the slopes (Figure 24). The individual lava flows are superposed on each other and collectively form extensive lava plains (lobate plains), occurrences of which have lobate boundaries and can be several hundred kilometres across. There are 168 large volcanoes on Venus and their diameters vary from 100 to 1000 km. Typically, the large volcanoes associate with major rift zones and many of them occur within the Beta–Atla–Themis region (Figure 17).

Major Volcano-Tectonic Features

Lakshmi Planum Lakshmi Planum is a high-standing (2–4 km above MPR) plateau almost completely surrounded by mountain ranges (Figure 25). These ranges, the highest mountains on Venus, average 7–8 km in height (some reach 11 km). Lakshmi Planum, which is a few thousand kilometres wide, is so dissimilar to other types of highlands on Venus that it can be considered a specific class of topographic province. The interior of the Planum, flat and slightly tilted to south, is covered by smooth volcanic plains that are morphologically similar to vast regional wrinkle-ridged plains elsewhere on Venus. These plains embay both the tessera-like terrain within the plateau and the individual ridges at the base of the surrounding mountains. Two major volcanic structures, Colette and Sacajawea paterae, dominate the interior of Lakshmi and are the centers of the abundant lava flows that are superposed on the wrinkle-ridged plains inside the Planum; these plains are similar to the lobate plains on the slopes of large volcanoes.

Coronae, arachnoids, and novae Coronae, arachnoids, and novae are circular or quasi-circular features tens to hundreds of kilometres across. Coronae (Figure 26) and arachnoids (Figure 27) are characterized by concentric deformational annuli that predominantly consist of extensional structures (fractures and graben) and sometimes ridges (contractional features) and novae form starlike patterns of radial fractures; graben (Figure 28). In the catalogue of volcano-tectonic landforms compiled by Crumpler and Aubele in 2000, 209 coronae, 265 arachnoids, and 64 novae are listed. All of these features are thought to be the surface manifestations of mantle diapirs at different stages of evolution. Coronae and other circular volcano-tectonic features occur predominantly in the midlands and only a few of them are either within the high-standing plateaulike highlands and dome-shaped rises or in the lowlands (Figure 29). The topographic configuration of these structures varies from rimmed depressions to plateaus to dome-shaped features. Many coronae and novae are surrounded by prominent lava flows, suggesting that these features are distinct volcanic centers. However, there are neither medium-sized nor large volcanoes in association with these features. Lava flows are rarely associated with arachnoids and these structures appear mostly as tectonic structures. In many cases, regional wrinkle-ridged plains embay tectonic

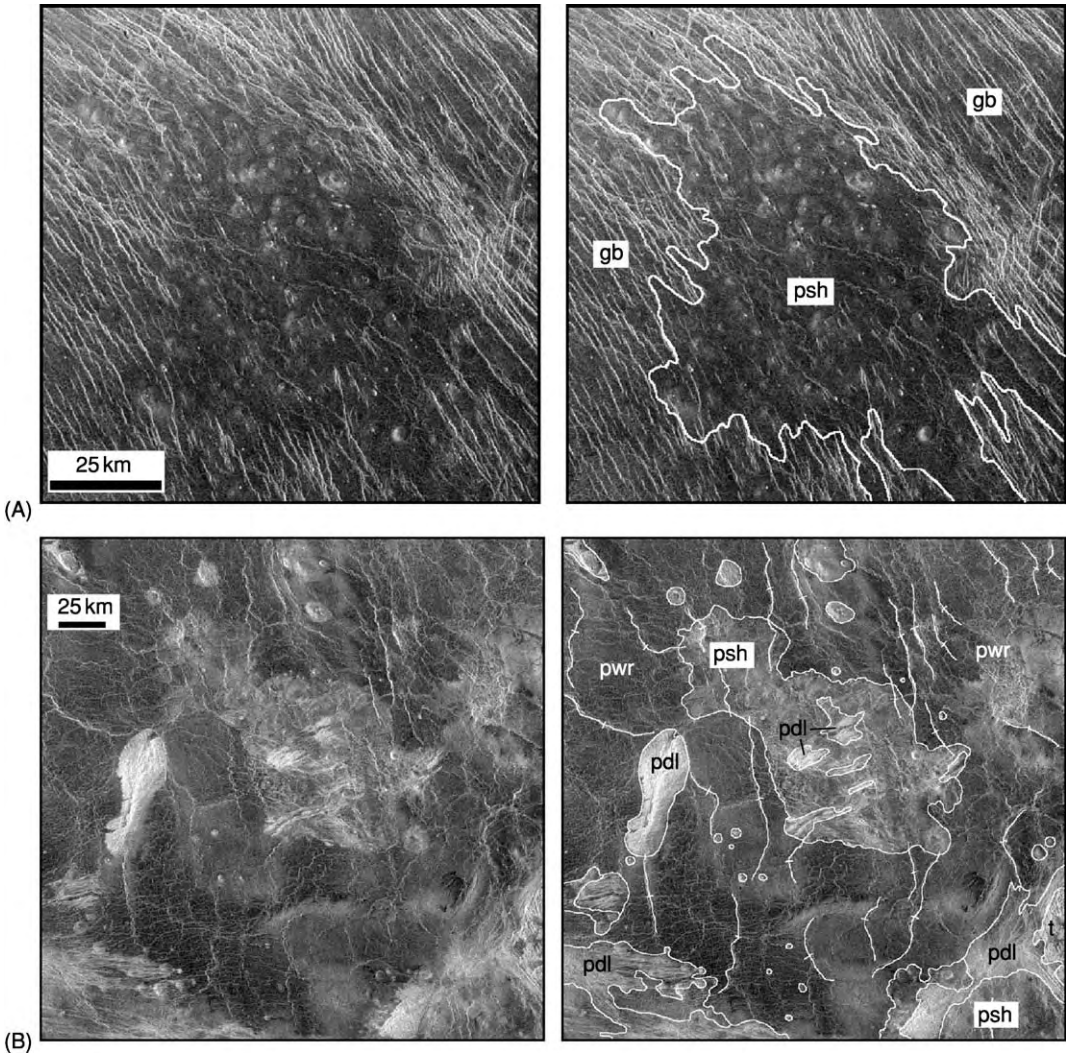

Figure 20 Relationships of shield plains (psh) with other units and structures. (A) Some portion of a groove belt (gb) is covered by deposits of shield plains that are obviously younger. A few shields, however, are cut by the fractures of the belt, suggesting that the formation of groove belt and shield plains partly overlapped in time. Fragment of C1 MIDR.30N333; illumination is from the left. (B) Occurrences of shield plains within regional plains are often characterized by a specific pattern of deformation confined within shield plains and a radar albedo that is different from the albedo of regional plains. Small individual shields that are seen within regional plains have morphological characteristics similar to these, typical of the main occurrences of shield plains. This suggests that the individual shields represent kipukas of more widespread shield plains covered by a mantle of wrinkle ridged plains (pwr).

structures of coronae and arachnoids, and fractures and graben of novae commonly cut the plains.

Major Topographic Features

The fact that the gravity and topography fields of Venus are highly correlated suggests that Venus may not have a low-viscosity layer, as in the asthenosphere of Earth, and that the Venusian mantle is strongly coupled with the lithosphere. Thus, the mantle circulation on Venus could be directly responsible for the formation of large-scale tectonic and topographic features. In the almost complete absence of erosion, on the other hand, the large-scale topographic features on Venus should much better reflect the balance between lithospheric buoyancy and mantle dynamics, compared to Earth. Thus the distribution of the major topographic features on Venus combines the present pattern of mantle convection with contributions from extinct patterns. The global altimetry data collected by Pioneer Venus, Venera-15/16, and Magellan show that three principal topographic provinces characterize the surface of the planet (Figure 1B). Lowlands (<0 km) make up $\sim$11% of the surface and consist of equidimensional basins and elongated depressions thousands of kilometres across. Their surface

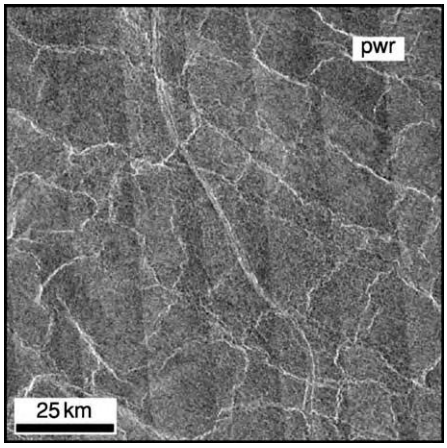

Figure 21 Regional plains with wrinkle ridges (pwr). The plains have a generally smooth surface with a relatively low and uniform radar albedo. Numerous narrow and sinuous ridges deform the surface of the plains. In the centre of the image, a narrow channel like feature that cuts the surface of the plains is visible. These channels are typical features on the surface of regional plains. Fragment of C1 MIDR.30N153; illumination is from the left.

is predominantly covered with regional wrinkle-ridged plains. Midlands constitute the majority of the surface of Venus (~80%), occur at elevations between 0 and 2 km, and host the richest variety of terrains, units, and structures.

Highlands are above 2 km and comprise ~9% of the surface. The highlands include two distinct classes of first-order features that are thousands of kilometres across. The first class consists of relatively steep-sided plateaulike features, the surface of which is typically covered by tesserae (e.g., Ovda Regio and Fortuna Tessera in eastern Ishtar Terra). These features appear to be isostatically compensated at relatively shallow depth, several tens of kilometres, suggesting that they are areas of thickened crust and probably relate to ancient regimes of mantle convection. This is consistent with the stratigraphic position of tesserae, which are the oldest terrain on the surface of Venus. The second class of highlands includes dome-shaped rises that are typically rifted and topped by large volcanoes (e.g., Atla and Ulfrun regiones).

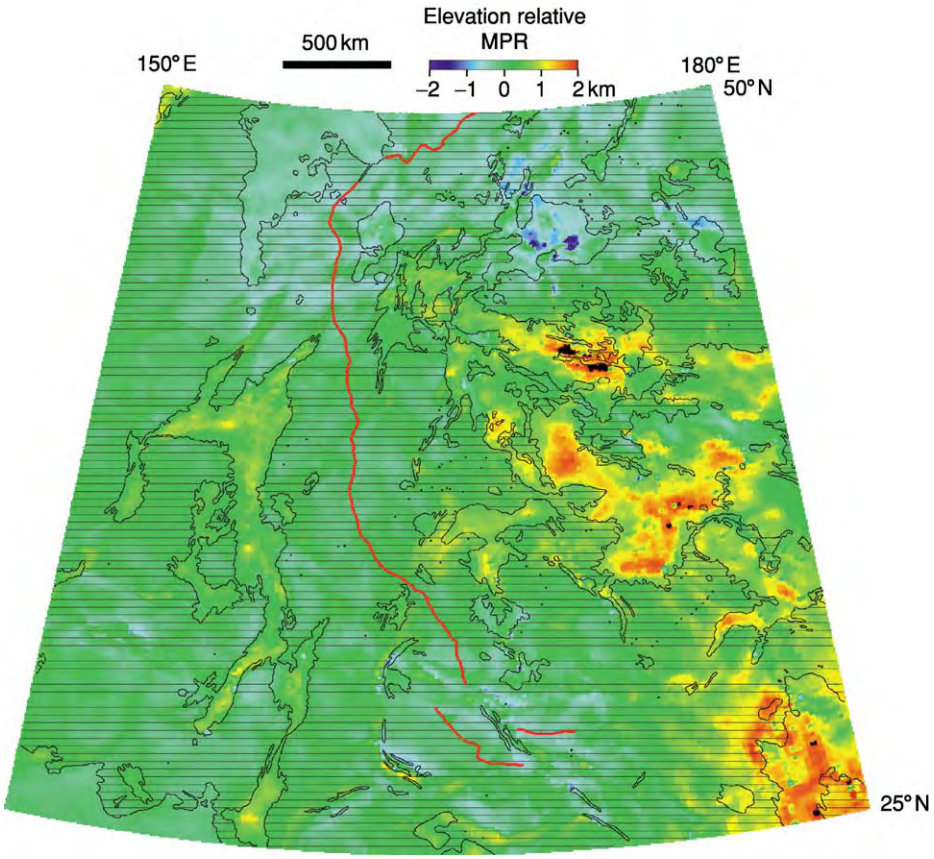

Figure 22 Spatial distribution of regional wrinkle ridged plains (ruled pattern). The plains occupy the relatively low portion of the area (Ganiki Planitia) between elevated territories to the west and east, where the older units and structures such as tesserae and ridge belts are exposed. The thick red line in the centre of the map is Baltis Vallis, which runs along the major continuous lowland. Colours show the distribution of elevation relative to mean planetary radius (MPR; 6051 km). The map is in Lambert conformal projection.

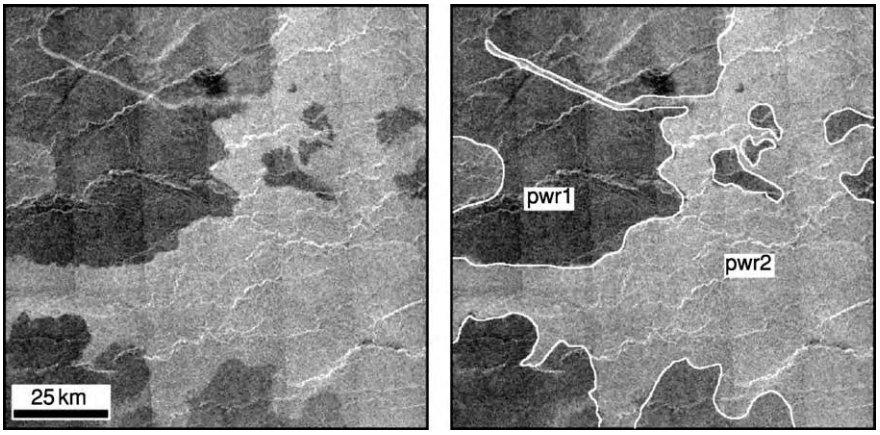

Figure 23 Varieties of regional wrinkle ridged plains. The upper member of the plains (pwr2) has a uniform and relatively higher radar albedo compared to the lower member of the plains (pwr1). Material of the brighter plains fills a portion of the lava channel (upper left), implying that pwr2 plains are younger. The same pervasive network of wrinkle ridges, however, deforms both varieties of the plains. Fragment of C1 MIDR.30N153; illumination is from the left.

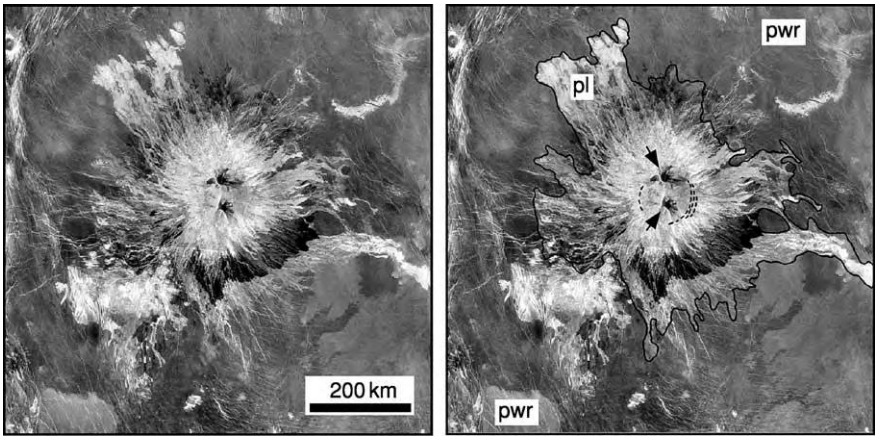

Figure 24 A large volcano (Sapas Mons) and lobate plains. Sapas Mons is a distinct volcanic centre from which issue a large number of radar bright and radar dark lava flows. In places, the flows merge with each other and form extensive lobate lava plains (pl) that are clearly superposed on the background of regional wrinkle ridged plains (pwr). Dashed lines (right image) show a series of arcuate graben in the summit area of Sapas Mons and black arrows indicate two steep sided domes. Mosaic of C1 MIDR.15N180, C1 MIDR.15N197, C1 MIDR.00N180, and C1 MIDR.00N197; illumination is from the left.

These rises appear to be compensated at much deeper levels, hundreds of kilometres, suggesting their dynamical support by active mantle upwelling. This is consistent with the geological characteristics of the rises, such as young rift structures and abundant young volcanism emerging through distinct sources.

Heat Loss Mechanisms

The style of volcanic and tectonic activity and the distribution of major topographic provinces are the specific manifestations of heat loss mechanisms operating on a planetary body. The global survey of the surface of Venus by Magellan has showed that except for a few possible sites, evidence for subduction is absent on the surface. Thus, the principal heat loss mechanism of Earth-like plate tectonics (lateral crust recycling, or "lateral" heat loss) apparently does not work on Venus. The alternative is a different orientation of the principal vector of heat loss mechanisms, vertical instead of horizontal. This means that Venus should be characterized by vertical crust accretion/recycling, or 'vertical' heat loss mechanisms. The manifestation of these is mantle upwelling and downwelling. The question of crucial importance in this context is the continuous or discontinuous nature of these mechanisms. Did they operate in a steady-state mode or did the temporal pattern of heat loss consist

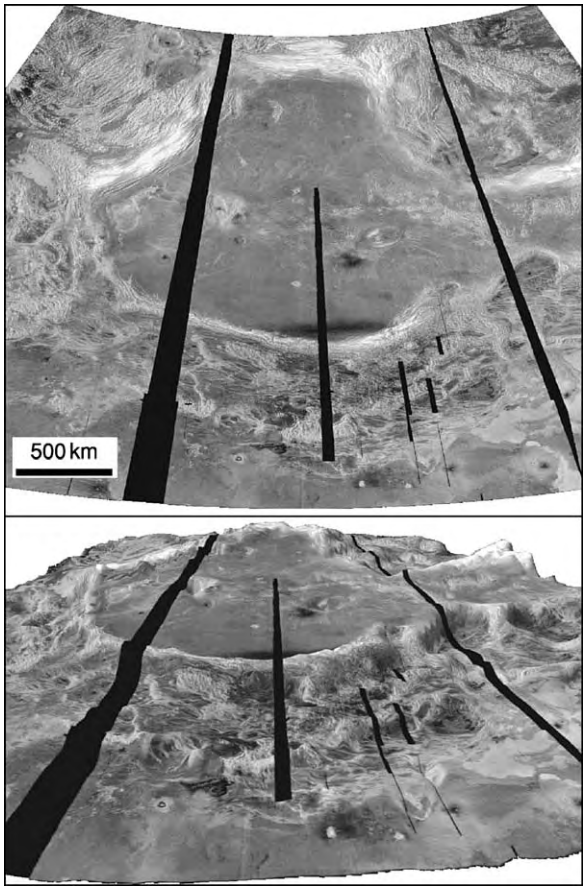

Figure 25 Lakshmi Planum, plan view (top) and perspective view (bottom). High mountain ranges (Danu Montes, south; Akna Montes, west and north west; Freyja Montes, north) almost com pletely border the interior of Lakshmi. Two large volcanic centres, Colette and Sacajawea Paterae, are distinct sources of relatively young volcanic materials (lobate plains) within the Planum. The plan view is in Lambert conformal projection.

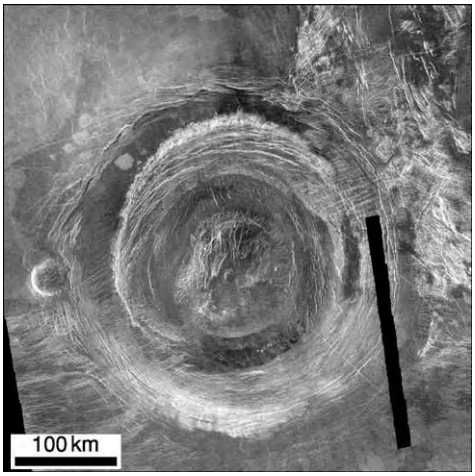

Figure 26 Corona Aramaiti is a typical example of this class of volcano tectonic structures. The corona has an outer and inner rim and a relatively flat floor populated with small shields. Within the outer rim, contractional ridges (northern portion of the rim) and extensional fractures (southern portion of the rim) are seen. Extensional features dominate the inner rim. A swarm of narrow lineaments (fractures and graben) appears to cut the outer rim (lower left and upper right) but disappears within the inner rim and the floor of the corona. Fragment of C1 MIDR.30S082; illumination is from the left.

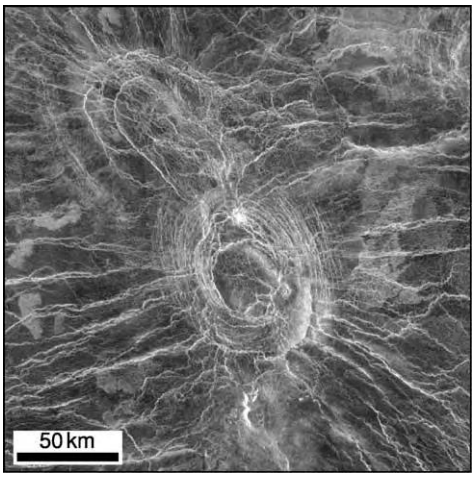

Figure 27 An example of an arachnoid. Swarms of concentric arcuate lineaments interpreted as fractures outline the doubled core of this feature (centre and upper left). Wrinkle ridges within regional plains appear to be focused at the arachnoid and form a radial pattern of structures around it. Fragment of C1 MIDR.45N011; illumination is from the left.

of a series of 'bursts' of endogenous activity intermittent with epochs of volcanic and tectonic quiescence, or was there one major change from a vigorous to a sluggish character of mantle convection?

The spatial distribution and morphology of impact craters place important constraints on the possible mode of heat loss/crust recycling on Venus. The catastrophic model of resurfacing is consistent with the characteristics of the crater population whereas the model of equilibrium resurfacing requires geological activity within small, ~400-km-diameter spots corresponding to the mean crater-to-crater distance. Thus, the characteristic horizontal scale of the mantle convection is also small, much smaller that the typical dimensions of many major features, both topographic and morphologic, on the surface. Thus, although the hypothesis of catastrophic resurfacing is an end-member model and almost certainly is incorrect in some details, it appears to describe better the geological situation on the surface of Venus.

There are two variants of the catastrophic resurfacing. In the first, the vertical accretion of crust and growth of the lithosphere lead finally to gravitational instability and large-scale delamination within the

lithosphere. Depending on the rheological properties of the material, horizontal scales of the instabilities, and the time-scale at which the instabilities exist, this process may lead either to transient plate tectonics or to large-scale mantle overturn. Both scenarios imply a cyclic nature of the heat loss mechanisms and may lead to a planet-wide resurfacing event on the surface.

The second variant of the catastrophic resurfacing is based on the secular cooling of the interior of the planet during most of the geological history of Venus. According to this scenario, the observable geological history of Venus begins after the transition from vigorous mantle convection under thin lithosphere to stagnant lid convection under thick lithosphere. In this model, tessera terrain is the remnant of the previous, thin-lithosphere regime, and the rifted dome-shaped rises topped with large volcanoes are the manifestation of the current regime of mantle convection under thicker lithosphere.

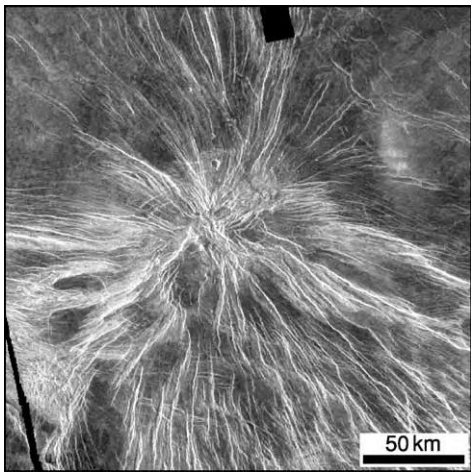

Figure 28 A typical nova is characterized by a star like pattern of broad radial fractures and graben originating at its centre. Fragment of C1 MIDR.30S279; illumination is from the left.

Models of Geological History on Venus

The high quality and global coverage of the Magellan data provide the possibility of detailed geological mapping of the surface based on defining distinct units and structures and establishing their relative ages. The results of the mapping efforts have led to two proposed end-member models for the correlation of regionally observed sequences of units and structures. In the first model, sequences of distinctive units mapped in different regions appear to have similar repetitive sequences in different places. This model has been called a "directional" geological history, implying a specific set of global trends in the evolution of Venus. For example, the consistently oldest relative age of tesserae suggests that a tectonic style of tessera formation has changed, with subsequent tectonic styles that led to the formation of other types of terrains. The important attribute of this model is its 'synchronism', implying that the sequences of events observed in different regions are broadly synchronous globally. For instance, regional wrinkle-ridged plains

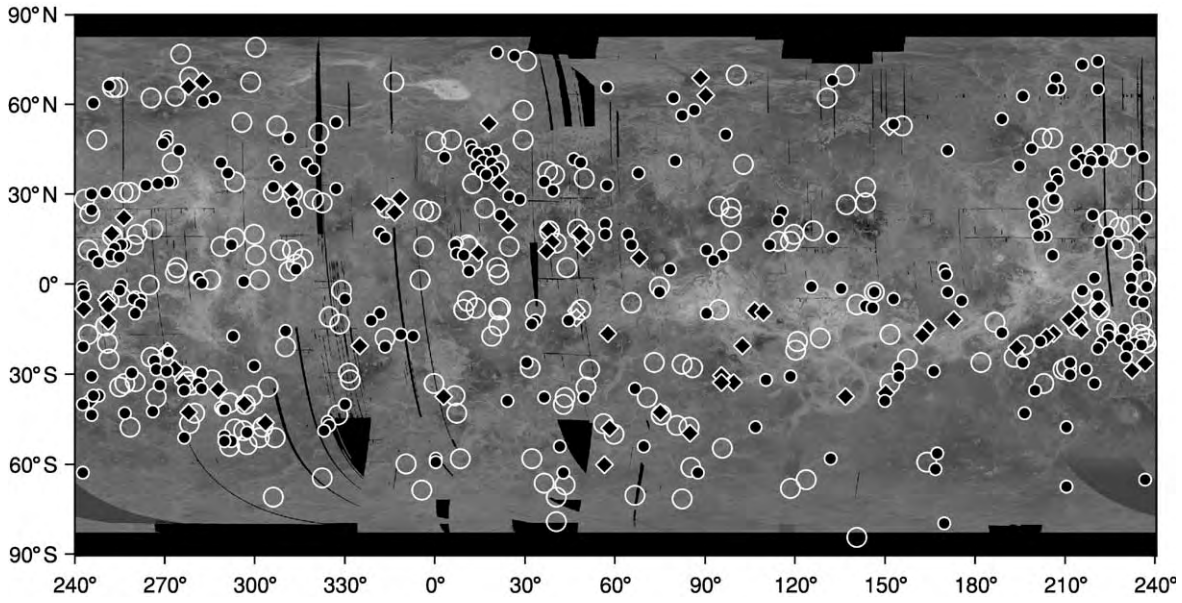

Figure 29 The spatial distribution of coronae (large circles), arachnoids (black dots), and novae (black diamonds) on the surface of Venus. The majority of these features, especially the novae, is concentrated in the Beta, Atla, and Themis regiones province and tends to be off of the large plateau shaped tessera highlands, such as Ovda and Thetis regiones. The map is in simple cylindrical projection.

appear to represent a broadly similar unit with a distinct stratigraphic position (either postdating or predating groups of other units) that can be traced continuously around the globe of Venus.

In the alternative model of geological history, the observed sequence of units is interpreted to be due to specific volcano-tectonic regimes that occur at different times on different parts of Venus, similar to Wilson cycles on Earth (individual plate-tectonic cycles that are repeated at different times and in different places on Earth). In this model for Venus, the local sequence of units represents only local or regional time-dependent sequential styles of endogenous activity. This is a 'non-directional' model of geological history, implying that the individual sequences represent local conditions occurring at different times in different places. Because the sequences of units and structures are almost the same in different regions on Venus, this model indicates that similar sequences of events resulted in similar stratigraphic columns occurring in these areas throughout the visible part of geological history. Another aspect of this model is its 'non-synchronous' nature, implying that the sequences of units/events are non-synchronous globally and that similar stratigraphic columns in specific regions are shifted relative to each other in terms of their age.

Further Investigation

The data collected during the exploration of Venus reveal the uniqueness of this planet. Venus does not have the surface age dichotomy characterizing the Moon and smaller planets such as Mercury and Mars. This fundamental characteristic implies that Venus, like Earth, has a prolonged history of geological activity that did not significantly decrease in intensity early in the evolution of the planet. In contrast to Earth, where the global heat loss mechanism is governed by plate tectonics, vertical crust accretion/recycling appears to be the principal style of geological activity on Venus.

Although current knowledge of Venus is great, there are still several major issues about its geology that are open to debate and further investigation. What is the evolution of the heat loss mechanisms on Venus? What are the paths of the evolution of the large-scale topographic features on the planet? How did the properties of the Venus lithosphere change as a function of time? Why are the Earth and Venus, the 'twin' planets, so different? What is the role of water in the evolution of both planets? Why is there little evidence on Venus for the presence of non-basaltic continental crust, which constitutes the major part of crustal material on Earth? How and when did the present atmosphere form and how has it evolved with time? How has the atmosphere interacted with the surface in recent and more ancient history of Venus? Obtaining answers to these questions requires continued exploration and key datasets, including seismic data, global high-resolution topography, *in situ* analysis of ancient terrains such as tesserae, and samples returned to terrestrial laboratories.

Moon

P Moore, Selsey, UK

Introduction

The Moon is our companion in space. It is usually regarded as the Earth's satellite, though since it has 1/81 the mass of the Earth it may be better to class the Earth–Moon system as a double planet. The Moon is a world of craters, mountains, and wide plains always referred to as seas (maria), though there has never been any water in them; the craters are generally accepted as having been produced by impacting meteorites, and some are well over 200 km in diameter. There have been six successful manned missions to the Moon, and many unmanned probes have been sent there. This article presents a general survey of the Moon, and summarises what has been learned from the lunar space-craft.

Origin

The Moon is so close to the Earth that even with the naked eye the surface markings are obvious. Physical and orbital data are given in Table 1.

For many years it was believed that the Earth and the Moon were one body, and that rapid rotation resulted in a portion being flung off to form the Moon – leaving the hollow now filled by the Pacific Ocean. This theory has long since been rejected, and only two serious theories remain. It is possible that the Earth and the Moon were formed at the same time and in the same region of the 'solar nebula', the cloud of material surrounding the young Sun; certainly the Earth and Moon are of the same age – about 4.6 thousand million years. However, most authorities now favour the 'giant impact' theory; the original

Table 1 Lunar data

Distance from Earth

Surface gravity, Earth 1:	0.1653
Mean albedo:	0.067
Atmospheric density:	10^{-14} that of the Earth's air at sea level.

body was struck by a 'planetary-sized body larger than Mars', so that the Moon condensed from the debris ejected during the collision.

Movements and Rotation

It is usually said that 'the Moon revolves round the Earth'. In fact the two bodies revolve together round the barycentre (the centre of gravity of the Earth–Moon system), but as the barycentre lies 1700 km below the Earth's surface the simple statement is good enough for most purposes.

The lunar orbit is not circular; the distance from Earth (centre to centre) ranges between over 400 000 km at furthest recession (apogee) and less than 360 000 km at closest approach (perigee). The orbital period is 27.32 days, but this is not the same as the synodic period, or interval between successive full moons or successive new moons, because the two bodies are moving together around the Sun; the synodic period is 29.53 days. It is often said that the Moon is 'new' when it appears as a slender crescent in the evening sky, but this is not strictly true; new moon occurs when the Moon lies between the Sun and the Earth, and its dark side is facing us, so that the actual new moon cannot be seen at all unless it passes directly in front of the Sun and produces a solar eclipse. A solar eclipse does not happen every month, because the lunar orbit is inclined at an angle of over 5°, and most new moons pass unseen either above or below the Sun.

During the crescent stage, the unlit hemisphere can usually be seen shining dimly. This is because of 'Earthshine' – light reflected on to the Moon from the Earth.

The axial rotation period of the Moon is exactly the same as its orbital period, so that the Moon always keeps the same hemisphere turned toward the Earth, and part of the surface is permanently turned away from us. This is not mere coincidence, it is the result of tidal effects over the ages. Originally the Moon spun much more quickly, but the tidal pull of the Earth slowed it down until the rotation had become 'captured' or synchronous. Note, however, that the Moon does not keep the same hemisphere turned sunward, so that day and night conditions there are the same all over the globe – apart from the fact that from the far side, the Earth can never be seen.

From Earth it is in fact possible to see 59% of the Moon's surface, though of course no more than 50% at any one time. This is because the Moon rotates at a constant speed, but the orbital velocity varies; the Moon moves quickest when near perigee. This means that the rotation and the position in orbit become 'out of step', and the Moon seems to rock very slowly to and fro. This libration in longitude means that narrow zones are brought alternately in and out of view. There are other minor librations, and only 41% of the surface is visually inaccessible, so that before the Space Age nothing definite was known about it.

Because of tidal effects, the Moon is receding from the Earth at the rate of 3.8 centimetres per year, and on average the Earth's rotation period is lengthening at a rate of 0.0000002 second per day.

Structure and Atmosphere

The outer surface layer of the Moon is termed the regolith; it is a loose layer or debris blanket probably, up to 10 metres deep in places, continually churned up by the impacts of micrometeorites (**Figure 1**). It is often referred to as 'soil', but this is misleading, as it contains no organic material. It overlies the rocky crust, which is on average just over 60 km in depth – thicker on the far side of the Moon than on the Earth-turned hemisphere. However, no unbrecciated rock outcrop has been encountered on Apollo missions and it remains uncertain how deep the zone of brecciation penetrates. At a fairly shallow level there are areas of denser material, which have been located because they affect the movements of orbiting spacecraft, they are called mascons (mass concentrations), and lie below some of the regular maria and very large basins. Below the crust lies the mantle, the structure of which may be fairly uniform; at a depth of around 1000–1200 km there seems to be a region where the rocks are hot enough to be molten. Finally, there may be a metallic core, no more than 1000 km in diameter; results from the Lunar Prospector spacecraft of 1998–1999 led to an estimate of an iron-rich core between 440 and 900 km in diameter. Most of what we know about the lunar interior comes from studies of moonquakes, which do occur and have been recorded by instruments left on the surface by the Apollo astronauts; some are shallow, but most occur in a zone from 800 to 1000 km below the surface. By terrestrial standards they are very mild, and never exceed a value of 3 on the Richter scale (*see* **Tectonics:** Earthquakes).

The Moon's low escape velocity means that there is only a trace of atmosphere, made up chiefly of helium and argon. If the entire atmosphere were compressed to a density equal to that of the Earth's air at sea-level, it would just about fill a cube with a side length of 65 metres. There is no detectable magnetic field, though the remnant magnetism of some rocks indicates that a definite field may have existed over 3.5 thousand million years ago.

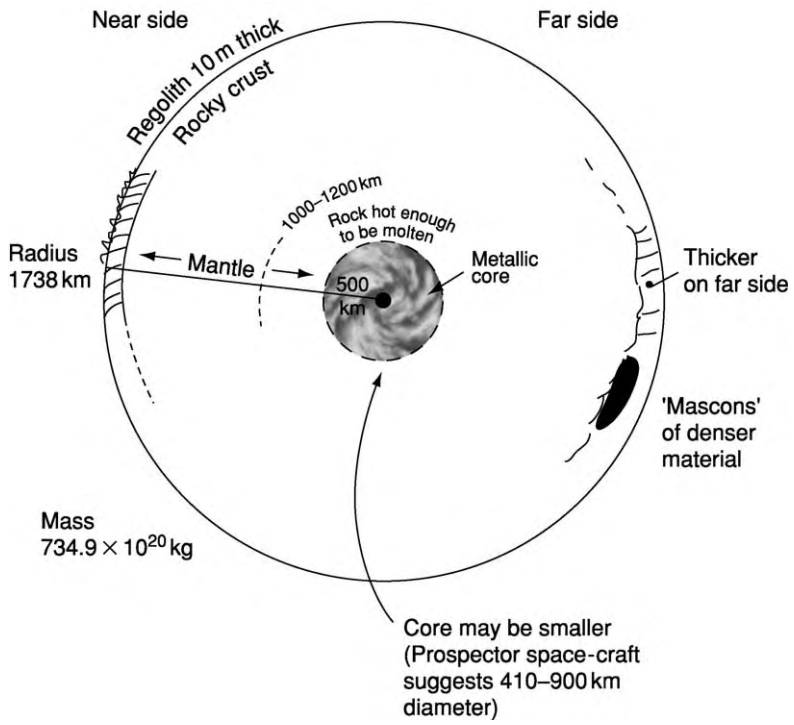

Figure 1 Structure of the Moon.

Table 2 Selected list of successful lunar missions

	Launch date	*Landing date*	
Name	*United States*		*Area*
Ranger 7	28 July 1964	31 July 1964	Mare Nubium hard lander, 4306 images returned.
Surveyor 1	30 May 1966	2 June 1966	Mare Nubium, near Flamsteed. Controlled landing. 11/150 images returned.
Surveyor 2	7 Jan 1968	9 Jan 1968	Nrim of Tycho. Controlled landing: 21 274 images
Orbiter 1	10 Aug 1966		207 images. (Uncontrolled impact, 29 Oct 1966.)
Orbiter 5	1 Aug 1967		212 images returned. (Impact, 31 Jan 1968.)
Clementine	25 Jan 1994		Mapping. Left orbit 3 May 1994.
Prospector	6 Jan 1998		Mapping, analysis. Uncontrolled impact, 11 July 1999.

Apollo manned missions

17	11 Dec 1972	Taurus Littrow	E. Cernan, H. Schmitt, R. Evans

Lunar Missions

Many space-craft have been sent to the Moon, quite apart from the manned Apollo missions. A list of the most important probes is given in Table 2.

The first successful missions were Russian, in 1959; in October of that year Luna 3 sent back the first images of the far side, always turned away from the Earth. On 3 February 1966, Luna 9 made the first controlled landing, showing that the surface was firm and disposing of an earlier theory that the maria at least were covered with deep dust. Controlled landings were made by the American Surveyors

(1966–1968) and the entire surface was mapped by the five Orbiters (1966–1967). The Apollo Programme extended from 1968 to 1972; of the seven planned landings, only Apollo 13 was unsuccessful. The Russians sent two automatic 'rovers', the Lunokhods (1970 and 1973). The latest lunar mapping probes have been the American Clementine (launched 1994) and Prospector (launched 1998, deliberately crashed on to the surface in 1999). Altogether 382 kg of samples have been returned to Earth, mainly by the Apollo astronauts but with small amounts from four Russian sample-and-return missions.

Surface Features

The most obvious features are, of course, the 'seas' (maria), which cover about 17% of the surface. A list of the major maria is given in Table 3. Most of these form a connected system, though the well-defined Mare Crisium is separate. Some of the maria are fairly regular in outline; others are very irregular. The largest of the regular maria is the Mare Imbrium, with a diameter of over 1000 km, bounded in part by the mountain ranges of the Apennines, Alps, and Carpathians, though the irregular Oceanus Procellarum has a longest diameter of over 2500 km and an area of well over 2 million square km. Of the major seas, only the Mare Orientale extends on to the far hemisphere of the Moon; there are no large maria wholly on the areas never visible from Earth. A small part of the Mare Orientale can be seen from Earth under favourable conditions of libration.

The whole lunar scene is dominated by craters, ranging from tiny pits up to huge enclosures well over 200 km in diameter (Figure 2). Basically they are circular, though often distorted by later formations, and near the limb they are foreshortened so much that it is sometimes hard to distinguish a crater wall from a ridge. A typical crater has a sunken floor, often with a central peak, and walls which rise to only a modest height above the outer surface. In profile, a lunar crater resembles a saucer rather than a steep-sided mine-shaft, and large formations would be better known as walled plains. Some have dark, relatively smooth floors, such as Plato in the region of the Alps (Figure 3), others have massive central structures which, however, never equal the height of the surrounding rampart. Some craters, notably Tycho in the southern uplands and Copernicus in the Oceanus Procellarum, are the centres of systems of bright rays which extend for hundreds of kilometres, and cross all formations in their path. A crater is at its most spectacular when seen at the terminator (the boundary between the sunlit and night hemispheres), as its floor will be wholly or partly filled with shadow. Near full moon there are almost no shadows, and the scene is dominated by bright rays, so that even a large crater will be difficult to identify unless it has a dark floor or very bright walls.

Large craters are often found in chains, such as the prominent. Ptolemæus, Alphonsus, and Arzachel, near the centre of the Earth-turned hemisphere, and Theophilus, Cyrillus, and Catharina, near the border of the Mare Nectaris. Chains of small craters are

Table 3 Selected list of Lunar maria

Name		*Diameter, km*	
Mare Australe	Southern Sea	600	Irregular, patchy area near SE limb
Mare Crisium	Sea of Crises	500	Well defined, separate
Mare Fœcunditatis	Sea of Fertility	900	Irregular; confluent with M. Tranquillitatis
Mare Frigoris	Sea of Cold	1600	Elongated, irregular, in places narrow
Mare Humboldtianum	Humboldt's Sea	270	Limb sea beyond Endymion
Mare Humorum	Sea of Humours	390	Regular; leads off Mare Nubium
Mare Imbrium	Sea of Showers	1120	Regular: area 863 000 sq km.
Mare Nectaris	Sea of Nectar	330	Leads off Mare Tranquillitatis. Fairly regular
Mare Nubium	Sea of Clouds	750	Ill defined border
Mare Orientale	Eastern Sea	340	Vast ringed structure; mainly on far side
Oceanus Procellarum	Ocean of Storms	2570	Irregular
Mare Serenitatis	Sea of Serenity	700	Regular. Few craters
Mare Smythii	Smyth's Sea	370	Well defined limb sea
Mare Tranquillitatis	Sea of Tranquillity	870	Adjoins M. Serenitatis
Mare Vaporum	Sea of Vapours	250	SE of the Apennines
Lacus Mortis	Lake of Death	150	Adjoins Lacus Somniorum
Lacus Somniorum	Lake of the Dreamers	380	Irregular darkish area leading off Mare Serinitatis
Palus Putredinis	Marsh of Decay	160	Part of Mare Imbrium
Palus Somnii	Marsh of Sleep	290	Curiously coloured area near Mare Crisium
Sinus Æstuum	Bay of Heats	290	Fairly dark area leading off Mare Nubium
Sinus Medii	Central Bay	260	Almost central on the disk
Sinus Roris	Bay of Dew	400	Joins Mare Frigoris to Oceanus Procellarum

Figure 2 Craters on the 'far side' of the Moon. The hemisphere always turned away from Earth is as crater scarred as the familiar hemisphere, though it lacks 'seas' similar in type to Mare Imbrium.

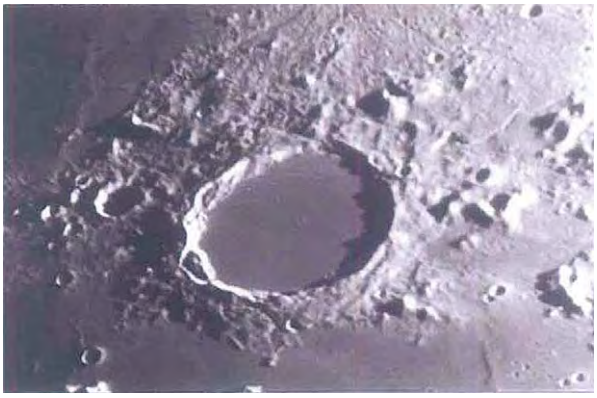

Figure 3 Plato, one of the most distinctive craters on the Moon. It is 109 km in diameter, and very regular. Its very dark grey floor makes it easy to locate whenever it is sunlit.

common, and so are crater-pairs, sometimes separated and sometimes joined. The brightest crater is the 40 km Aristarchus, which has even been mistaken for a volcano in eruption; the huge walled plain, Grimaldi, near the western limb, has the darkest floor.

The system of naming craters after people (usually, though not always, astronomers) was introduced by the Italian Jesuit Riccioli, who drew a lunar map in 1651. The system has been extended since, and is universally accepted. A selected list of some prominent craters is given in Table 4. One crater, the 84 km Wargentin, is filled with lava, so that it is in effect a large plateau.

Other features of the surface include wrinkle-ridges, crossing the maria; valleys, such as the magnificent valley which cuts through the Alps near Plato; low swellings or domes, with gentle slopes and often with summit pits, together with isolated peaks and the crack-like features known as rills, rilles, or clefts. Of special interest is the Straight Wall, in the Mare Nubium. In fact, it is not a wall, but a fault, appearing dark before full moon, because it casts a shadow, and bright after full moon, when its inclined face is illuminated.

Lunar Rocks

All the rocks brought back for analysis are breccias of igneous rocks; the Apollo astronauts brought back 2196 samples (Figure 4) (*see* **Analytical Methods:** Geochronological Techniques). Sedimentary and metamorphic rocks were absent. In the lavas, basalts are dominant; the youngest has been given a radiometric age of 3.08 thousand million years, while the oldest dates back 3.85 thousand million years. The basalts contain more titanium than terrestrial lavas – over 10% in the Apollo 11 samples – and there are small amounts of metallic iron. Many lunar rocks are also comparatively low in sodium and potassium, but one particular type of basalt is rich in potassium (chemical symbol K), the Rare Earth elements, and phosphorus (P), so that it is known as KREEP. Anorthosite – rock containing the minerals plagioclase, pyroxene, and/or olivine in various proportions – is plentiful; one specimen collected by the Apollo 15 astronauts is radiometrically dated as 4 thousand million years old, and is white. It is known as the Genesis Rock! A sample collected from Apollo 12 is about the size of a lemon; it consists largely of SiO_2, and is rich in uranium, potassium, and thorium, making it exceptionally radioactive. It is composed of a dark grey breccia, a light grey breccia, and a vein of solidified lava (Figure 5).

It is now known that some meteorites found on Earth have come from the Moon. Most are breccias, of the same type as mare basalts the anarthosites of the highlands or the regolith. Such lunar-sourced meteorites have been found in Antartica, Australia, North Africa and Oman (*see* **Solar System:** Meteorites). The subsurface rocks of the Moon have so far proved elusive to manned exploration, but lunar meteorite Dhofar 310 recovered from the Oman desert is reported by S.I. Demidova and others in 2003, to be a polymict breccia with deep-seated lunar crustal

Table 4 Some important craters

Name	*Latitude*	*Longitude*	*Diameter, km*	
Albategnius	11.7 S	4.3 E	114	Adjoins Hipparchus
Alphonsus	13.7 S	3.2 W	108	Ptolemæus chain
Anaxagoras	73.4 N	10.1 W	50	Ray centre
Archimedes	29.7 N	4.0 W	82	On Imbrium; trio with Aristillus, Autolycus
Aristarohus	23.7 N	47.4 W	40	Brilliant walls and central peak
Aristillus	33.9 N	1.2 E	55	Archimedes group
Aristotle	50.2 N	17.4 E	87	Pair with Eudoxus
Arzachel	18.7 S	1.9 W	96	Archimedes group
Autolycus	30.7 N	1.5 E	39	Archimedes group
Bailly	66.5 S	69.1 W	287	Field of ruins, near S. limb
Bessel	21.8 N	17.9 E	15	Bright; on Serenitatis
Bullialdus	20.7 S	22.2 W	60	On Nubium; massive walls, central peak
Catharina	18.1 S	23.4 E	104	Theophius group
Clavius	58.8 S	14.1 W	245	Southern highlands
Copernicus	9.7 N	20.1 W	107	Great ray crater
Cyrillus	13.2 S	24.0 E	98	Theophius group
Democritus	62.3 N	35.0 E	39	Highlands N of Mare Frigoris
Dionysius	2.8 N	17.3 E	18	Brilliant crater on edge of Tranquillitatis
Doppelmeyer	28.5 S	41.4 W	63	Bay leading off Humorum
Encke	4.7 N	36.6 W	28	On Procellarum; Kepler area
Endymion	53.9 N	57.0 E	123	Near Humboldtianum; darkish floor
Eratosthenes	14.5 N	11.3 W	58	End of Apennines
Fra Mauro	6.1 S	17.0 W	101	On Nubium, group with Bonpland, Parry
Fracastorius	21.5 S	33.2 E	112	Great bay off Nectaris
Gassendi	17.6 S	40.1 W	101	Edge of Humorum
Grimaldi	5.5 S	68.1 W	172	W of Procellarum, very dark floor
Hercules	46.7 N	39.1 E	69	Pair with Atlas
Hevel	2.2 N	67.6 W	115	Grimaldi chain
Hipparchus	5.1 S	5.2 E	138	Pair with Albategnius
Hyginus	7.8 N	6.3 E	9	Depression in Vaporum; great crater rill
Janssen	45.4 S	40.3 E	199	Southern Uplands, rim broken by Fabricius
Kepler	8.1 N	38.0 W	31	In Procellarum; ray centre
Langrenus	8.9 S	61.1 E	127	Patavius chain
Longomontanus	49.6 S	21.8 W	157	Clavius area
Macrobius	21.3 N	46.0 E	64	Crisium area
Maginus	50.5 S	6.3 W	194	Clavius area
Maurolycus	42.0 S	14.0 E	114	Stofler group
Menelaus	16.3 N	16.0 E	26	Edge of Serenitatis; brilliant
Moretus	70.6 S	5.8 W	111	Southern uplands
Newton	76.7 S	16.9 W	78	Moretus area
Olbers	7.4 N	75.9 W	74	Grimaldi area, ray centre
Petavius	25.1 S	60.4 E	188	Langrenus chain
Phocylides	52.7 S	57.0 W	121	Schickard area
Piccolomini	29.7 S	12.7 E	47	End of Altai Scarp
Pitatus	29.9 S	13.5 W	108	Sedge of Nubium; passes connected with Hesiodus
Plinius	15.4 N	23.7 E	43	Between Serenitatis and Tranquillitatia
Posidonius	31.8 N	29.9 E	95	Edge of Senenitatis
Ptolemæus	9.3 S	1.9 W	464	Trio with Alphonsus and Arzachel
Purbach	25.5 S	2.3 W	115	Walter group
Pythagoras	63.5 N	63.0 W	142	NW of Iridum
Riccioli	3.3 S	74.6 W	139	Adjoins Grimaldi; dark patches on floor
Rømer	25.4 N	36.4 E	39	Taurus area
Schickard	44.3 S	55.3 W	206	Great walled plain
Schiller	51.9 S	39.0 W	180 × 97	Schickard area; fusion of two rings
Stadius	10.5 N	13.7 W	60	'Ghost ring' near Copernicus
Stevinus	32.5 S	54.2 E	74	Petavius area; pair with Snellius
Taruntius	5.6 N	46.5 E	56	On Fœcunditatis
Thales	61.8 N	50.3 E	31	Near Strabo; ray centre
Theophilus	11.4 S	26.4 E	110	Trio with Gyrillus and Catharina
Triesnecker	4.2 N	3.6 E	26	Vaporum area; great rill system

Figure 4 Astronaut Schmitt, of Apollo 17, standing by a huge boulder. Schmitt was a professional geologist who had been trained as an astronaut specially for the mission; December 1972, He and his companion, Eugene Cernan, are (so far) the last men to have been to the Moon. Courtesy of NASA.

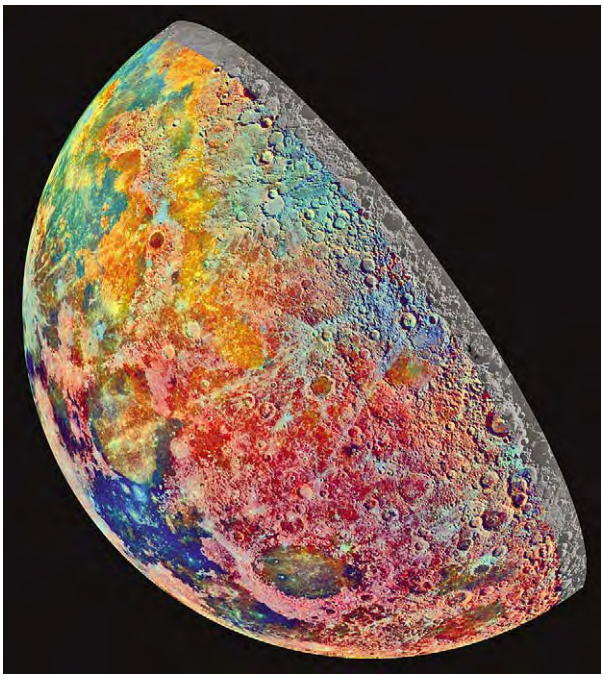

Figure 5 The minerals of the Moon. This is a mosaic of 53 images, obtained in 1992 by the Galileo space craft. The exaggerated false colour shows the differences in surface structure. Blue to orange indicate volcanic lava showing the dark blue Mare Tranquillitatis (lower left) is rich in titanium. Near the bottom of the image, right at Mare Tranquillitatis, is Mare Crisium, pink colours indicating material of the lunar highlands.

material within it as clasts – granulites and igneous rocks of anorthosite, gabbronorite and troctolite composition, also minor dunite and pyroxenite. A unique Al-rich orthopyroxenite/Al-spinel clast is compatible with pressure at a depth of ~20 km within the lunar crust at its source.

Origin of the Craters

It was long believed that the craters were of volcanic origin, similar in type to terrestrial calderæ, but it is now widely accepted that the vast majority are of impact origin, and we have at least a reasonable idea of the sequence of events.

When the Moon came into existence as a separate body, the heat generated melted the outer layers, and for a time there must have been a magma ocean many kilometres deep. Eventually, a crust was formed, thicker on the far side of the Moon than on the Earth-facing side; by cosmic standards it did not take long for the axial rotation to become synchronous. At that stage there was a vast amount of debris moving round the Sun, and the newly-formed planets and satellites swept it up. Between 4400 and 3900 million years ago came the Great Bombardment, when meteorites rained down on the Moon to produce the first major basins such as the Mare Tranquillitatis. Then, between 3900 and 3800 million years ago, came the tremendous impact which resulted in the Imbrian basin and affected the whole of the Moon. As the Great Bombardment ceased there was widespread vulcanism, with magma pouring out from below the crust and flooding the basins to produce structures such as the Mare Orientale. The lava flows ended rather suddenly; as the outpouring slackened, many craters were left undamaged, so that the youngest, such as Tycho and Copernicus, are unflooded. On the far hemisphere, with its thicker crust, there was less flooding, which explains the absence of major Maria and the presence of large,

light-floored walled plains known as palimpsests. Since then, the Moon has seen little activity, though it has been claimed that Copernicus is no more than a thousand million years old and Tycho even younger. One thing is certain: the dinosaurs would have seen the Moon looking very much as it does today!

The lunar cratered surface is remarkably like that of the planet Mercury (*see* **Solar System:** Mercury).

Transient Lunar Phenomena (TLP)

Many observations have been made of elusive glows and obscurations in parts of the Moon, notably in and near the brilliant crater Aristarchus. The reality of these events was demonstrated in 1992, when A. Dollfus, using the 83 cm refractor at the Meddon Observatory (Paris) saw and photographed moving glows inside the large walled plain Langrenus (Figure 6). TLP are almost certainly due to dust lifted above the surface under the effect of gas escaping from below the crust.

Ice on the Moon?

Some of the polar craters are deep by lunar standards, and their floors are always in shadow, so that they remain very cold indeed. The temperatures may be as low as −230°C. In 1966, NASA made the unexpected announcement that ice had been found in the bottoms of these deep polar formations.

The results came from an unmanned probe, Clementine, which had been orbiting the Moon since 1994. It carried a neutron spectrometer, reported effects which indicated the presence of hydrogen, which could combine with oxygen to produce water. Extravagant claims were made, and one NASA scientist went so far as to comment that there are a bunch of craters filled with water ice could a significant resource that would allow a modest amount of colonization for many years. Water would now be mined directly on the Moon instead of having to be shipped from Earth. Yet how could the ice have got there? Rock samples had shown no sign of hydrated material, and the impact of an icy comet would have generated a great deal of heat. Similar results were announced from the next probe, Prospector, launched into lunar orbit in 1998, but many authorities were sceptical. Finally, on 31 July 1999, a test was carried out. Prospector had come to the end of its career, and was deliberately crashed into a polar crater to see whether any signs of water could be found. Predictably, the results were negative. Further tests of the same kind are being planned, but it must be said that the idea of lunar ice seems decidedly far-fetched.

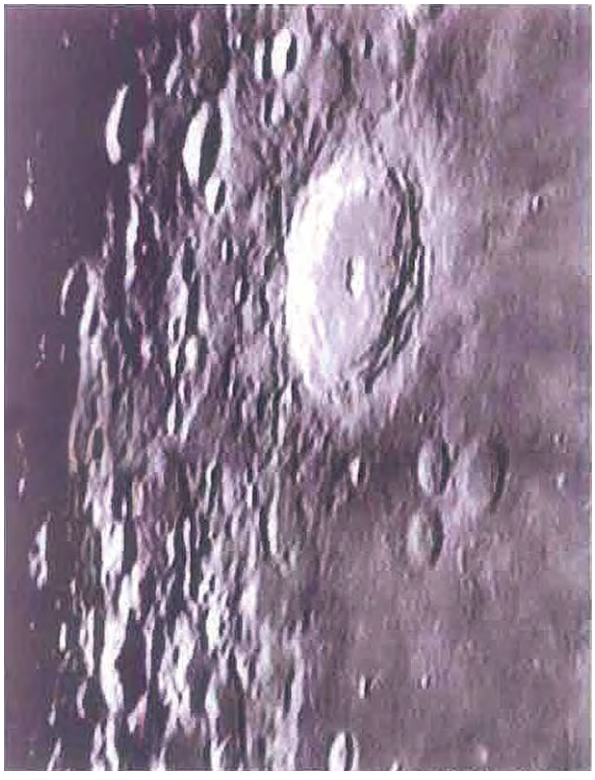

Figure 6 The lunar crater in Langrenus, diameter 127 km, with high walls and a central peak. It is one member of a large chain of craters, including Petavius and Vendelinus.

Life on the Moon?

There seems no chance that life has ever appeared on the Moon; it has been sterile throughout its long history. The crews of the first two Apollos, 11 and 12, were quarantined on return from the Moon to make sure that they had brought back nothing harmful, but quarantining was then abandoned as being unnecessary.

Occultations

As the Moon moves, it may pass in front of a star and hide or occult it. The star shines steadily until it is covered. When it snaps out abruptly; this was one of the early proofs that the Moon has practically no atmosphere.

Eclipses

Eclipses of the Moon are caused by the Moon's entry into the cone of shadow cast by the Earth. The supply of direct sunlight is cut off, but in general the Moon does not disappear, because some sunlight is refracted on to it by the layer of atmosphere surrounding the Earth; the Moon becomes dim and often coppery in colour.

Table 5 Lunar eclipses, 2004 2020

Date	Type	Time of mid eclipse, GMT	Duration of totality minutes	Percentage of Moon eclipsed
2004 May 4	Total	20.32	38	100
2004 Oct 28	Total	03.05	40	100
2005 Oct 17	Partial	12.04		6
2006 Sept 7	Partial	18.52		18
2007 Mar 3	Total	23.22	37	100
2008 Feb 21	Total	03.27	24	100
2008 Aug 16	Partial	21.11		81

Table 6 The Danjon scale

0	Very dark; Moon almost invisible at totality
1	Dark grey or brownish, details barely identifiable
2	Dark or rusty red, with a dark patch in the middle of the shadow: brighter edges
3	Brick red, sometimes a bright or yellowish border to the shadow
4	Coppery or orange red; very bright, with a bluish cast and varied hues

Lunar eclipses may be either total or partial. Because the Sun is a disk, not a point source of light, there is an area to either side of the main shadow cone (the umbra), through which the Moon has to pass; this region is termed the penumbra, and produces only a slight dimming of the surface. Some eclipses are penumbral only. The last eclipses were those of 16 May and 9 November 2003; a list of umbral eclipses up to 2008 is given in Table 5.

No two eclipses are alike; everything depends upon conditions in the Earth's upper air through which the sunlight has to pass. If there is an unusual amount of dust, following an event such as a volcanic eruption, the eclipses is liable to be dark. Observers use a scale given by A. Danjon (Table 6).

Lunar eclipses do not happen at every new moon, because of the inclination of the lunar orbit. Astronomically, they are not important, but they are certainly beautiful to watch, some displaying a wonderful range of hues.

Mars

M R Walter, A J Brown, and S A Chamberlain, Macquarie University, Sydney, NSW, Australia

Introduction

Mars, the fourth planet from the Sun, is Earth's second closest planetary neighbour. As a nearby terrestrial planet with an atmosphere, it shares some geological processes with Earth. However, our impressions of Mars are most clearly drawn into perspective by considering the differences between the geology of Earth and the geology of Mars.

Mars has an elliptical orbit, ranging from 207 to 249 million km from the Sun. Earth is much closer to the Sun (147 to 152 million km) and therefore is warmer. It takes 687 Earth days for Mars to orbit the Sun (670 Martian days, or 'sols'). A day on Mars lasts 24 h and 37 min. The diameter of the planet is 6780 km, about half that of Earth. Its surface area is about the same as that of the land area on Earth. At present, its axis is inclined at 25° to the ecliptic (the plane of rotation around the Sun), much like Earth's, and so it has similar seasons. Compared to the northern hemisphere, southern-hemisphere winters on Mars are more intense; springs and

summers are shorter but, because they occur when the planet is closer to the Sun, peak temperatures are as much as 30°C higher than northern-hemisphere spring and summer temperatures are. This is demonstrated by the fact that the southern polar cap has been known to disappear entirely during southern Summer, though the northern polar cap has never done so. Southern hemisphere winters on Mars are longer and colder than those of the northern hemisphere since Mars is further from the Sun during this period.

Interior of Mars

Some of the physical characteristics of Mars are listed in Table 1. An interpretation of the interior of Mars is presented at Figure 1. The interior structure of Earth is well constrained due to our ability to measure seismic reflections throughout the mantle and into Earth's core. At present, without similar seismic information on Mars, it is possible only to postulate what the Martian interior may be like – for example, does it have a solid core, or a partly liquid core like Earth has? The current view is that Mars has a liquid outer and a solid inner core with a radius of approximately 1700 km. The resultant reduced mantle depth compared to Earth implies that the Martian interior is likely to have cooled substantially faster than Earth did, and convection of the mantle, if it ever occured, may now have slowed or ceased. This implies that volcanism on the Martian surface is less likely today, and may provide an explanation for the current lack of a strong magnetic field on Mars.

The Mars Global Surveyor orbiter did find enigmatic strong local magnetism in rocks of the southern highlands, but an extremely weak overall global magnetic field on Mars. The absence of crustal magnetism near large impact basins such as Hellas and Argyre implies cessation of internal dynamo action during the Early Noachian epoch (similar to 4 billion years ago). Although massive tectonic events most probably caused the formation of Valles Marineris, plate tectonics as is understood on Earth is unlikely to have played a major role in Martian geology. This implies that granites, which are dependent on recycling of the crust in the presence of water, are unlikely to form on Mars. To date, this has been borne out by spectroscopic investigations of the planet.

Table 1 Physical characteristics of Earth and Mars

Characteristic	*Mars*	*Earth*
Orbit (million km)	207 249	147 152
Year (in Earth days)	687	356.25
Day (hours)	24.6	23.9
Mean radius (km)	3390	6371
Core radius (km)	~1700	3485
Average mantle depth (km)	1690	2886
Present obliquity to orbit (degrees)	25.19	23.45
Surface temperature variations (degrees C)	100 to +17	82 to +54

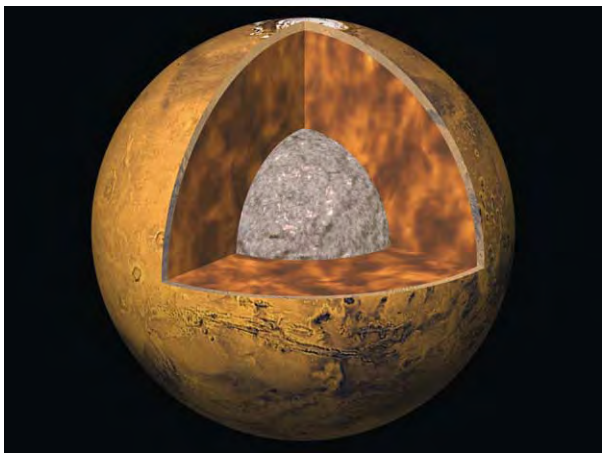

Figure 1 An interpretation of the interior of Mars, showing the core, mantle, and crust. Image courtesy of Calvin J. Hamilton.

Martian Atmosphere and Aeolian Processes

The atmosphere is 95% carbon dioxide, 2.7% nitrogen, 1.6% argon, and 0.13% oxygen, plus minute traces of other gases. In contrast, Earth's atmosphere is 78.1% nitrogen, 20.9% oxygen, 0.93% argon, and 0.03% carbon dioxide. Mars' atmosphere is thin, with the pressure at the surface of the planet (5.6 mbar) being less than one-hundredth of that on Earth. Despite the thin atmosphere of Mars, aeolian (wind-driven) processes have played a large role in shaping many surface features on Mars. These include dunes, yardangs, and etched and eroded terrains. Active dust devils have even been observed by the Mars Orbiter Camera on Mars Global Surveyor (Figure 2). Due to the low gravity of Mars, these features have greater height than their counterparts on Earth have. Dust, blown by the wind over the entire planet, tends to blanket rock features with a homogeneous layer that hampers identification of rock outcrops by orbital and telescopic spectroscopic methods. Dust storms, which periodically turn the Martian atmosphere into an opaque red layer, appear to be coupled with the heating of the atmosphere

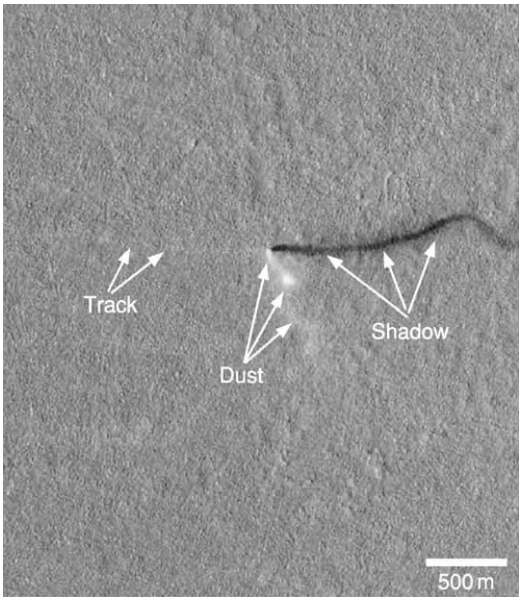

Figure 2 An image of a dust devil taken by the Mars Orbiter Camera. NASA/JPL/Malin Space Science Systems.

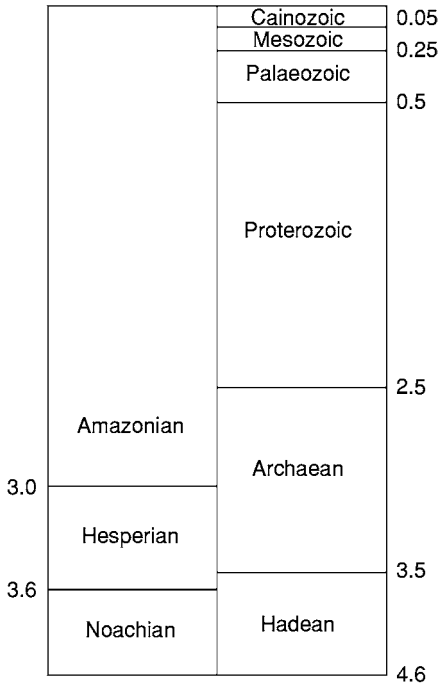

Figure 3 Geological time scales on Mars (left) and Earth (in billions of years).

by the Sun as Mars approaches perihelion (i.e., the closest part of its elliptical orbit).

Obliquity and Climate Variations

It has been calculated that over the past 10 million years, the angle of the spin axis of Mars (the 'obliquity') to the ecliptic, the plane of rotation around the Sun, has ranged from 13° to 4°. The obliquity varies chaotically, on a time-scale of hundreds of thousands to millions of years. In contrast, the obliquity of Earth is stabilized by the presence of the Moon. When the obliquity of Mars is at a minimum, the poles would have permanent caps of frozen carbon dioxide, because, as on Earth, little of the Sun's warmth would reach the poles; when the obliquity of Mars is at a maximum, the polar caps would melt in summer. At times of high obliquity, the water and carbon dioxide stored at the poles would vaporize and be released into the atmosphere, possibly raising the pressure to high enough levels to make liquid water stable for short times.

Cratering Record

The lack of a thick atmosphere and active fluvial processes relative to Earth gives Martian impact craters great preservation potential. Assuming no preference for the location of impact sites, observations of the distributions of craters on the Martian surface can be used to date the surface units. The great Martian impact basins of Hellas and Argyre are thought to have formed early in the history of the Solar System. By correlating the crater distributions with those seen on the Moon (assuming Mars and the Moon have similar impact histories), it is possible to assign ages to regions of the Martian crust, providing a rough guide to when areas of Mars were last resurfaced. Figure 3 relates the Martian geological time-scale to the major geological time periods of Earth. All values are approximate and are given in billions of years. It should be noted that since the current dating of the Martian surface depends on interpretation of impact craters, and these may be incorrect for several reasons, chief amongst them the possibility of one impact causing multiple craters, and also that volcano calderas may be mistaken for craters.

Global Hemispheric Dichotomy and Crustal Thickness

The analysis of images returned by the Viking orbiters of the 1970s revealed a hemispheric dichotomy on Mars. When these results were coupled with those of the Mars Global Surveyor laser altimeter instrument in the late 1990s, a picture of two halves of Mars emerged. The young and smooth northern lowlands have developed separately from the old, cratered southern highlands. The origin of this

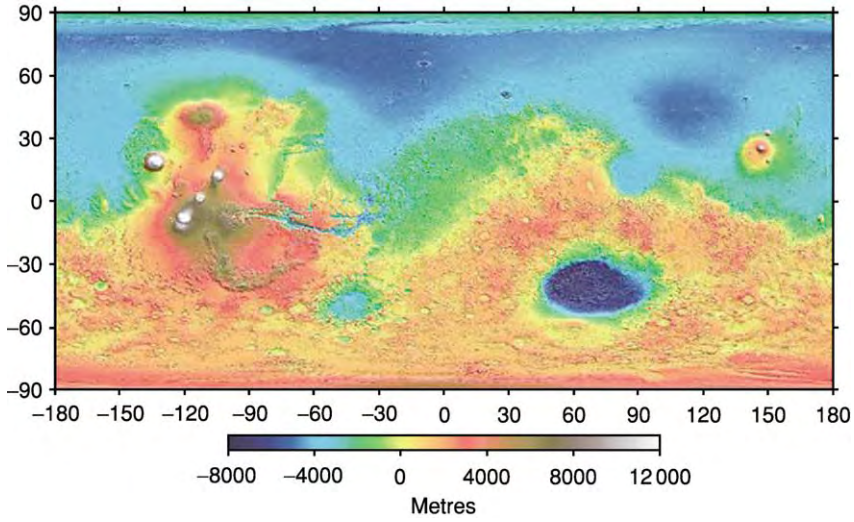

Figure 4 The elevation map of the topography of the Martian surface as determined by the Mars Orbital Laser Altimeter. Image courtesy of NASA.

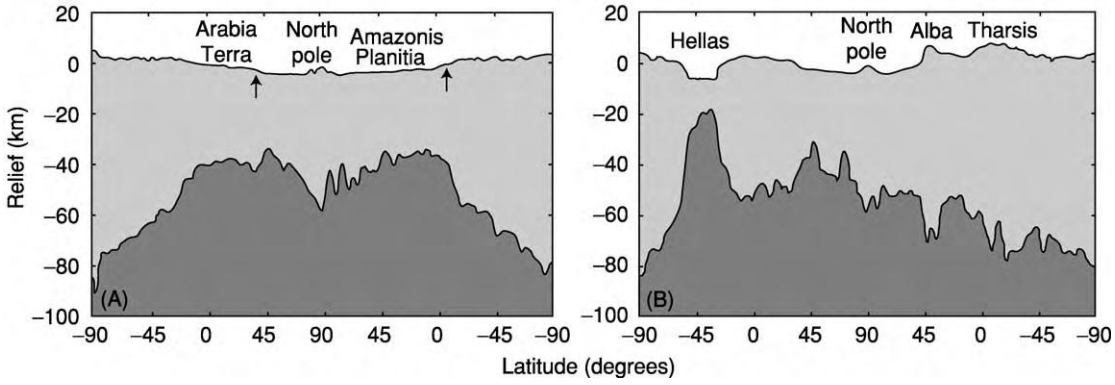

Figure 5 The estimated crustal depth on Mars. (A) Longitude line from 0° to 180°; areas indicate the regions of hemispheric dichotomy: note no major crustal depth variations that might indicate a collision origin of the dichotomy. (B) Longitude line from 70° to 250°. Reprinted with permission from Zuber MT, *et al.* (2000) *Science* 287: 1788 1793. Copyright 2004.

dichotomy is still the subject of debate. Suggestions have included the former presence of a shallow ocean in the northern hemisphere, or low-viscosity lava flows recently covering the northern plains.

An impact origin for the global dichotomy appears to have been ruled out by topography and gravity data obtained by Mars Global Surveyor. The data show that the crust thickness variations are fairly smooth across the dichotomy boundary, as shown in Figure 4. The crustal thickness shows a minimum crustal average depth of 50 km (Figure 5). This compares with approximate Earth values of 30 km for oceanic crust and 80 km for continental crust. The evidence from the Shergottite meteorites, as well as remote sensing from spacecraft and Earth, suggest that the upper crust of Mars is of volcanic origin and mainly of basaltic or andesitic origin, but there is very little in-depth information about the composition.

Mineralogy and Petrology

Thick, homogeneous layers of dust on the Martian surface have hampered efforts to map the surface mineralogy of Mars. The majority of orbital mapping has been conducted by the National Aeronautics and Space Administration (NASA) Viking mission, Mars Global Surveyor, and Mars Odyssey and European Space Agency (ESA) Mars Express missions. This has been complemented by results of landed missions, including Viking 1 and 2, Pathfinder (including the rover Sojourner), and the Mars Exploration rovers

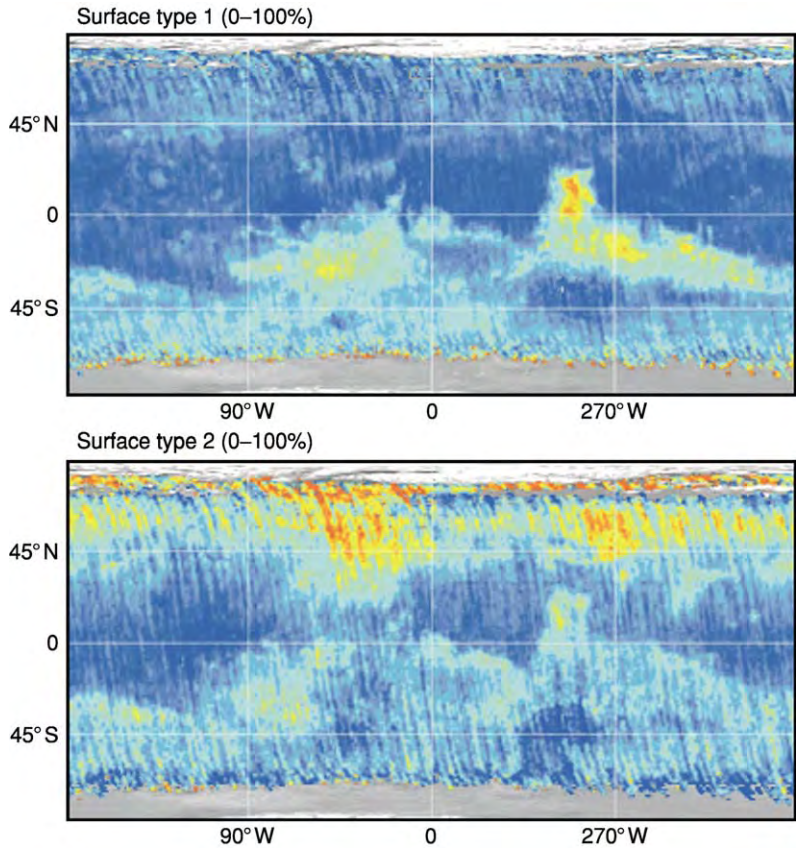

Figure 6 Map of surface types 1 and 2 as determined by thermal emission spectrometry. Red and yellow colours indicate high abundances; blue and light blue indicate low abundances. Type 1 is a basaltic type rock. Type 2 is a more silicic rock that matches the composition of andesite on Earth, though it is probably formed by different processes. Image courtesy of NASA.

(Opportunity and Spirit). Orbital thermal infrared spectroscopy has revealed two different predominant rock types which have been interpreted as the volcanic rocks basalt and andesite. Spatially limited areas of hematite and olivine have been recognized by remote sensing from orbit (Figure 6).

The detection of olivine, which weathers easily in the presence of water, supports the generally held view that water has not existed in its liquid form on the Martian surface for large periods of time. Five of the six possible modes of formation for the detected hematite deposits, however, involve water. A possible resolution to this conundrum is the proposal that frozen glacial deposits or permafrost existed early in the history of Mars, then melted slowly over time to produce water that seeped into the ground and was later heated by a shallow magma, thereby reacting in the subsurface to form the oxidized iron mineral, hematite. Although these analyses effectively represent point measurements on widely dispersed locations on the Martian surface, they give a landed context for the orbital observations. Generally, the Mars Pathfinder analyses are thought to represent the more andesitic basalt member discovered by Mars Global Surveyor, whereas Viking analyses match the more mafic basalt end member.

The results of soil and dust geochemical analyses on Mars by orbital, landed, and telescopic missions have revealed soils relatively high in Fe and S and low in Si and Al. The mineralogy of the soil is not well defined, but is inferred to consist of poorly crystalline weathering products of basalts, analogous to palagonite, which is a hydrous weathering product of basaltic glass. The presence of large amounts of S and Cl in the dust suggests the presence of soluble salts such as sulphates, possibly deposited in the soil as a result of deposition of volcanic aerosols from the atmosphere. To the current time, only small amounts of carbonate have been detected in the homogeneous dust covering Mars. No outcrops of carbonate have been discovered. The lack of carbonates is a strong argument against a long-lived ocean or standing water, which might be expected to deposit carbonate in the presence of the CO_2-rich Martian atmosphere, just as limestone forms in the shallow coastlines on Earth.

Water on Mars

At low latitudes, daily temperatures on Mars range from about −100° to +17 °C, and the average is −60°C. Because of the low pressure exerted by the very thin atmosphere, at these temperatures liquid water is everywhere unstable. Consequently, the water ice at the poles sublimes (goes straight from ice to vapour) into the atmosphere. Down to latitudes of about 40°, ice can exist in the ground as 'permafrost' as shallow as 1 m. Water ice has been detected at the north pole when it is exposed as the overlying carbon dioxide ice ('dry ice') sublimes in summer.

Since the 1970s, when Viking orbiters sent back high-resolution images of the surface of Mars, scientists have puzzled over features that resemble the gullies and water-eroded valleys seen on Earth. The lack of liquid water on the Martian surface today begs the question as to how the gully and valley features formed. Some scientists have postulated that a thicker atmosphere in the past may have led to liquid water being stable on the Martian surface. Probable water-influenced features on Mars have been recognized on three different scales and are commonly grouped into 'outflow channels', 'valley systems', and 'gullies', in order of descending scale.

Giant outflow channels on Mars are several tens to hundreds of kilometres across and many thousands of kilometres in length. They are mostly Hesperian in age and commonly start in chaotic terrain, as seen in the image of Hydaspis Chaos (Figure 7). They are usually associated with streamlined islands and terraces, indicating massive fluid flow, with the probable source being water, although some researchers have suggested CO_2 as a possible fluid.

Valley networks, such as those seen in the Thaumasia region in Figure 8, superficially resemble branching valley fluvial systems here on Earth; however, the lack of fine-scale structure, low drainage densities, and differing morphology argues against a rainfall and subsequent surface runoff origin. Instead, groundwater flow from seeps or hydrothermal systems is a plausible mode of formation. Most of the valley networks are Noachian in age, but there are younger systems, including those developed on Amazonian-age terrain around volcanic centres in the Tharsis region.

Martian gully systems often develop in the rims of impact craters, and have fine-scale features that suggest they are very young. They do not occur near the equator, appearing only at latitudes poleward of 30° in both hemispheres. A possible mode of formation is by melting of water beneath snow or ice packs. The lack of gullies around the equator may indicate that

Figure 7 (A) Hydaspis Chaos, the source of Tius Valles, as imaged by Viking, showing a typical giant outflow channel. Note streamlined island features. The image is approximately 200 km across (north is up). formation of ice in impact craters was insufficient to produce these deposits.

The gamma ray spectrometer (GRS) on the orbiting spacecraft Mars Odyssey has been able to map hydrogen abundance in the top metre of the surface of Mars. The most likely source of the hydrogen in the Martian crust is molecular water or hydroxyl (OH^-) ions in weathered rocks. The distribution of hydrogen in the Martian surface is shown in Figure 9.

Large-Scale Features

Due to the smaller size of Mars in comparison to Earth, and the apparent lack of plate tectonics in the past 4 billion years, some topographic features have taken on exaggerated forms. The Tharsis bulge is a large region of volcanism and deformation crossing the equator. The formation process of the Tharsis uplift is still under discussion; it may be due to convection in the interior of the planet or to there being a region of intense volcanism. The Tharsis complex consists of two broad rises, the largest southern rise containing three of the largest volcanoes on Mars, Ascraeus Mons, Pavonis Mons, and Arsia Mons. The smaller northern rise is dominated by the volcanic construct Alba Patera.

Olympus Mons (Figure 10) is situated to the west of the Tharsis region and though not surficially connected to the region, it is thought to be connected in origin. Olympus Mons is the largest known volcano in the Solar System. Like some of Earth's volcanoes, it

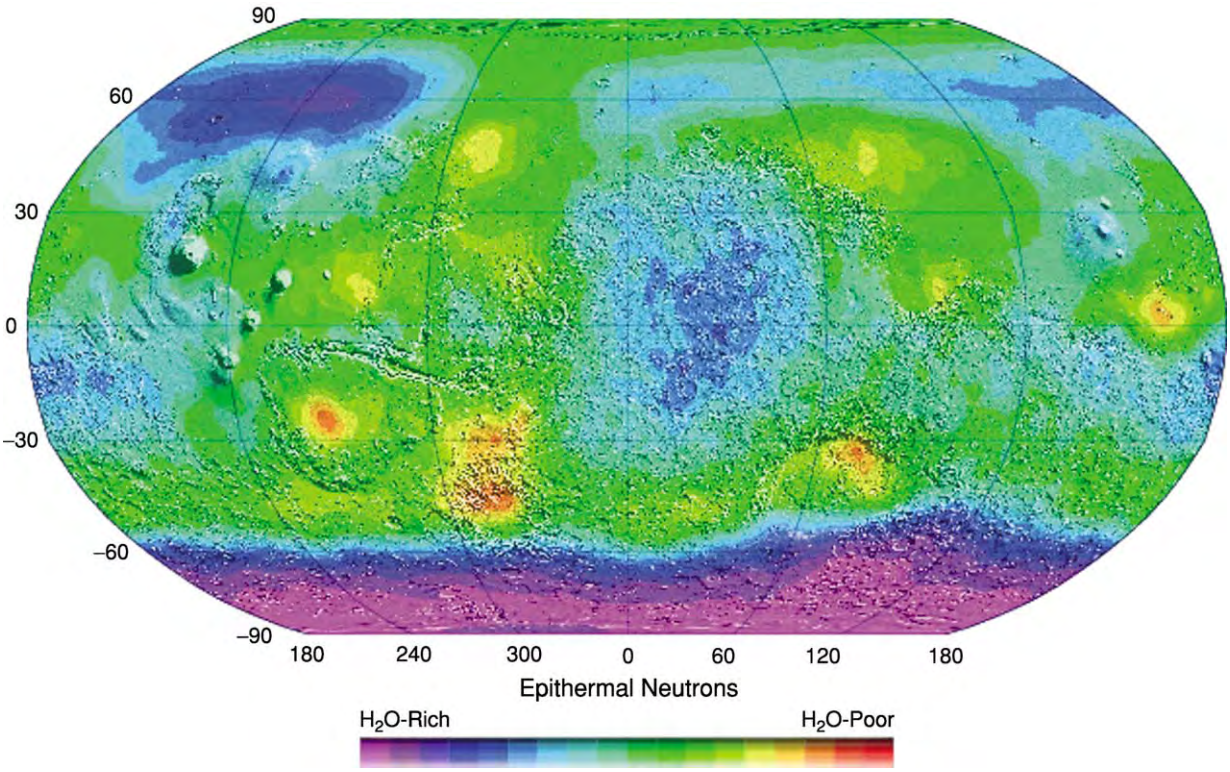

Figure 9 Map of hydrogen (or epithermal neutrons) in the shallow Martian crust (late southern summer), as detected by the gamma ray spectroscope on Mars Odyssey. Image courtesy of Dr William V. Boynton, University of Arizona.

Figure 10 Image of Olympus Mons, as observed by the NASA Viking Orbiters. Image courtesy of NASA.

is thought to have been an area of the crust situated above a region of advecting hot mantle material, known as a hotspot. Unlike Earth analogues, Olympus Mons continued to build, because at the time of formation Mars lacked the plate tectonics to move the volcano away from the source. At 21 183 m above the global reference datum, Olympus Mons is 2.5 times higher than Earth's largest shield volcano, Mauna Loa, and 100 times its volume.

Valles Marineris, named for the spacecraft that first discovered it (Mariner 9), is a giant canyon system that extends eastward some 4500 km from the central regions of the Tharsis complex. The troughs are generally about 50 to 100 km wide and the depth of the floor drops down to 5310 m below the global reference datum (six to seven times as deep as the Grand Canyon). This feature is thought to have formed as the uplift of Tharsis created tension in the cooled crust.

Martian Polar Regions

The polar regions are broadly composed of four geological units: the basal plains, the polar layered deposits, the residual ice, and the seasonal frost. The basal plains differ north from south, In the south, they are believed to date from the Noachian Period. There is evidence of intense cratering, contractional deformation, resurfacing of low areas, and local dissection producing valley networks. There is no evidence for polar deposits, ice sheets, or glaciation at these times. During the Hesperian, these deposits were altered by waning impacts and volcanism. In the north, the basal plains are much younger, being buried by a water or debris ocean during the Hesperian Period.

The polar layered deposits began building up during the late Hesperian or later and appear to be similar at both poles. Polar layered deposits extend further than do the icecaps that overlie them (to a greater and more asymmetric extent in the south). The deposits are composed of dust, water ice, and other volatiles such as CO_2, in varying ratios for each layer. Each of these layers, shown in Figure 11, was deposited under differing environmental conditions.

Due to the small number of superimposed craters at each polar icecap, the caps have been interpreted to be of late Amazonian age, with the southern cap being slightly older than the northern. This means that the Martian environment has only recently allowed the current polar icecaps to form. This is likely to be due to the changing obliquity (0°–60°) of the planet, causing the icecaps to reform continuously. There is evidence of advance and retreat at both poles, but exact timing remains unknown. The residual ice in the north appears to be mainly H_2O, whereas the south polar surface residual ice appears to be CO_2. Little is known of the bulk composition of residual ices at either pole, because thin overlying layers of CO_2 ice can mask signatures of the composition beneath. The seasonal frost is composed of CO_2

ice that condenses from the atmosphere during winter and sublimes again in the Martian summer.

Satellites of Mars

Mars has two small satellites, Phobos (27 km maximum diameter) and Deimos (25 km maximum diameter), both irregular potato-shaped bodies. Both have cratered surfaces and Deimos is also strongly grooved. Their origin is obscure – they may be captured asteroids. The orbit of Phobos is unstable and it will eventually crash into Mars.

Shergottite–Nakhlite–Chassigny Meteorites

Meteorites, widely accepted as being from Mars have been collected here on Earth. They are collectively called SNC meteorites after the discovery locations of the first three meteorites – Shergotty, Nakhla and Chassigny. They are believed to come from Mars because: 1.) their young age of formation relative to the Solar System, suggesting they were formed on a rocky planet, and 2.) trapped gases inside solidified molten rock produced by high shock pressures in some of the meteorites display chemical and isotopic characteristics matching those of the Martian *atmosphere* (as reported by the Viking landers). The trapped gases are interpreted to represent samples of the atmosphere when these rocks were ejected from Mars by impacts. The Martian meteorites have contributed greatly to knowledge about Mars, but naturally have also raised many scientific questions. The inability to pinpoint a source location on Mars is the greatest limitation on the utility of the SNC meteorites, but the ability to analyse the rocks with the most modern of terrestrial scientific equipment is a great advantage lacking as we do any rock samples directly recovered from the planet.

At the current time, there are 30 known SNC meteorites. The reported crystallization ages of SNC meteorites range from 154 Ma to 1.3 Ga, with the exception of ALH84001, which has a crystallization age of about 4 Ga. ALH84001 was discovered in Antarctica in 1984 and was held in storage by NASA for some years. In 1996, it was reported that a team of NASA scientists had found possible signs of life in small amounts of carbonate within ALH84001. Six lines of evidence were cited that would be explained best by invoking a biological origin. These lines of evidence have been debated within the scientific community in the intervening years and thus the question of life on Mars still remains open, lacking rock samples directly recovered from the planet.

Mars Exploration Rover Missions

The Mars Exploration Rovers, Spirit and Opportunity, have added to the data from the planet's surface. Designed as mobile remote geologists, they were equipped with various instruments to study the rocks they found, including panoramic cameras, infrared spectrometers, abrasion tools and a microscopic camera. '*Opportunity*' has been successful in

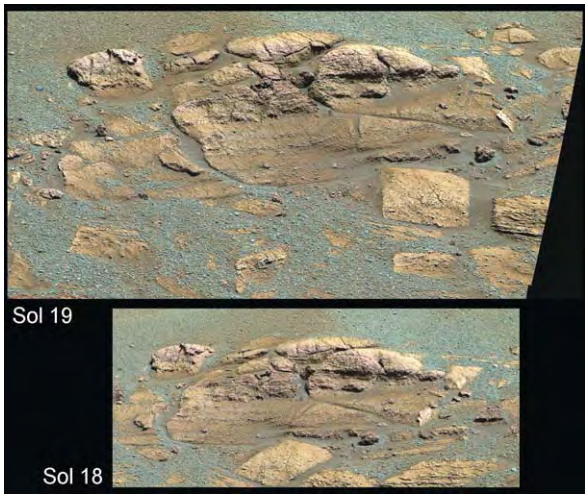

Figure 12 Images of the rock 'El Capitan', the first bedrock to be investigated by a Mars landed rover, on two days (sols). The outcrop is approximately 10 cm high. Image courtesy of NASA.

studying a number of fascinating outcrops which are only now starting to be interpreted. An image of the first competent rock outcrop found by a rover on Mars is shown in false colours in Figure 12. It reveals layered successions which could be volcanic or sedimentary in nature. Interplanetary investigations like these will continue to reveal the true extent of apparent differences in the geology of Earth and Mars.

Jupiter, Saturn and Their Moons

P Moore, Selsey, UK

Introduction

Jupiter and Saturn, the largest and most massive planets in the Solar System, have no visible solid surfaces and are therefore not of real concern to the geologist. However, their satellite systems are of immense interest. Jupiter has four major satellites (the Galileans) which are of planetary size, and which differ markedly from each other geologically; there are also over four dozen small satellites, almost certainly captured asteroids, which seem to be icy. Saturn has one very large satellite (Titan), which has a dense atmosphere obscuring the surface; there are also eight medium-sized icy satellites as well as numerous ex-asteroids. These various bodies are discussed in this article.

Jupiter

Jupiter is the giant of the Sun's system. It is more massive than all the other planets combined, and is generally the brightest object in the sky apart from the Sun, the Moon, and Venus. Physical and orbital data are given in Table 1.

Telescopically, Jupiter shows a yellowish, obviously flattened disk, crossed by dark belts and bright zones (Figure 1). It has always been assumed that the belts are regions of descending gases while the bright zones are regions where gas is rising from the interior, though some recent (2003) observations may indicate that the reverse is true. There are generally two very prominent belts, the North Equatorial and the South Equatorial, with others in higher latitudes. Jupiter does not rotate in the way that a solid body would do. The region between the north edge of the South Equatorial Belt and the south edge of the North Equatorial Belt (System I) has a mean period of 9 h 50 m 30 s, while the period of the rest of the planet (System II) is 9 h 55 m 41 s, but individual features have periods of their own. Radio methods indicate that the interior (System III) has a period of 9 h 55 m 29 s, though this is subject to some uncertainty.

Much of our knowledge of Jupiter has been derived from five space-craft: two Pioneers, two Voyagers, and Galileo. Details are given in Table 2. Useful data were also obtained from two fly-by probes, Ulysses in February 1992 (the solar polar probe) and Cassini in December 2000 (en route for an encounter with Saturn).

Jupiter is assumed to have a hot silicate core at a temperature of at least 20 000°C, probably rather more. The core is surrounded by a thick shell of liquid metallic hydrogen, which is itself surrounded by a shell of liquid molecular hydrogen; above lies the atmosphere, made up chiefly of hydrogen and helium, with hydrogen compounds such as methane and ammonia. Windspeeds in the visible clouds are high, and the surface details are always changing. Of special note is the Great Red Spot, which has been visible for most of the time since regular observations began in the seventeenth century. Once thought to be a glowing volcano, it is now known to be a phenomenon of Jovian meteorology – a high-level anticyclonic vortex, elevated by 8 km above the adjacent cloud deck.

Jupiter's magnetic field is much the strongest in the Solar System. The magnetic axis is inclined to the rotational axis at an angle of 9.6°; the polarity is opposite to that of the Earth's field. The planet is a powerful radio source, and is surrounded by zones of radiation which would quickly be fatal to an astronaut unfortunate enough to enter them. There is a system of dark, obscure rings, probably formed from material released from the small inner satellites by meteoritic impact. They are quite unlike the glorious icy rings of Saturn.

Table 1 Data for Jupiter

Distance from the Sun	Max 815 700 000 km (5.455 astronomical units)
	Mean 778 350 000 km (5.203 a.u.)
	Min 740 900 000 km (4.951 a.u.)

Table 2 Space craft to Jupiter

Name	*Launch date*	*Encounter date*	*Nearest approach, km*	
Pioneer 10	2 Mar. 1972	3 Dec. 1973	131 400	Fly by
Pioneer 11	5 Apr. 1973	2 Dec. 1974	46 400	Fly by. Went on to Saturn
Voyager 1	5 Sept. 1977	5 Mar. 1979	150 000	Images of Jupiter and the Galileans. Went on to Saturn
Voyager 2	20 Aug. 1977	9 July 1979	714 000	Complemented Voyager 1. Went on to Saturn, Uranus, Neptune
Galileo	18 Oct. 1989	7 Dec. 1995	Entry	Orbiter and entry probe

Data were also obtained from Ulysses (1992) and Cassini (2001).

Satellites

The four Galilean satellites – Io, Europa, Ganymede, and Callisto – were observed by Galileo as long ago as 1610 (hence the name of the space-craft). Four small inner satellites were discovered between 1892 and 1979, and there are many small bodies moving round Jupiter beyond the path of the outermost Galilean, Callisto. The total number of known satellites by April 2004 was 62. Data for all the satellites over 8 km in diameter are given in Table 3.

Io Io is violently volcanic. In March 1979, S Peale and his colleagues in America suggested that since Io's orbit is not perfectly circular, the interior might be 'flexed' by the gravitational pulls of Jupiter, and also the other Galileans, sufficiently to produce active surface volcanoes. Only a week later the first volcanic plume was detected on an image from the Voyager 1 space-craft, and many dozens have since been identified, both from the space probes and with the Hubble Space Telescope. Lava-flows and lava lakes are plentiful; the average temperature of the lavas is about 1600°C. Many explosive eruptions are driven by sulphur dioxide gas emission; the surface is remarkably colourful, with yellow, orange, red, and black areas (Figure 2). The surface is 'young' and virtually without surviving impact craters. One volcano, Loki, is the most powerful in the Solar System, emitting more heat than all the Earth's active volcanoes combined. Io is connected to Jupiter by a strong flux tube, and has a marked effect upon the Jovian radio emission; material sent out by the volcanoes is spread along the orbit, producing a torus.

Europa Europa is only slightly smaller than Io, and rather further from Jupiter, but the two satellites are very different. Europa has a smooth, icy surface with very limited vertical relief and few impact craters, though one of these, Pwyll, shows bright rays extending outward and crossing all other features. There are plains, chaotic areas, and low ridges, together with shallow pits. Detailed views from space-craft (particularly Galileo) show what look remarkably like icebergs, and it is widely believed that an ocean of salty water lies below the visible surface, with the icebergs floating around (Figure 3). Fragmented blocks of ice seem to look very like the blocks in the Earth's polar seas during a springtime thaw.

Europa does not have a strong internal magnetic field, but it orbits within Jupiter's magnetosphere, and the instruments on Galileo have detected an induced magnetic field which produces significant effects linked with the rotational period of the planet. Jupiter's magnetic field at Europa changes direction every $5\frac{1}{2}$ h, and this indicates the existence of a layer of electrically conducting material, such as salty water, not far below the icy surface of Europa. It seems that the ocean may lie at a depth of less than 100 km. If it really does exist (and as yet there is no

Table 3 Satellites of Jupiter

? doubtful value.

Figure 2 Io, imaged by the Galileo probe, the colour is very accurate. The volcanoes, such as Pele, are violently active. Reproduced from NASA.

final proof) there will be tidal effects. There have been the inevitable speculations about possible life-forms, but conditions in such a strange, sunless sea would not appear to be inviting!

Figure 3 Europa, imaged from the Galileo space craft in orbit round Jupiter. The icy surface, unlike any other in the Solar System, may cover a salty ocean. Hubble Space Telescope Image, NASA.

Ganymede Ganymede is the largest satellite in the Solar System, and is actually larger than the planet Mercury, though not so massive; the mean density of the globe is less than twice that of water. There is an excessively tenuous atmosphere, and a marked magnetic field. Presumably this indicates the presence of a metallic core surrounded by a mantle composed of a mixture of rock and ice; the surface is icy. There are two types of surface terrain, about equal in area, very ancient, thickly cratered dark regions and somewhat younger light regions, marked with an extensive array of ridges and grooves. Evidently there has been marked tectonic activity in the past. In general, the craters have little vertical relief. The largest indiviual

feature is a dark plain which has been given the appropriate name of Galileo.

Callisto Callisto is rather smaller than Ganymede, and is less dense, so that ice is a major constituent of the globe. The surface is heavily cratered, and there are two huge ringed plains, Valhalla and Asgard. Unexpectedly, it has been found that the local magnetic field fluctuates in the same way as that of Europa, and there may be a similar salty ocean deep inside the globe. Space-craft data indicate that the interior of Callisto is made up of compressed rock and ice, with the percentage of rock increasing with depth.

Amalthea Amalthea the only other Jovian satellite over 200 km in diameter, was discovered in 1892 by EE Barnard, using the 91 cm refractor at the Lick Observatory (this was the last visual discovery of a planetary satellite). It is irregular in form; the surface is red, due possibly to contamination from the volcanoes of Io. In November 2002, the Galileo space-craft flew past Amalthea and found that the density is very low; indeed the satellite has been described as an 'ice rubble pile'. The rotation is synchronous, with the longest axis pointing to Jupiter. Images from Galileo show that there are two craters, Gaea and Pan, which are very large relative to the overall diameter of Amalthea; there are ridges, troughs, and two bright patches which seem to be hills. Amalthea is one of four satellites known to move within the orbit of Io; the others are Metis, Adrastea, and Thebe. They are icy in nature, and impact craters have been imaged.

Outer Icy Satellites By April 2004, the total number of known Jovian satellites had risen to 62, but few of these were more than a few kilometres in diameter. Several satellites, including Himalia (diameter 184 km) move at between 11 and 12 million kilometres from Jupiter; these have direct motion, and those that have been imaged show the usual impact craters. Much further out move small satellites, many of which have retrograde motion; the largest, known before the space-probe era, are Ananke, Carme, Pasiphaë, and Sinope. They are so far from Jupiter that their orbits are not even approximately circular, and no two cycles are alike. There seems no doubt that all the outer icy satellites are captured asteroids; their small size means that they are very difficult to record.

Saturn

Saturn the largest and most massive planet in the Solar System, apart from Jupiter, is distinguished by its magnificent icy ring system, making it probably the most beautiful object in the entire sky. Physical and orbital data are given in Table 4.

Saturn's globe shows belts not unlike those of Jupiter, but much less prominent, and sensibly curved. Predictably, the globe is flattened; this is because of the rapid rotation. It is thought that there is a silicate core at a temperature of perhaps 15 000°C, overlaid by layers of metallic hydrogen, molecular hydrogen, and then the atmosphere, which is not unlike that of Jupiter.

There is no surface feature comparable with the Great Red Spot on Jupiter, but prominent, temporary white spots are seen occasionally, as in 1933, 1960, and 1990 (Figure 4). The 1933 spot was discovered on 3 August by WT Hay, using a 15 cm refractor; it remained identifiable until 13 September, and was considered to be of an eruptive nature. The 1990 spot, discovered by S Wilber, was in the same latitude.

Table 4 Data for Saturn

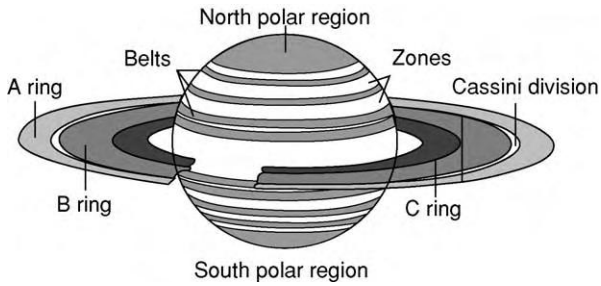

Figure 5 Diagram of Saturn and its ring system. There are some less prominent rings behind the main system.

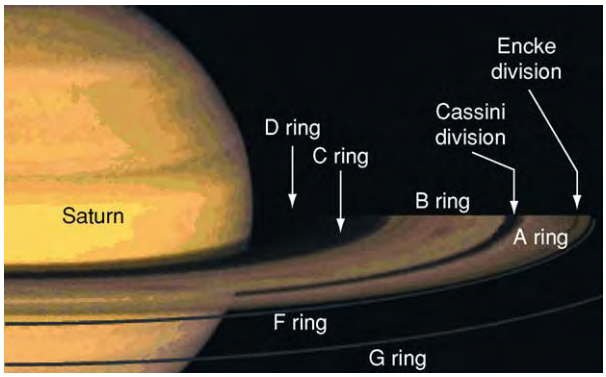

Figure 6 Diagram showing the main ring system. The bright rings are A and B, C is the Crepe or Dusky Ring. D is not well defined. Reproduced from Kennod R (1990) *The Journeys of Voyager NASA reaches for the planets, BDD*, New York.

Table 5 The ring system of Saturn

Feature	*Distance from centre of Saturn, km*
Inner edge of ring D	66 900
Outer edge of ring D	73 150
Inner edge of ring C	74 510
Outer edge of ring C	92 000
Inner edge of ring B	92 000
Outer edge of ring B	117 500
Centre of Cassini division	119 000
Inner edge of ring A	122 200
Centre of Encke division	135 700
Outer edge of ring A	136 800
Centre of ring F	140 210
Centre of ring G	168 000
Inner edge of ring E	180 000
Brightest part of ring E	230 000
Outer edge of ring E	480 000

Within a few days the spot had been spread out by Saturn's strong equatorial winds, and by October had been transformed into a bright zone all round the equator. Extra outbreaks were seen in it, clearly indicating an uprush of material from below. Saturn has a strong magnetic field, though less powerful than that of Jupiter; the rotational axis and the magnetic axis are almost coincident.

There are three main rings (Figure 5); A and B, separated by a gap known as the Cassini Division is honour of its discoverer, and an inner semi-transparent ring, C (the Crepe Ring) (Figure 6). Details of the ring system are given in Table 5. The rings are made up of ice particles, from grains up to several metres across; the brightest ring, B, shows curious 'spokes', presumably particles elevated away from the main ring plane by magnetic or electrostatic forces. The irregular F ring, outside the main system, is stabilized by two small 'shepherd' satellites, Prometheus and Pandora. Though the system is very extensive, with a total diameter of 270 000 km, it cannot be more than 200 m thick, and if all the particles could be combined they would make up an icy satellite less than 300 km across.

Three space-craft have now encountered Saturn; Pioneer 11, and the two Voyagers. Data are given in Table 6. The Cassini/Huygens probe, launched in 1997, was scheduled to reach its target in late 2004.

Satellites

The satellite system of Saturn is very different from that of Jupiter. There is one very large satellite, Titan, and seven icy satellites with diameters between 200 and 1600 km; the rest are much smaller. By May 2003, the total number of known satellites had risen to 31. Data are given in Table 7.

Titan Apart from Ganymede, Titan is the largest, satellite in the Solar System. Its surface is permanently hidden by its dense atmosphere, made up chiefly of nitrogen with appreciable amounts of methane and ethane; organic compounds are plentiful. The atmospheric pressure on the surface is 1.6 times that of the Earth's air at sea level; the surface temperature is −178°C.

Table 6 Space craft to Saturn

Name	*Launch date*	*Encounter date*	*Closest approach, km*	
Pioneer 11	5 Apr. 1973	11 Sept. 1979	20 880	Preliminary results
Voyager 1	5 Sept. 1977	12 Nov. 1980	124 200	Images included Titan

Phoebe	12 952 000	550.48 (ret)	220	0.77	0.07

The remaining outer satellites are below 50 km in diameter.

Nothing definite is known about the nature of the surface. The Voyagers could do no more than send back images of the top of a layer of orange haze; infrared images taken with the Hubble Space Telescope and, the Keck II telescope in Hawaii have shown bright patches and darker regions. It has been suggested that there could be frozen landmasses and frigid hydrocarbon seas or lakes, but we must await the arrival of the Huygens probe, scheduled to land on Titan in early 2005. Certainly Titan is unlike any other body in the Solar System. It does not seem to have an internal magnetic field, but orbits near the outer edge of Saturn's vast magnetosphere. As with most of the other satellites, its rotation is synchronous, so that the same hemisphere always faces Saturn.

Medium-sized icy satellites These seem to form 'pairs'; Rhea/Iapetus (Figure 7), Tethys/Dione, and Mimas/Enceladus. Two very small satellites, Telesto and Calypso, move in the same orbit as Tethys, while Helene shares the orbit of Dione. Hyperion, moving between the orbits of Titan and Iapetus, is irregular in shape, and has a darkish surface often regarded as 'dirty ice'; the rotation is not synchronous, and on average the rotation period is around 13 days, There are several craters, and one long ridge or scarp. It is possible that Hyperion is part of a larger body which broke up. Phœoebe, outermost of the named satellites, is much further from Saturn, and has retrograde motion, so that it must be a captured asteroid. Little is known about its surface, but it was imaged in 2004 by the Cassini probe and found to be crater scarred. It

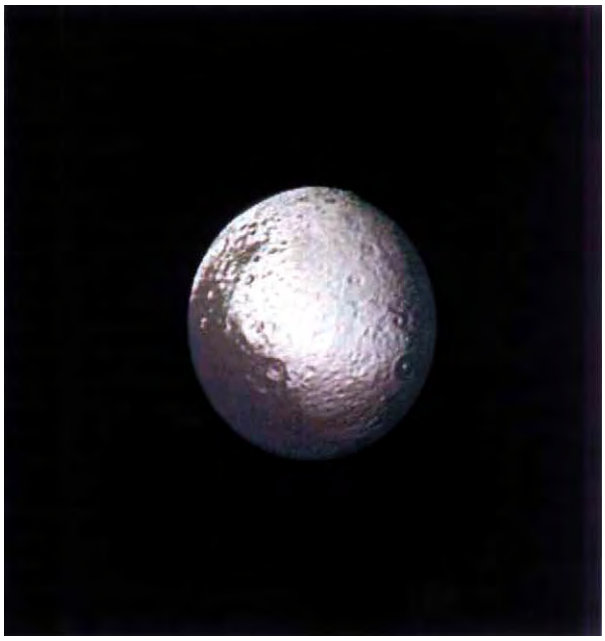

Figure 7 Iapetus, imaged by Voyager 2, 1981. The dark area is well defined; like the bright areas, it is cratered. Copyright Cawin J. Hamilton 1999.

was the first satellite to be discovered photographically (by WH Pickering in 1898).

Mimas Mimas is only slightly denser than water, and consists largely of ice, though there may well be a small rocky core. The surface is dominated by a huge, deep crater named Herschel in honour of the discoverer of Mimas. The 130 km crater is one-third

the diameter of Mimas itself, so that the impact which formed it must have come close to disrupting the entire satellite. Parallel grooves indicate that the surface must have been subjects to considerable strain.

Enceladus Enceladus is the most interesting of all the satellites from a geological point of view, because there are at least five different types of terrain. Craters exist in many areas, and give the impression of being young and sharp; there is also an extensive grooved plain which is crater-free. Surprisingly, Enceladus may be active, with a liquid interior; if so, we are seeing what is termed cryovulcanism, the icy equivalent of volcanic action. The interior of Enceladus is presumably being tidally flexed by the gravitational pulls of Saturn and the more massive satellite Dione, the orbital period of which is twice that of Enceladus. Re-surfacing has led to the obliteration of old craters.

Tethys Tethys has a very low density, and is probably composed almost entirely of ice. One crater, Odysseus, has a diameter of 400 km larger than Mimas. The main surface feature is a huge trench, running from near the north pole across the equator and along to the south polar region.

Dione Dione is only slightly larger than Tethys, but much denser and more massive. The surface is not uniform. The trailing hemisphere is relatively dark and heavily cratered, the leading hemisphere is much lighter. One prominent feature, named Amata, is associated with a system of bright wispy features which extend over the trailing hemisphere and are accompanied by narrow linear troughs and ridges. Geologically, Dione seems to have been much more active than Tethys.

Rhea Rhea is heavily cratered; as with Dione the trailing hemisphere is the darker of the two, and there are not many really large formations. There are two distinct types of terrain, the first contains craters over 40 km across, while the second, covering parts of the polar and equatorial regions, is characterized by craters of much smaller size. Rhea seems to have a rocky core, around which most of the material is ice.

Iapetus Iapetus is unusual in many ways. The trailing hemisphere is bright and icy, but the leading hemisphere is as dark as a blackboard. The demarcation line is not abrupt; there is a 200–300 km transition zone. The low density of Iapetus shows that the dark areas are due to surface materials, which have welled up from below, but their thickness is not known. It is also notable that many of the craters in the bright areas have dark floors. There have been suggestions that the dark material has been wafted on to Iapetus from the outer satellite Phœoebe, but this seems unlikely, partly because Phœoebe is so small and remote but mainly because the colours do not match. We know little about the dark area, but the bright regions contain craters of the usual type. As seen from Earth, Iapetus is very variable; it is brightest when west of Saturn, with the bright hemisphere facing us.

Minor satellites Pan, discovered on a photograph taken by the Voyager 2 space-craft, moves within the outer division of Saturn's ring system (the Encke Division). Atlas, moves near the edge of Ring A: nothing is known about its surface details. Prometheus and Pandora, the F-ring 'shepherds' have been imaged; both consist mainly of ice, and both are cratered, Prometheus shows ridges and valleys, while Pandora has two 30 km craters. Janus and Epimetheus have the same mean distance from Saturn; every four years they approach each other, and actually exchange orbits. They are irregular in shape, and may well be the remnants of a larger body which has broken up. Predictably, both are cratered.

Outer minor satellites All these are small, though one, known at present as S/2000 S3, may be almost 50 km in diameter. By May 2003 the total number of satellites had risen to 31. The outer minor satellites tend to form clusters, some with direct motion and others retrograde; most of them seem to be fragments of larger satellites which have broken up. Nothing is known about their surface features. No doubt many more tiny satellites await discovery.

Future space probes, and more powerful Earth-based telescopes, will add greatly to our knowledge. Certainly there is no doubt that to the geologist, the giant planets and their satellites are of surpassing interest.

Neptune, Pluto and Uranus

P Moore, Selsey, UK

Introduction

Five planets have been known since ancient times: Mercury, Venus, Mars, Jupiter, and Saturn, all of which are prominent naked-eye objects. Since the invention of the telescope, three more planets have been discovered beyond the orbit of Saturn: Uranus in 1781, Neptune in 1846, and Pluto in 1930, though the planetary status of Pluto is a matter for debate. This article describes the outer members of the Solar System, together with their numerous satellites.

Uranus

Uranus was discovered in March 1781 by William Herschel, one of the greatest of all observers. He was Hanoverian by birth, but spent most of his life in England; by profession he was a musician, but his main interest was in astronomy, and he built excellent reflecting telescopes. With one of these he began systematic 'reviews of the heavens', and came across an object which was certainly not a star. It showed a perceptible disk, and it moved from night to night. Herschel believed it to be a comet, but before long its planetary nature became evident.

Uranus is a giant world, but it is not of the same type as Jupiter and Saturn. Rather than being described as a gas-giant, it is better referred to as an 'ice-giant' (Figure 1). The outer atmosphere is made up chiefly of hydrogen (probably about 83% by number of molecules) and helium (15%); methane accounts for 2%, so that there are only traces of other substances. Methane freezes out at a very low temperature, and forms a thick cloud layer above which is the predominantly hydrogen atmosphere. Methane absorbs red light, which is why Uranus appears bluish-green. Minor constituents such as ethane C_2H_6 and acetylene (C_2H_2) play a role in forming 'hazes'.

Below the atmosphere come the 'ices', a mixture of water, methane, and ammonia with traces of other substances. These materials behave as liquids under the temperature and pressure conditions inside the globe. However, Uranus differs from the other giant

Figure 1 Uranus, imaged from Voyager 2 in January 1986. Compared with the other giants, Uranus is bland in appearance, and there are no well marked features.

Table 1 Data for Uranus and Neptune

	Uranus	*Neptune*
Distance from Sun	Max 3 005 200 000 km (20.088 a.u.)	4 347 000 000 km (30.316 a.u.)

Albedo	0.51	0.35
Mean surface temperature, °C	214	220

planets in that it seems to have at best a very weak internal heat-source. This means that the temperatures of the surfaces of Uranus and Neptune are almost equal, even though Neptune is so much farther from the Sun.

Uranus is unusual in one respect; its axial inclination makes more than a right angle to its orbit, so that the rotation is technically retrograde, though not usually classed as such (Table 1). From Earth the equator of Uranus is regularly presented, as was the case in 1923 and 1966; at other times a pole may lie in the centre of the disk – the south pole in 1985, for instance, and the north pole in 2030. The rotation period is only 17.2 h, so that the Uranian calendar is strange. During one orbit each pole has a 'night', lasting for 21 Earth years, with corresponding daylight at the opposite pole. The reason for the extreme axial inclination is not known.

Uranus has a magnetic field, the polarity of which is opposite to that of the Earth, and the magnetic axis is displaced from the axis of rotation by 57.6°, again for reasons which are unknown; neither does the magnetic axis pass through the centre of the globe – it is offset by 8000 km.

Our main knowledge of Uranus has been drawn from Voyager 2, the only probe to have encountered the planet. Launched in 1977, Voyager 2 encountered Jupiter in 1979 and Saturn in 1981, and on 24 January 1986, it passed over the north pole of Uranus, only about 80 000 km above the cloud-tops, before going on to rendezvous with Neptune in 1989. Clouds were recorded on the globe, and images were obtained of all the major satellites, as well as the ring system.

Table 2 Rings of Uranus

	Distance from Uranus, km	*Width, km*	*Eccentricity*	*Period, h*
6	41 837	1.5	0.0010	6.1988
5	42 235	2	0.0019	6.2875
4	42 571	2.5	0.0010	6.3628
Alpha	44 718	4 10	0.0008	6.5808
Beta	45 661	5 11	0.0004	7.0688
Eta	47 176	1.6	0.004	7.4239
Gamma	47 626	1 4	0.0001	7.5307
Delta	48 303	3 7	0.0	7.6911
Lambda	50 024	2	0.0	8.1069
Epsilon	51 149	20 96	0.0079	8.3823

The rings of Uranus are quite unlike those of Saturn; they are thin and dark, so that they are not easy to study with Earth-based telescopes. Details of the system are given in Table 2. Ten rings are known; their thickness is between 0.1 and 1 km, and only one, the outermost (the Epsilon ring), is of considerable width. This ring is appreciably eccentric; the tiny satellites Cordelia and Ophelia, discovered by Voyager 2, act as 'shepherds' to it. The rings seem to be made up mainly of particles a few metres in diameter.

Uranus has an extensive satellite system; data are given in Table 3. Only Miranda, Ariel, Umbriel, Titania, and Oberon were known before the Voyager mission (the names come from Shakespeare and Pope's poem *Rape of the Lock* – a strange departure from the usual tradition of mythology). All these were imaged by Voyager 2. The largest satellites, Titania and Oberon, are heavily cratered, but are not alike. Titania has clearly been the site of much past tectonic

Table 3 Satellites of Uranus

	Mean distance from Uranus, km	*Orbital period, d*	*Diameter, km*	*Magnitude*	*Escape velocity, km s* ^{1}	*Density, water 1*
Cordelia	49 471	0.330	26	24.2	V. low	?

Titania	435 000	8.206	1578	13.7	1.6	1.6
Oberon	583 500	13.463	1523	13.9	1.5	1.5
Caliban	7 230 000	579	60	22.3	V. low	?
Stephano	8 002 000	676	39	24.0	V. low	?
S/2001 UI	8 571 000	769	20	25	V. low	?
Sycorax	12 179 000	1 283	120	20.7	V. low	?
Prospero	16 418 000	1 992	40	23	V. low	?
Setebos	17 459 000	2 202	40	23	V. low	?

activity; there are ice cliffs, fault valleys, and trench-like features, one of which extends for over 1450 km. Oberon has a brownish surface; some of the craters are dark-floored, and there are several systems of bright rays. Ariel is also cratered, but the dominant features are broad, branching, smooth-floored valleys which look as though they have been cut by fluid, though water is not a likely candidate because of Ariel's small size and low temperature. Umbriel has a darker and more subdued surface, with one prominent feature of uncertain nature near the edge of the best image (it must be remembered that Voyager could cover only half of the total surface). Miranda, passed by Voyager at a mere 3000 km, has an amazingly varied landscape; there are several distinct types of terrain – old, cratered plains, brighter areas with cliffs and scarps, and large, trapezoidal regions known as corona. Large craters are lacking, but there are fault valleys, parallel ridges, and graben up to 15 km across. Miranda presents real problems of interpretation, particularly because the various types of terrain seem to have been formed at different periods. It has been suggested that the satellite may have been shattered and re-formed several times, but this would involve considerable heating, which, in view of Miranda's small size, and icy nature, does not sound probable.

All the remaining satellites are small, only Puck is as much as 100 km in diameter. The five outer satellites have retrograde motion, and are presumably captured asteroids.

Neptune

Neptune was discovered in 1846 by J Galle and H D'Arrest, from the Berlin observatory. Irregularities in the movements of Uranus had enabled the French mathematician UJJ Le Verrier to calculate the position of the body responsible for them (similar calculations by JC Adams in England had given much the same result). Neptune is a twin of Uranus, but the two worlds are by no means identical. Neptune is very slightly the smaller of the two, but it is appreciably denser and more massive, and is a much more dynamic world (Table 1). Unlike Uranus, it has a strong internal heat source, and sends out 2.6% more energy than it would do if it depended entirely upon what it receives from the Sun. It does not have an exceptional axial inclination; at the time of the Voyager 2 pass it was the south pole which was in sunlight. There is a magnetic field, but the magnetic axis is displaced by 47° from the axis of rotation and does not pass through the centre of the globe, so that in this respect Neptune really does resemble Uranus. The interior of Neptune is presumably not unlike that of Uranus, apart from the greater internal heat source.

The atmosphere consists mainly of hydrogen, with an appreciable amount of helium and some methane together with traces of other substances such as hydrogen cyanide, acetylene, and ethane. Voyager identified various cloud layers, at a level where the pressure is 3.3 bars there is a layer which seems to be of

hydrogen sulphide, above which are layers of hydrocarbons, with a methane layer and an upper methane haze. Above the hydrogen sulphide layer there are discrete clouds with diameters up to 100 km, casting shadows on the cloud deck 50 to 75 km below. These clouds may be described as 'methane cirrus'. Temperature measurements from Voyager show that there is a cold mid-latitude region, with a warmer equator and pole (we know little about the north pole, which was in darkness during the Voyager encounter). There are strong winds; most of them blow in a westerly direction (that is to say, opposite to the planet's rotation), and are distinctively zonal. At the equator they blow westward at up to 450 m s ^{1}. Further south they slacken, and beyond latitude $-50°$ they become eastward (prograde) up to 300 m s ^{1}, decreasing once more near the south pole. There is, in fact, a broad equatorial retrograde jet between latitudes $+45°$ and $-50°$, with a relatively narrow prograde jet at around latitude $-70°$.

At the time of the Voyager encounter the most conspicuous feature on the disk was the Great Dark Spot, a huge oval with a longer axis of 10 000 km, drifting westward relative to the adjacent clouds, it was a high-pressure area, rotating counter-clockwise and showing all the signs of an atmospheric vortex. Hanging above it were methane cirrus clouds, and between these and the main cloud deck there was a clear region 50 km deep. Other, smaller spots were seen at different latitudes, and the whole disk was extremely active. Later images obtained with the Hubble Space Telescope show that the Great Dark Spot has disappeared, so that the surface shows marked changes over relatively short periods.

Neptune has an obscure ring system (Table 4). The outer ring, named after Adams, is 'clumpy', with three brighter arcs, while the Lassell ring is a diffuse band of material containing a high percentage of very small particles. There may be 'dust' extending from the inner Galle ring almost down to the cloud-tops.

Eleven satellites are known (Table 5), but of these only two, Triton and Nereid, were discovered before the Voyager 2 fly-by. Triton is one of the most remarkable bodies in the entire Solar System. It was found by the English astronomer W Lassell a few weeks after the discovery of Neptune itself, and is brighter than any of the satellites of Uranus; it is also more reflective, with an albedo in places of 0.8, and it is the coldest world ever encountered by a space-craft – the temperature is $-235°$C, a mere $18°$ above absolute zero. The globe seems to be made up of a mixture of rock and ice. There is an extensive though very tenuous atmosphere, made up almost entirely of nitrogen with a trace of methane. Triton has retrograde motion, and there seems no doubt that it is a captured body rather than a bona fide satellite.

The surface is very varied. There is a general coating of ice, presumably water ice overlain by nitrogen ice; there is little surface relief, and there are few craters. The area surveyed by Voyager 2 was divided into three parts: polar (Uhlanga Regio), eastern equatorial (Monad) and western equatorial (Bubembe Regio). The polar area is covered with a pink cap of nitrogen snow and ice, and there are geysers, completely unexpected before the Voyager mission. Apparently there is a sub-surface layer of

liquid nitrogen. If any of this migrates upward, the pressure is relaxed and the nitrogen explodes in a shower of ice and vapour, travelling quickly up the nozzle of the geyser-like vent – fast enough to make it rise to several kilometres before falling back; the outrush sweeps dark débris along it, blown by winds in the tenuous atmosphere. The edge of the cap is well-defined, and north of it there is a darker, redder region. Monad Regio is part smooth, part hummocky, with rimless pits (paterae), mushroom-like features (guttae) and low-walled plains; Bubembe Regio is characterized by the so-called cantaloupe terrain – a nickname given to it because of its superficial resemblance to a melon-skin! Fissures cross it, meeting at elevated X or Y junctions; this is probably the oldest part of Triton's surface. Of course, we have no information about the hemisphere which was in darkness at the time of the Voyager encounter.

Nereid, the other satellite known before the Voyager mission, was discovered by G Kuiper in 1949. It is small, only 340 km in diameter, and has a very eccentric orbit, so that its distance from Neptune ranges between 1.35 million km and 9.62 million km. The orbital period is just over 360 days, but it is unlikely that its rotation period is synchronous; as with Hyperion in Saturn's system, the rotation period may be chaotic. It has direct motion, and although not well imaged from Voyager 2, it seems to be fairly regular in shape; there were vague indications of a few large craters. Of the other satellites, Proteus is actually larger than Nereid, but its closeness to Neptune means that it is not observable with Earth-based telescopes. The rotation is synchronous, and the albedo is low; it has been said that Proteus is 'as dark as soot'. The area imaged by Voyager is dominated by a circular depression, Pharos, 225 km in diameter and up to 15 km deep. The remaining inner satellites are small, icy, and presumably cratered; Voyager sent back one image of Larissa. The orbit of the 158 km satellite Galatea is very close to the Adams Ring. Three outer asteroidal satellites were discovered in 2001.

Pluto

Pluto, discovered by Clyde Tombaugh in 1930, is an enigma; it is smaller than the Moon or even Triton, and has an orbit which is both eccentric and inclined. It has one satellite, Charon. Data for Pluto and Charon are given in Table 6.

The calculations leading to the discovery of Pluto were made from 1905 by Percival Lowell, and were based upon perturbations of Neptune and (particularly) Uranus. Searches carried out with the Lowell refractor at Flagstaff in Arizona were unsuccessful, but the planet was finally identified at Flagstaff by Tombaugh, not too far from the position predicted by Lowell. After some discussion it was named Pluto, after the God of the Underworld. When near perihelion, it is closer-in than Neptune, as was the case between 1979 and 1999, but there is no danger of collision, because Pluto's orbit is inclined at an angle of 17°. After the discovery it was found that Pluto had been photographed at Flagstaff in 1915 and Mount Wilson in 1919, but had been missed because it was so much fainter than had been expected. A telescope of fair size is needed to show it at all; Voyager went nowhere near it, but some surface features have been recorded by the Hubble Space Telescope (**Figure 2**). There are indications of a dark equatorial band and brighter polar areas. The axial inclination is 122°, so that, as with Uranus, the rotation is technically retrograde; the rotation period is 6.34 days.

Pluto's density, twice that of water, indicates that the globe contains more rock than in the icy satellites of the giant planets, but our knowledge of the internal structure is decidedly meagre. Pluto may or may not be differentiated, but the gravitational pressure may not be adequate to increase the rock density deep inside the globe to a marked degree. The surface is coated with methane ice at least in some areas. There is a tenuous but surprisingly extensive atmosphere, made up chiefly of nitrogen together with methane. As Pluto moves out toward aphelion, due in the year 2114, the temperature will drop and the atmosphere may freeze out, so that for part of its long 'year' there may be no atmosphere at all.

Table 6 Pluto and Charon

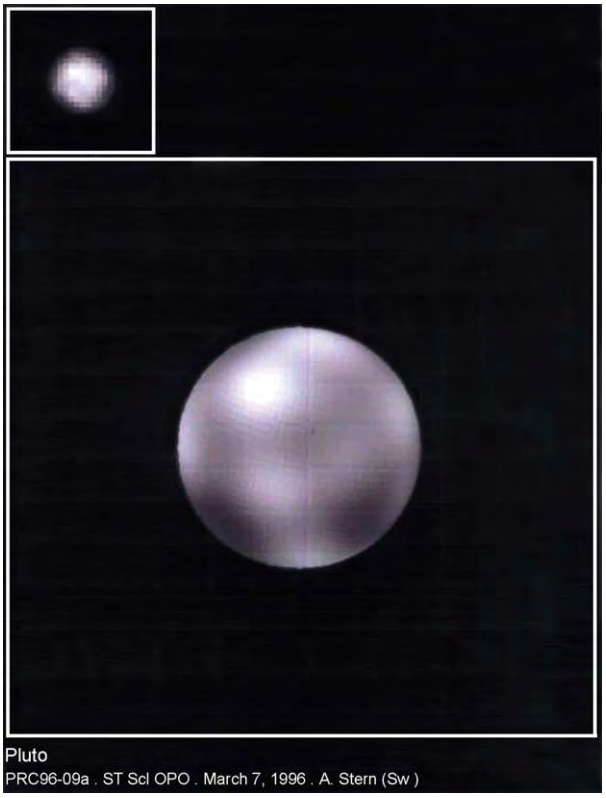

Figure 2 Pluto, imaged with the Hubble Space Telescope. Regions of different brightness are shown, but of course no definite surface features.

Pluto has a companion, Charon, discovered in 1978. Its diameter is more than half that of Pluto, so that it cannot be regarded as a conventional satellite. Its orbital period is the same as Pluto's rotation period, and the surface-to-surface distance between the two bodies is no more than 18 000 km. To an observer on Pluto, Charon would remain 'fixed' in the sky. The density of Charon is lower than that of Pluto; the surface is probably coated with water ice, and there is no trace of atmosphere. Mutual transit and occultation events for Pluto and Charon were observed between 1985 and 1990, and were very informative. When Charon passed behind Pluto it was completely hidden, and Pluto's spectrum could be seen alone, when Charon passed in front of Pluto the two spectra were seen together, so that of Pluto could be subtracted.

From 1992 many small bodies have been found orbiting the Sun beyond Neptune. These make up the Kuiper Belt, named after the Dutch astronomer GP Kuiper, who suggested its existence (*see* **Solar System:** Asteroids, Comets and Space Dust. One of these, Quaoar, may be as large as Charon, and others are around 1000 km in diameter. There are grounds for proposing that Pluto and Charon should be regarded simply as the largest known Kuiper Belt objects, though some astrnonomers are reluctant to deprive Pluto of its planetary status!

Is there another large planet moving far beyond Neptunes and Pluto? Slight irregularities in the movements of Uranus and Neptune indicated that this might be the case, and periodical searches for 'Planet X' have been carried out, but with no success. Recently it has been claimed that improved values for the masses of Uranus and Neptune show that no unexplained perturbations occur, and there is no need for Planet X, but one thing is certain; Pluto's mass is too small to cause the effects which led Lowell to calculate a position for it. Therefore, either Lowell's reasonably correct result was purely fortuitous, or else the planet for which he was searching has yet to be discovered. If Planet X really exists, it will no doubt eventually be found.

Sedna, discovered in 2004, may be 1300 km in diameter, its orbital period is over 12 000 years and it may recede almost as far as the Oort Cloud.

STRATIGRAPHICAL PRINCIPLES

N MacLeod, The Natural History Museum, London, UK

Introduction

Stratigraphy is the branch of geology that deals with the formation, composition, sequence, and correlation of stratified rocks. Since the whole Earth is stratified, at least in a broad sense, bodies of all the different types of rock – igneous, sedimentary, and metamorphic – are subject to stratigraphic study and analysis. In most cases, however, stratigraphy focuses on the evaluation of sedimentary rock strata. Modern principles of stratigraphic analysis were developed in the eighteenth and nineteenth centuries by geologists such as Niels Stensen, James Hutton, Georges Cuvier, William Smith, and Charles Lyell. By 1900 all the intellectual tools needed for the description, sequence, and correlation of strata were in place. Shortly after 1900, the tools needed to establish the absolute ages of minerals containing unstable radioisotopes also became available, giving stratigraphers a physical basis for making chronostratigraphic correlations, at least in certain favourable stratigraphic situations. Since the 1950s efforts have been made to establish international standards for stratigraphic nomenclature and the usage of stratigraphic terms and the internationally agreed designation of 'type-sections' or stratotypes for various sorts of stratigraphic unit, especially those relating to chronostratigraphy.

First Principles

The study of stratigraphy began with attempts to understand common observations, such as what the rocks we call fossils are and how the rocks that comprise mountains came to be elevated above the land surface. Of course, both fossils and mountains were well known to ancient Greek natural historians, such as Plato, Hereodotus, Aristotle, Xenophanes, and Pliny. Although a variety of explanations were offered for these phenomena, no systematic investigations of modern aspect were carried out by these classical scholars, according to the intellectual style of their time. The organic nature of fossils was recognized by a number of Renaissance scholars, including Leonardo da Vinci (1452–1519) and Conrad Gesner (1516–1565). Da Vinci's writings were particularly prescient in that he recognized that fossil mollusc shells from the tops of mountains were similar to the shells of modern molluscs and that this similarity implied that sediments occupying the mountain tops must originally have been deposited beneath marine waters. These were isolated musings, however.

The first modern treatment of a stratigraphic problem was published by Niels Stensen (1638–1686, also known by his anglicized literary name, Nicholas Steno) in 1669 (*see* **Famous Geologists:** Steno). Most scholars mark Steno's *De solido intra solidum naturaliter contento disseratiinis prodomus* as the first stratigraphic treatise. In this short work–which was presented to Steno's patron, the Grand Duke Ferdinand II of Tuscany – Steno establishes three cardinal principles of stratigraphic analysis and then uses these to reconstruct the geological history of Tuscany. Steno's principles are as follows.

1. Original horizontality: unconsolidated sediments deposited on a solid base must have originally formed horizontal layers, since the sediment particles would have 'slithered' to the lowest point. Thus, consolidated strata inclined at an angle must have become tilted after consolidation.
2. Original continuity: layers of unconsolidated sediments deposited on a solid base would have formed continuous sheets of material. Thus, bands of consolidated sediments whose ends have been broken must have experienced this breakage and erosion after consolidation.
3. Superposition: since each layer of unconsolidated sediment deposited on a solid base must have formed after the basal layer had been deposited, overlying layers of sediment are younger than underlying layers.

Using these principles, Steno argued that Tuscan geology, and especially the stratified sediment layers

forming its mountains, represented the remains of a series of subterranean-erosion and land-surface-collapse events (Figure 1). Not only did this model reconcile the cyclic and directional aspects of the Tuscan stratigraphic record, it also established the principal of stratigraphic correlation as the matching of stratigraphic observations from distant outcrops in order to obtain a sense of a rock body's geometric structure (Figure 2).

The next significant contribution to stratigraphic principles was made in 1785 by the Scottish lawyer–gentlemen farmer James Hutton (1726–1797) (*see* **Famous Geologists:** Hutton), who stressed the cyclic aspects of the stratigraphic record in his doctrine of

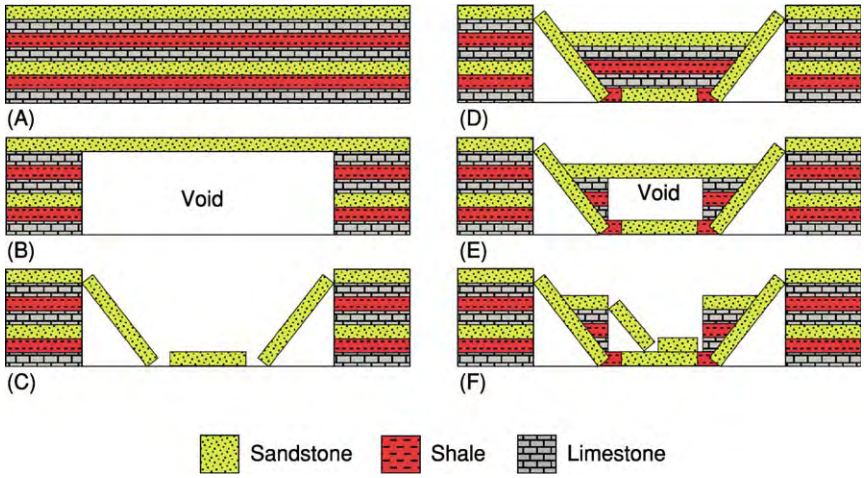

Figure 1 Steno's conceptual interpretation of the stratigraphic history of Tuscany. (A) Flat lying continuous sediments were deposited beneath marine waters. (B) Lithified sediments were uplifted, and subterranean voids or caverns developed through the erosive action of subsurface waters. (C) When the subterranean voids grew sufficiently large, the roofing layers collapsed, elevating the cavern walls, down dropping flat laying layers that remained intact, and tilting blocks adjacent to the elevated areas. (D) Submergence of the entire land surface once again caused flat lying continuous sediments to be deposited. (E) These new sediments were lithified and uplifted, after which new cavernous voids developed. (F) A new round of erosional collapse further modified the landscape. Note how Steno's model encompasses both the apparently directional nature and the cyclic nature of stratigraphic deposits and landscape formation. (Redrawn from Steno's diagram in *De solido intra solidum naturaliter contento disseratiinis prodomus*.)

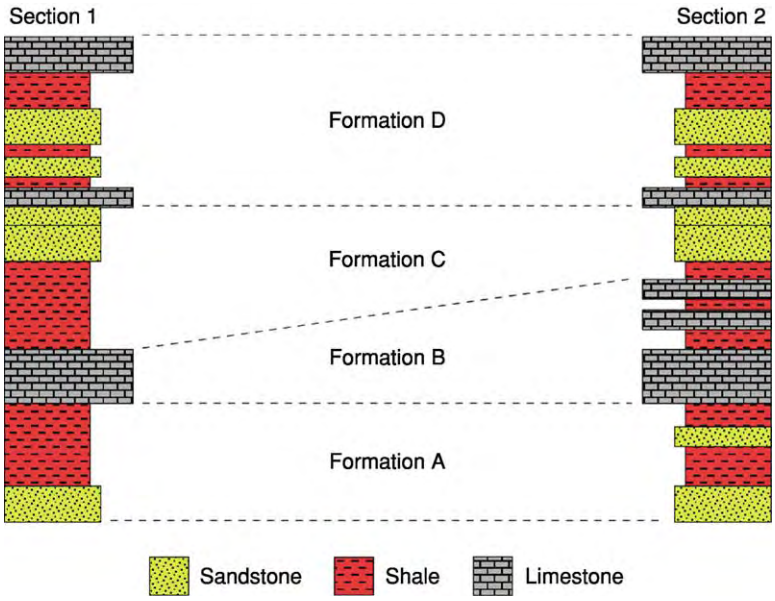

Figure 2 In addition to developing his theory of landscape formation, Steno stressed the importance of stratigraphic correlation the matching of stratigraphic sequences between outcrops. In this illustration two hypothetical outcrop sections have been correlated based on rock type and subdivided into lithologically unified packages of strata.

uniformitarianism. Citing evidence from the angular unconformities exposed at such Scottish localities as Jedburgh and Siccar Point, Hutton reasoned that the originally horizontal marine sediments of the lower succession must have been consolidated, then tilted as they were raised up above the water's surface, planed off by erosion, submerged, and buried by additional horizontally deposited sediments, which were then consolidated, before the entire sequence was lifted again to become the rock bodies we see before us at these, and other, localities. Hutton believed that these erosion–deposition–uplift cycles had been repeated endlessly in Earth history, implying that: first, the Earth itself is very old; second, the processes we see working today (e.g. erosion, deposition, gradual uplift) operated in the past; third, the power for uplift came from the heat generated by compaction, supplemented by heat at depth left over from the Earth's initial formation; and, fourth, the ultimate purpose of this system was to produce a self-renewing Earth that was 'adapted to the purposes of man'. In particular, Hutton denied that fossils provided any evidence for the directional passage of time because each uniformitarian cycle's biota was 'perfect'.

Slightly later (in 1812), the French Baron Georges Cuvier (1769–1832) (*see* **Famous Geologists:** Cuvier) published a summary of his palaeontological studies in the Paris Basin in his book *Recherches sur les Ossemens Fossils*, the first chapter of which took issue with Hutton's uniformitarian approach to stratigraphic analysis. Cuvier argued that the abrupt disappearances of entire fossil marine faunas that characterize several horizons within this basin, and the equally abrupt appearances of new terrestrial faunas in strata lying just above these marine beds, were evidence for the repeated, sudden, and, in ecological terms, catastrophic elevation of the land. In contrast to Hutton, who believed in endless cycles, Cuvier and his colleagues – who came to be known as 'catastrophists' – envisioned an Earth whose internal core was undergoing constant thermal contraction. As this core pulled away from the hard crust gaps opened up. It was these gaps that were responsible for the catastrophes. In a manner analogous to that proposed in Steno's model, crustal failure occurred when the subterranean gaps become too large to support the burden of the overlying crust. It was supposed that these failures happened suddenly, down-dropping entire regions, the surrounding parts of which would appear to be thrust up (in relative terms) as mountains. Unlike Hutton's endless uniformitarian cycles, Cuvier's hypothesis of Earth history was resolutely directional and finite. The Earth would eventually cool to the point where no more contraction would take place, thus bringing the catastrophes to an end. Also, unlike Hutton, the catastrophists saw extinction as a real phenomenon, with new biotas responding to the changed environment in unique ways.

The next major contribution to stratigraphy was made by the English canal surveyor and geologist William Smith (1769–1839) (*see* **Famous Geologists:** Smith). Smith was the first to recognize the difference between lithostratigraphy (the characterization of rock strata by the kind and/or arrangement of their mineralogical constituents) and biostratigraphy (the characterization of rock strata by their biological constituents). Before Smith, the remains of once-living creatures and the mineral particles of which sedimentary rocks are made were considered to be of equal value in recognizing strata. Smith made a conceptual distinction between lithological and palaeontological sources of stratigraphic information and, by careful analysis of the fossils contained in stratigraphic bodies, demonstrated that strata with very similar lithological constituents could be distinguished on the basis of their fossil content. Even more importantly, Smith showed that the successive biotas preserved in the sedimentary strata of the British Midlands always occurred in the same sequence, regardless of the character of the local lithological sequences. This key stratigraphic principle later became known as the 'principle of faunal succession' (Figure 3). By applying the principle of faunal succession to his biostratigraphical observations, Smith was not only able to predict more accurately the types of rock that would be encountered during canal construction, but also able in 1815 to produce the first modern geological map. While William Smith was not given to abstract theorizing, his commitment to field observations, his willingness to accept those observations at face value, and his use of fossil extinction events as a basis on which to recognize the directional passage of time were far more in line with the philosophical tenets of catastrophism than with those of uniformitarianism.

Uniformitarianism's champion was Charles Lyell (1797–1875) (*see* **Famous Geologists:** Lyell). Lyell accepted the cyclic nature of Huttonian uniformitarianism to the extent that he denied the possibility of both extinction and evolution (though, to be fair, it must be said that the latter was denied by Cuvier as well, albeit on different grounds). Lyell also emphasized and greatly developed Hutton's idea of a mechanistic uniformitarianism in which known natural laws and processes operated at rates comparable to those observed today. Lyell believed that these mechanisms were responsible for all features of the geological record. It is interesting to note that Cuvier, Agassiz, (*see* **Famous Geologists:** Agassiz) and the other

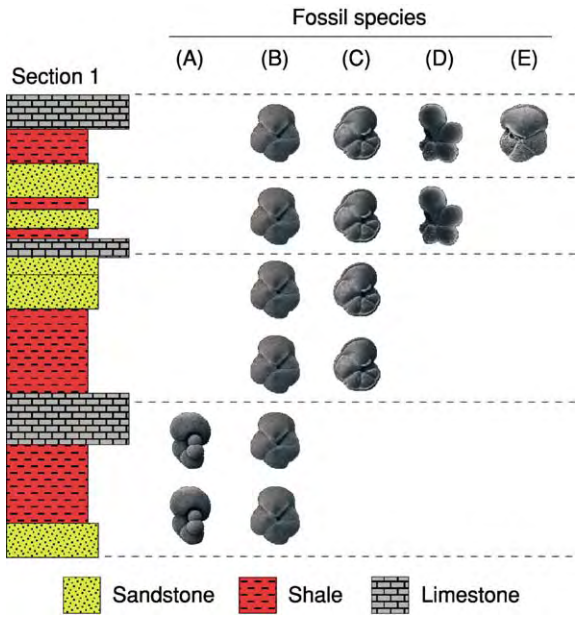

Figure 3 Organization of stratigraphic sequences into units based on their fossil content using the principle of faunal succes sion. In this illustration the distributions of five fossil planktonic foraminiferal species have been used to recognize stratigraphic units on the basis of unique associations of species. The principle of faunal succession can be used to recognize stratigraphic units because fossil species are individualized in the sense that they have definite and unique starting (speciation) and ending (global extinction) points. Thus, the stratigraphic range of a fossil species encompasses a distinct time interval. Note also that palaeontolo gically defined stratigraphic units differ in both number and kind from lithologically defined units (compare with **Figure 2**).

scientific catastrophists were aligned with Lyell in accepting the principle of mechanistic uniformitarianism. Lyell summarized his arguments, and supported them with examples drawn from his geological travels throughout Europe, in a massive three-volume work *Principles of Geology* published in 1830–1833.

While the uniformitarian–catastrophist debate has often been portrayed as a triumph of dispassionate scientific reason over theologically driven special pleading, with the Lyell uniformitarians founding the sciences of stratigraphy and sedimentary geology as we know them today, a more faithful description of the historical record reveals a far more interesting story. Lyellian uniformitarianism did indeed triumph, but not so much over the scientific catastrophism of Cuvier, Brongniart, d'Orbigny, and Agassiz as over the theological catastrophism embraced by the school of Natural Theology (especially in England) and sheer scientific fantasy. Lyell's reasoned approach, which emphasized modern processes working over long periods of time, appealed to many, not least Charles Darwin (*see* **Famous Geologists:** Darwin) who read Lyell's treatise during the *Beagle* voyage and used Lyellian principles as a basis for his geological explorations. Lyell's commitment to the basic uniformitarian doctrine of endless and ahistorical cyclicity, however, was not accepted even among Lyell's contemporaries. Lyell was caricatured for his position by Henry de la Beche in a famous cartoon (**Figure 4**) and was forced to retract from it by stages in subsequent editions of his *Principles* volumes. Neither was Lyell's view of the value of fossils in stratigraphic correlation – at least for higher taxonomic groups – accepted by his contemporaries, much less by contemporary stratigraphers. Modern uniformitarianism is a combination of the Huttonian–Lyellian emphasis on modern observable processes operating over long periods of time, but nevertheless allowing for the incorporation of processes that have no modern counterpart (e.g. Louis Agassiz's continental glaciations, enormous flood-basalt volcanic eruptions, asteroid impacts), and a thoroughly catastrophist emphasis on extinction, the existence of intervals of (geologically) rapid and widespread global change, and the directional nature of geological time.

Following Smith's demonstration of the power of biostratigraphy, the forefront of stratigraphic research turned to the identification of biostratigraphic zones that could be used to facilitate long-range stratigraphic correlation (e.g. intrabasinal, interbasinal, and intercontinental). This immediately raised a further conceptual problem. Did the identification of the same biozone in different localities mean that the resulting correlation located the two sections in terms of their position in the sequence of biotas preserved over geological time (homotaxis) or in terms of geological time itself (homochrony)? These concepts are distinct because the same sequence of events could be preserved at different localities without the individual events having taken place at the same time.

Until 1900 stratigraphers had been forced to couch their observations in terms of relative time (e.g. event A took place before or after event B) because there was no way to measure absolute time in stratigraphic successions. Of course, attempts to estimate absolute time were made, usually based on modern rates of sediment accumulation and estimates of compaction ratios for different types of sedimentary rock. Nevertheless, since these rates and ratios vary widely, and since there was no way of confirming that any given estimate was correct, such calculations were approximate at best.

This situation changed in the early 1900s, however, with the discovery of natural radioactivity and unstable radioisotopes of naturally occurring elements. Radioisotopes have unstable nuclei that spontaneously decay

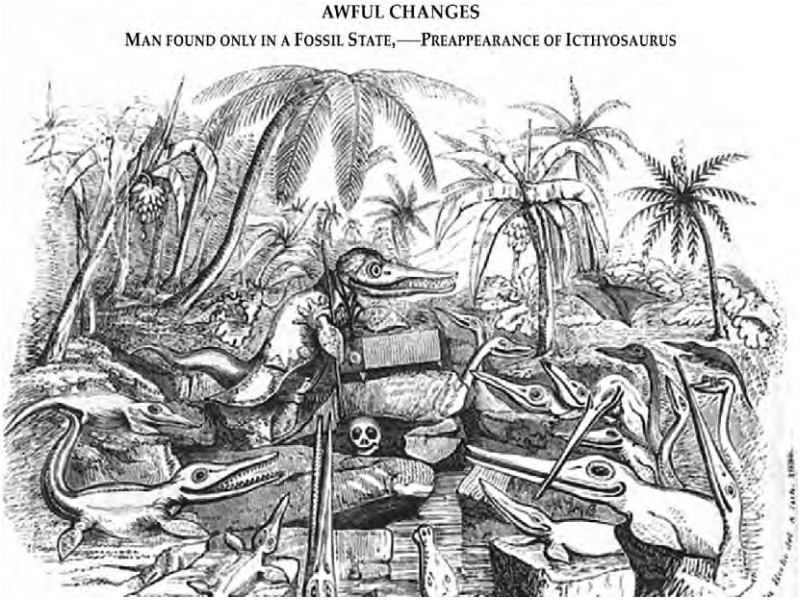

Figure 4 Henry de la Beche's caricature of Charles Lyell as 'Professor Icthyosaurus' lecturing to an eager audience of saurian students at some time in the future on the topic of an 'insignificant' and 'lower order' fossil animal from Earth's distant past (the representation of a human skull in the drawing's centre). This image, which was originally published as the frontispiece to Frank Buckland's *Curiosities of Natural History*, poked fun at Lyell's belief in the cyclic, or uniformitarian, nature of geological processes, which predicted the re emergence of extinct fossil forms when future environmental conditions matched those of the past. Modern uniformitarianism no longer embraces this aspect of Hutton and Lyell's original formulation but represents a dynamic amalgam of nineteenth century uniformitarian and catastrophist theory. See text for discussion.

through the emission of subatomic particles from the isotope's nucleus at a fixed and measurable rate. Daughter isotopes are produced as the products of this decay process, along with various types of radiation. If the amounts of original radioisotopic material of a specific type in a particular mineral species and the daughter-product isotope are known, the absolute age of the mineral can be calculated, subject, of course, to several assumptions (e.g. a correct value of the decay constant, accurate measurements, no loss of daughter-product isotope) (*see* **Time Scale**).

Unfortunately, accurate isotopic dating cannot usually be carried out on sediments directly. Most sedimentary rocks are composed of mineral grains whose origin predates that of the sedimentary rock body by a substantial time interval. In some instances, though, a layer of volcanic material (e.g. an ash-fall tuff) with newly formed mineral crystals can become interbedded in a suite of sedimentary rock. In such cases, the age obtained from the volcanic deposit can be used to constrain the ages of the immediately overlying and underlying sediments, subject, once again, to assumptions. By using isotopically datable materials located stratigraphically near major biostratigraphically defined boundaries in the stratigraphic record (*see* below and **Time Scale**), it is possible to estimate absolute ages for these boundaries.

Stratigraphic Classification

As stratigraphers combined the principles of stratigraphic analysis set down by Steno, Hutton, Cuvier, Smith, Lyell, and others with lithostratigraphic, biostratigraphic, and geochronological observations during the first half of the twentieth century, the true geometric relations between observed lithostratigraphic and biostratigraphic units emerged, along with their mutual relations to an entirely conceptual 'chronostratigraphy' (the characterization of rock strata by their temporal relations). These concepts are illustrated in Figure 5, and are usually discussed in terms of the distinction between rock stratigraphic units (that are distinguished by physical or biotic criteria that can be observed at the outcrop, core, well-log, etc.) and time stratigraphic units (that are in all cases inferences based on stratigraphic observations, but have the advantage of being referable to a common geological time-scale). There has been, and continues to be, much confusion over the use of these terms, primarily because of the genuine subtlety of the distinction, but also because of problems stemming from the definition of certain sorts of stratigraphic unit (e.g. biostratigraphic Oppel zones, which are defined on rock-stratigraphic criteria chosen for their supposed ability to achieve time-stratigraphic

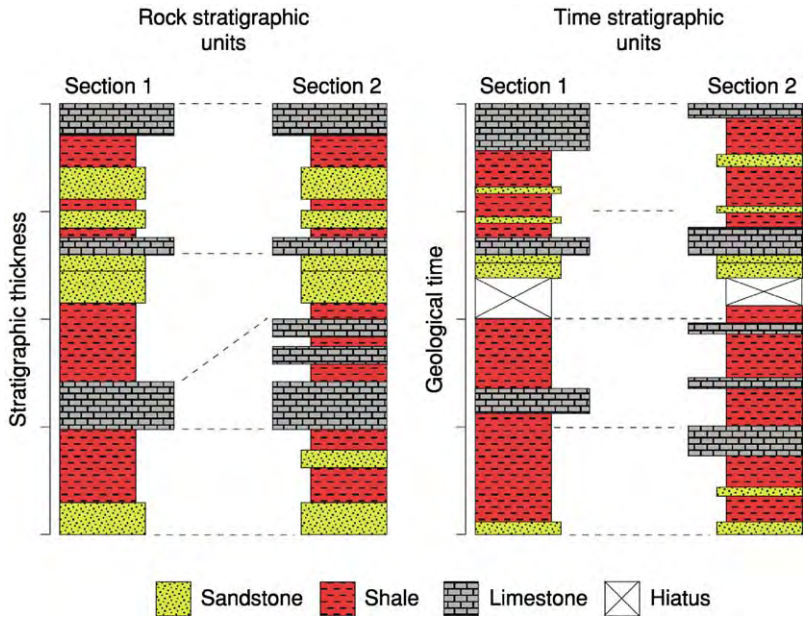

Figure 5 The difference between rock stratigraphic units (left) and time stratigraphic units (right). In this illustration the rock stratigraphic units, along with their lithostratigraphic correlation, are scaled to stratigraphic thickness, as they would be observed in a field study. When these same sections are portrayed as time stratigraphic units (and organized according to the time intervals during which they were deposited), however, the character of their comparative relations (both inter sectional and intra sectional, as well as their inter section correlations) changes.

correlations) and the fact that many stratigraphers prefer to report their rock-stratigraphic observations (e.g. position in a measured section or core) in terms of time-stratigraphic inferences.

In order to stabilize stratigraphic classification and nomenclature, the International Subcommisson on Stratigraphic Classification (ISSC) (originally the International Subcommission on Stratigraphic Terminology (ISST)) was created in 1952 at the 19th International Geological Congress (Algiers). From 1952 to 1965 the ISSC operated as a standing committee under successive international geological congresses. In 1965 responsibility for the ISSC was transferred to the International Union of Geological Sciences (IUGS), where it remains. The ISSC maintains a web site at http://www.geocities.com/issc arg/. The ISSC has several purposes. Among these is to publish and maintain the International Stratigraphic Guide, whose purpose is to promote international agreement on principles of stratigraphic classification and to develop a common internationally acceptable stratigraphic terminology and rules of stratigraphic procedure. The various stratigraphic-unit concepts and definitions currently recognized by the ISSC are summarized briefly below.

Lithostratigraphic Units

The basic unit of lithostratigraphy is the formation, which is the smallest mappable rock unit possessing a suite of lithologic characteristics that allow it to be distinguished from other such units. Formations need not be lithologically homogeneous, but the entire interval of strata should be diagnosable. Moving up the lithostratigraphic hierarchy to more inclusive units, a set of contiguous formations may be combined to form a group (e.g. the Lias Group), membership of which is usually identified based on common lithological characteristics (e.g. dominantly argillaceous facies) or genetic characteristics (e.g. a suite of formations bounded by two basin-wide unconformities). Occasionally, contiguous groups will themselves be placed into subgroups or supergroups (e.g. the Newark Supergroup, the Wealden Supergroup) based on genetic characteristics. Subgroups and supergroups may also include formations not previously assigned to a group. The most inclusive lithostratigraphic unit is a complex, which is distinguished by its diverse lithological composition – including sedimentary, metamorphic, and/or igneous rocks – and its intricate structure.

Moving down the lithostratigraphic hierarchy to more exclusive units, a member is a subdivision of a formation, recognized on lithologic criteria (e.g. the sandy member of a formation representing a suite of deltaic strata). Typically, members consist of more than a single bed, although some massive bodies with no internal stratification are recognized as members. The smallest formal lithostratigraphic unit is a bed,

which is a thin lithostratigraphically monotonous sequence with some locally unique lithological character (e.g. the *Hypsilophodon* Bed). A hypothetical example of this lithostratigraphic hierarchy is presented in Figure 6.

Igneous and/or metamorphic rock bodies of tabular form and stratified nature may be admitted within this lithostratigraphic classification, either in themselves or in combination with adjacent sedimentary units. Igneous rock bodies that cut across stratified rocks of any type can be handled within this scheme under the informal designation of being associated with (in the sense of 'bounded by' or 'included within') a larger, formal, lithostratigraphic unit.

Biostratigraphic Units

The basic unit of biostratigraphy is the biozone, which is any unit of rock distinguished from other such units on the basis of its fossil content. Unlike formations, biozones do not need to be mappable units and so can vary greatly in thickness and geographical extent. Biozones may be defined on the basis of a wide variety of criteria (*see* **Biozones**). Intervals of strata between biozones that lack fossils are referred to as barren interzones, while barren intervals within biozones may be termed barren intrazones. Moving up the biostratigraphic hierarchy, a set of contiguous biozones may be grouped into superbiozones. Superbiozones do not need to be genetically linked in the same way as do the higher-level lithostratigraphic units, but some justification for the designation should be made at the time of the superbiozone's proposal. Biozones may also be subdivided into sub-biozones in order to express finer levels of biostratigraphic detail or identify a biotically distinctive regional grouping of strata. The term zonule is used to refer to a biostratigraphically diagnosable unit that is subordinate to a subbiozone. Finally, individual stratigraphic surfaces characterized by a distinctive biotic component are referred to as biohorizons. A hypothetical example of this biostratigraphic hierarchy is presented in Figure 7.

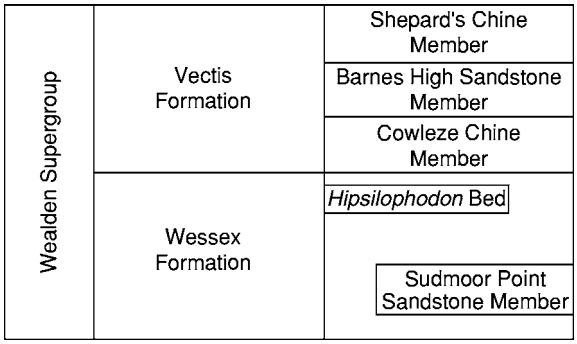

Figure 6 The use of lithostratigraphic units to subdivide a classic Lower Cretaceous suite of non marine sediments in the Wessex Basin of Great Britain. See text for discussion.

Chronostratigraphic and Geochronological Units

Chronostratigraphic units comprise groups of strata that are recognized as having formed during a specific interval of geological time. While chronostratigraphic terms are conceptual rock stratigraphic units, their classification is mirrored by the geochronological or time-stratigraphic classification scheme. To understand the difference between these two scales, consider an hourglass. Sand falling through the neck of the hourglass is deposited in the lower reservoir over a certain time interval (say 1 h). A chronostratigraphic unit is equivalent to the sand deposit, while the associated geochronological unit is equivalent to the amount of time over which the sand deposit accumulated (1 h). The chronostratigraphic unit accumulated over the time interval and can be said to represent that interval in terms of the deposit's thickness and

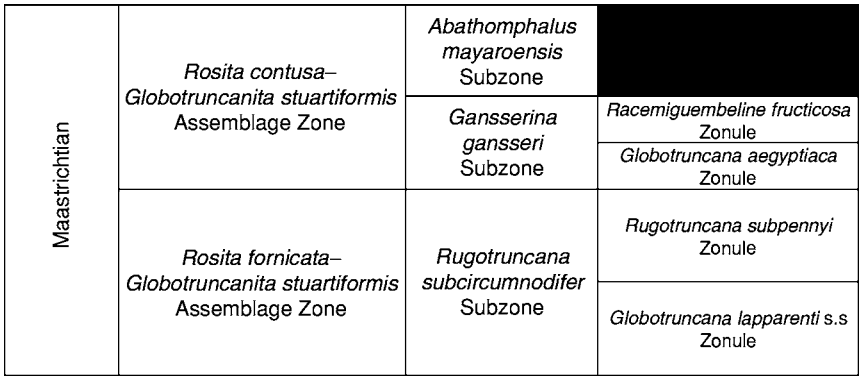

Figure 7 The use of biostratigraphic units to zone a classic Upper Cretaceous suite of deep marine sediments in north central Texas on the basis of their planktonic foraminiferal content. Note the chronostratigraphic series unit (Maastrichtian) and that not all sub biozones are divided into zonules. See text for discussion.

extent. But the sand deposit itself cannot be said to be time. Table 1 lists the chronostratigraphic and geochronometric unit equivalents.

The application of chronostratigraphic unit classification may be illustrated by the chronozone, which is equivalent to a geochronological chron. All stratigraphic intervals represent potential chronozones and chrons, as do all lithostratigraphic and biostratigraphic units. For example, the (hypothetical) *Exus alphus* biozone represents a chronozone that begins with the stratigraphic horizon deposited at the time of the speciation of this (hypothetical) species and ends with the stratigraphic horizon deposited at the time of its global extinction (Figure 8). This chronozone corresponds to the chron, which is defined as the time interval between this species' global speciation and extinction events. Both the chronozones and the chrons are worldwide in extent, though it may not be possible to recognize either in localities remote from the geographical range of the species. The chronozones and chrons will also be estimates (at least for biostratigraphic zones) and are subject to revision.

Stages (equivalent to geochronological 'ages') are the most common chronostratigraphic unit and are usually defined on the basis of the chronozones of a series of biozones (e.g. the Maastrichtian Stage/Age). Note that biozone boundaries themselves cannot be used to achieve a true chronostratigraphic system because they are inherently diachronous (see Figure 8). Stages

Table 1 Nomenclatural equivalents with examples

Chronostratigraphic units	*Geochronological units*	*Example*
Eonathem	Eon	Phanerozoic
Erathem	Era	Mesozoic
System	Period	Cretaceous
Series	Epoch	Upper Cretaceous
Stage	Age	Maastrichtian
Chronozone	Chron	*Belemnella occidentalis* Zone

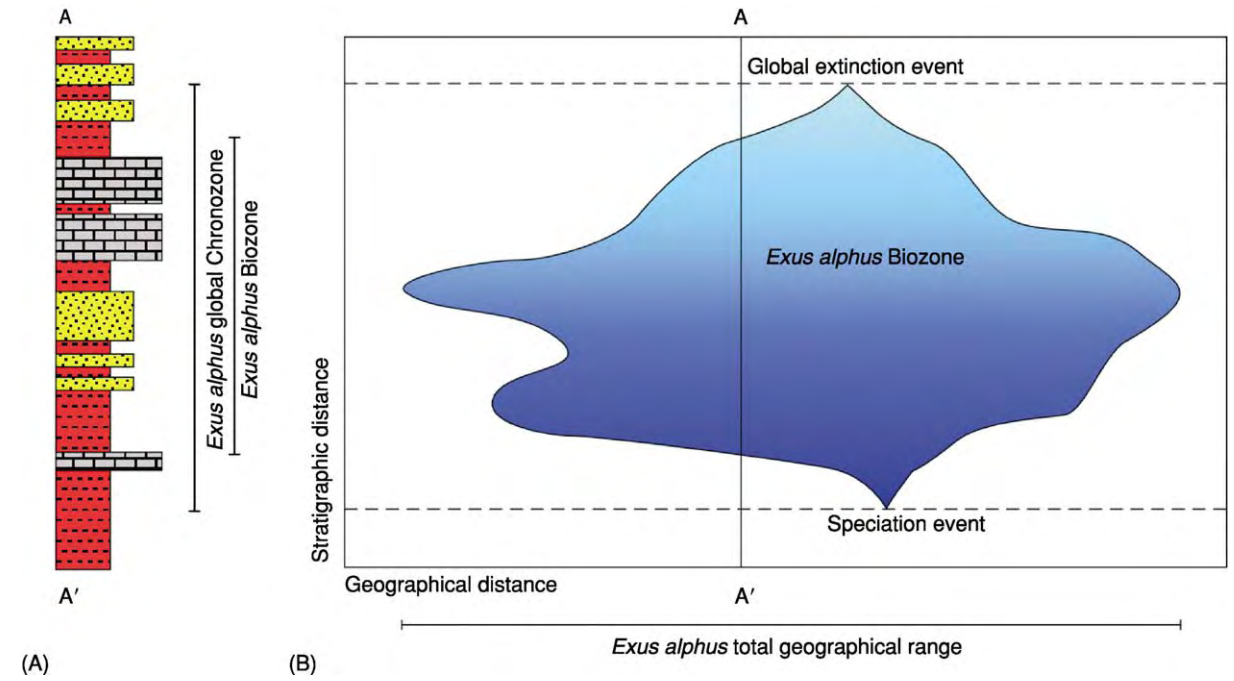

Figure 8 Relation between the (hypothetical) *Exus alphus* Biozone and its corresponding chronozone. (A) Zone expression at the level of a local stratigraphic sequence A A′. (B) Two dimensional slice through the *Exus alphus* Biozone containing the A A′ sequence. Note that the rock stratigraphic expression of the local biozone (which also represents a local chronozone) underestimates the extent of the global chronozones based on the interval between the species' speciation and global extinction horizons. See text for discussion.

may be subdivided into substages. Systems (equivalent to geochronological 'periods') are composed of a sequence of stages. For example, the Induan, Olenekian, Anisian, Laningian, Carnian, Norian, and Rhaetian stages/ages, all of which are defined on the basis of biochronozones, combine to form the Triassic System/Period. Similarly, erathems (equivalent to geochronological 'eras') are composed of a sequence of systems. Three erathems/eras are currently recognized, the Palaeozoic, Mesozoic, and Cenozoic. Finally, eonathems (equivalent to geochronological 'eons') are composed of a sequence of erathems. Thus, the Palaeozoic, Mesozoic, and Cenozoic combine to form the Phanerozoic Eonathem/Eon. This was preceded in geological time successively by the Proterozoic and Archaean eonathems/eons.

There have been several recent proposals (*see* **Time Scale**) to dispense with the dual chronostratigraphic/geochronological classifications of rock units and time units in favour of a single scheme based on the current geochronological classification. Under this scheme, little-used terms such as 'eonathem', 'erathem', 'age' and 'chron' would be considered redundant in favour of their more frequently seen geochronological equivalents. The reasoning behind this proposal does not challenge the logical distinction between the rock-stratigraphic and time-stratigraphic concepts of the dual classification, but instead appeals to the advantages of simplicity, greater ease of imparting the relevant concepts to students, editorial efficiency, and the fact that acceptance of the concept of global stratotype sections and points (GSSP) (see below) by most stratigraphers has rendered – at least to some – the dual rock–time system unnecessary. On the other side of this argument is the simple fact that, by blurring the distinction between rock-stratigraphic and time-stratigraphic units, one is, to some extent, blurring the distinction between observation (rock) and interpretation (time) in chronologically orientated stratigraphic investigations and, in doing so, losing the ability to distinguish between the two. What will become of these proposals remains to be seen.

Other Types of Stratigraphic Unit

With the advent of geophysical methods of analysis, several special types of lithostratigraphic classification have been developed to take advantage of the chronostratigraphic implications of such methods. Perhaps the best example is the study of rock magnetism, which can be used in some lithologies to determine the ancient polarity of the Earth's magnetic field. Based on such observations, a magnetozone can be defined as an interval of strata possessing a characteristic magnetic polarity, either normal or reversed (*see* **Magnetostratigraphy**). These can then be related to time through the use of the chronostratigraphic equivalent of the magnetozone, the magnetochron.

Magnetozones are particularly useful for chronostratigraphic analysis because the time interval over which the Earth's magnetic field changes polarity is short compared with the duration of the magnetozones, biozones, and formations. However, magnetozones can rarely be recognized on the basis of their magnetic properties alone, necessitating the use of other types of stratigraphic analysis – usually biostratigraphy – to achieve the identifications. This increases the complexity of the analysis (and the corresponding chance of error) significantly. Nevertheless, combined magneto-bio-chronostratigraphic analysis has resulted in marked improvements in our understanding of the stratigraphic record. Other types of lithostratigraphic observation that have proven useful in this context include chemical stratigraphy, isotope stratigraphy, seismic stratigraphy, climate stratigraphy, cycle stratigraphy, and orbital stratigraphy.

Stratotypes

With recognition of the distinction between rock stratigraphic units and time stratigraphic units, the ISSP recognized the need to designate 'type-sections' or stratotypes that would constitute standards of reference for various sorts of stratigraphic unit. There are two primary kinds of stratotype: unit stratotypes, which serve as the standard of definition for a stratigraphic unit, and boundary stratotypes, which serve as the standard of definition for a stratigraphic boundary. Unit stratotypes can be either single sections or suites of sections that, when taken together, form a composite unit stratotype. The primary requirement for a stratotype is that it adequately represents the concept of the stratigraphic unit or boundary in all essential particulars. This ideal, however, is rarely met in practice. All real stratigraphic sections exhibit a collection of generalized and idiosyncratic characteristics, and no stratigraphic section can be regarded as truly representative of all other sections and cores worldwide. In addition, disagreements over which section to select as an official ISSP-recognized stratotype have tended to incorporate appeals to historical precedent, priority, and even nationalism, as well as more objective scientific criteria. There is also the ever-present danger that new discoveries might render a designated stratotype incorrect. For example, the boundary at the base of the Cambrian System is defined as the level of the first occurrence of the trace fossil *Treptichnus pedum*, which was thought to occur

2.4 m above the base of Member 2 of the Chapel Island Formation at Fortune Head, Newfoundland, but which subsequent investigations have shown occurs at least 4 m below that horizon in the same section. (Note that, in recognition of the inherently provisional nature of stratigraphic boundary definitions, the ISSP now provides a procedural means for updating boundary stratotype definitions.) Despite these practical deficiencies, the stratotype concept has proven to be popular and has undoubtedly contributed to stabilizing the definitions of stratigraphic units.

One recent modification of the boundary-stratotype concept that has proven to be particularly useful is the 'topless' mode of boundary-stratotype designation. Under this convention, a boundary stratotype designated to serve as the reference for the base of one stage is automatically regarded as defining the top of the underlying stage. This convention elegantly solves the problem of designating unit stratotypes for two successive stages and then finding that the upper boundary of the lower unit and the lower boundary of the upper unit have been placed at different horizons, leading to the artificial production of a stratigraphic gap or overlap.

Conclusion

The principles of stratigraphic analysis were worked out during the nineteenth century. During the twentieth century they were applied at an intercontinental scale and modified to accommodate technological developments that allowed more and different types of geological observations to be employed in stratigraphic correlation. No doubt the former trend will be further refined, and the latter extended, during the twenty-first century. New developments will involve the creation of databases that summarize stratigraphic observations over the Earth's surface (and extending into its subsurface), the development of automated algorithms for comparing the data included in such databases and resolving conflicts between alternative sources of information, and the training of stratigraphers to better appreciate the proper use, strengths, and weaknesses of each source of stratigraphic information so that they may apply the age-old principles of stratigraphy to optimal effect.

Glossary

Angular unconformity A surface of erosion separating lower strata that dip at a different angle from the overlying younger strata.

Biochronozone The associated chronozone of a biozone.

Biostratigraphy The characterization of rock strata by their biological constituents.

Chronostratigraphy The characterization of rock strata by their temporal relations.

Depositional hiatus A horizon within a body of sedimentary rock that represents a gap in time due to the non-deposition of sediment, active erosion, or structural complications.

Diachrony The condition of taking place at different times.

Facies A stratigraphic body distinguished from other such bodies by a difference in appearance or composition.

Geochronology The geological study of absolute time.

Homochrony The condition of taking place at the same time.

Homotaxis The condition of occupying the same position in a sequence.

Isochrony The condition of being created at the same time.

Lithostratigraphy The characterization of rock strata by the kind and/or arrangement of their mineralogical constituents.

Radioisotope An isotope of an element that is capable of changing spontaneously into an isotope of another element by emitting a charged particle from its nucleus.

Stratotype The original or subsequently designated type of a named stratigraphic unit (unit stratotype) or stratigraphic boundary (boundary stratotype).

Stratum (plural strata) A tabular section of a rock body that consists throughout of the same type of rock material.

Convergent Plate Boundaries and Accretionary Wedges

G K Westbrook, University of Birmingham, Birmingham, UK

Introduction

At subduction zones, some of the material on the subducting plate is scraped off and added to the leading edge of the overriding plate to form an accretionary wedge (prism, complex), so-called because it is predominantly wedge-shaped in cross-section. The material removed from the subducting plate is primarily sedimentary. Occasionally, igneous crust is transferred to the overriding plate, and when this process occurs at a large scale, it is usually called obduction. Accretionary wedges are analogous to the foreland fold-and-thrust belts of mountain ranges, but they are predominantly submarine and the rates of convergence are typically hundreds of times greater. Where wedges grow large ($\geq$200 km wide and $>$20 km thick), parts of them emerge as islands; examples include Barbados, which is off the Lesser Antilles island arc, and Nias, off Sumatra. Large areas of south-eastern Iran and south-western Pakistan form the Makran accretionary complex, which occupies a belt 240 km across and extends a further 160 km offshore. In the deeper parts of accretionary wedges, the accreted rocks are metamorphosed in a low-temperature/high-pressure environment to produce blueschists, which may be brought to the surface by exhumation following continental collision or other events that halt subduction. Accretionary wedges are not ubiquitous at subduction zones. Their presence is favoured by thick sequences of sediment on the subducting plate and by low rates of subduction. At most subduction zones, low sediment supply, sediment subduction, and tectonic erosion conspire to suppress the formation of accretionary wedges, which are absent or small and transitory.

Wedge Geometry and Fluid Pressure

The geometry of an accretionary wedge is controlled by the shape of the bounding basement surfaces and by the shear stress on the slip surface between the wedge and the subducting plate. If the surface of the crystalline crust of the overriding plate dips seaward, then the landward part of the accretionary wedge overlies it and forms the seaward margin of the fore-arc basin (Figure 1). If the surface of the crystalline crust of the overriding plate dips landward, then the landward part of the accretionary wedge lies beneath it, and a leaf of crystalline basement separates the accretionary wedge from the fore-arc basin.

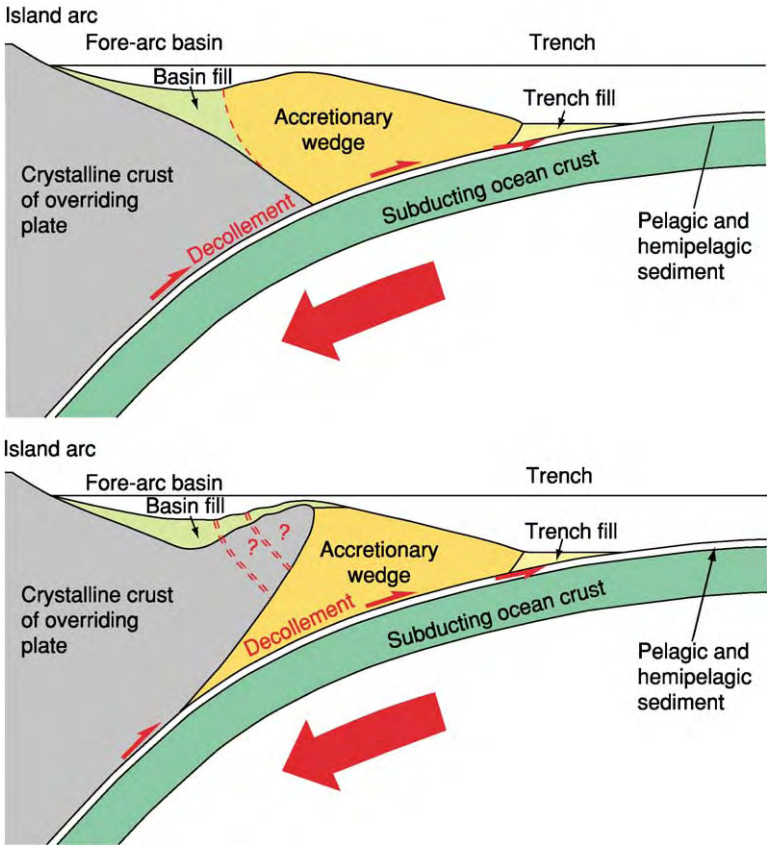

Figure 1 Accretionary wedges are formed at the leading edge of the overriding plate at a subduction zone. They occupy the region between the trench and the fore arc basin, filling the tectonic depression created by subduction, of which the trench is its bathymetric expression. The boundary with the fore arc basin may be provided by a leaf of crystalline crust of the overriding plate (lower), or may be a dynamic boundary (upper) at which fore arc basin sediments lap onto the deformed sediments of the accretionary wedge and may be progressively incorporated into the wedge by deformation as the wedge grows. Copyright Graham Westbrook.

The angle of taper of the wedge (the angle between the dip of the surface and the dip of the basement) depends on the shear stress along the base of the wedge and the strength of the wedge (Figure 2). There is a critical taper at which the force imparted by the basal shear stress is matched by the gravitational spreading force produced by the weight of the wedge. If the basal shear stress is reduced, then the critical taper is reduced, and vice versa. The major factor controlling the strength of the wedge and the shear stress along its base is the frictional resistance, which is the product of the coefficient of friction and the stress normal to any plane of potential movement. The accretion of material to the toe of the wedge lengthens the wedge and changes its taper. In response to this, the wedge deforms internally, thus maintaining its critical taper. So, during accretion, the wedge is continually deforming.

The shear strength of rocks is dependent on the pressure of fluid present in them. The ratio of fluid pressure to the lithostatic pressure (the pressure exerted by the weight of rock) is usually called λ (lambda). Shear failure is governed by the effective stress, which is the difference between the normal stress (across a potential plane of failure) and the fluid pressure. The shear stress, τ, on a plane of motion between two rock masses, such as the decollement at the base of the wedge, is $\tau = \mu\sigma(1 - \lambda)$, where μ is the coefficient of friction, σ is the stress normal to the decollement, and λ is the fluid pressure ratio. The normal stress, σ, is approximately equal to the weight of the sediment in the wedge above the decollement at any particular point. If the load acting on the rock increases more rapidly than the rock can respond by compacting and expelling water, the water bears some of the increased load and becomes overpressured (i.e., its pressure is greater than hydrostatic). If λ exceeds a value of 1, fractures in rocks can be opened by the pressure of water alone (hydrofracturing). Differences in the nature of the rocks in which the decollement is situated affect the stability of the wedge. Clays have low coefficients of friction and low

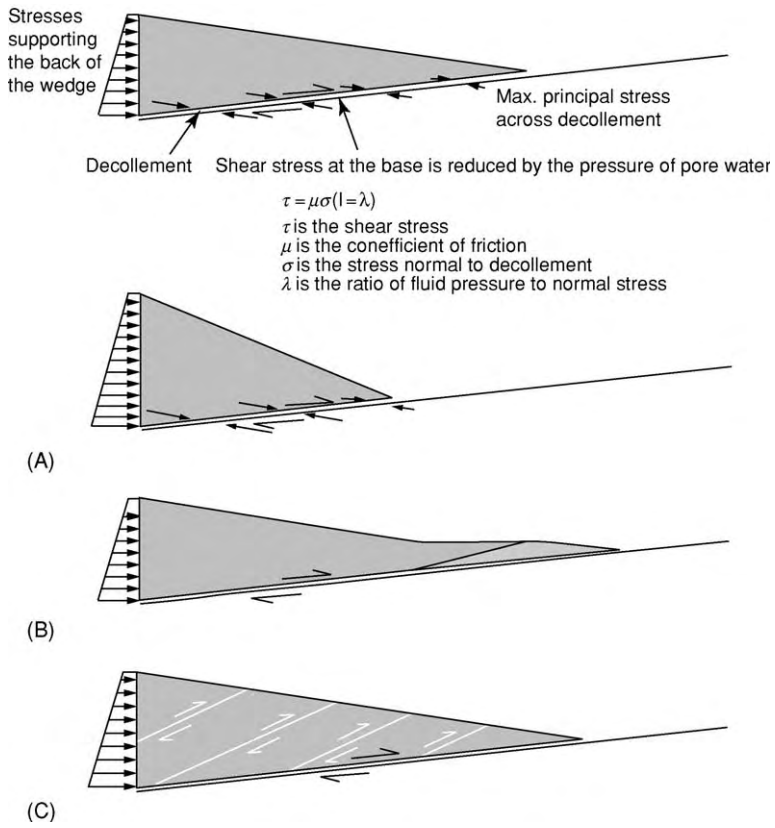

Figure 2 The stability of an accretionary wedge is dependent on the balance between the shear stress along its base, by the motion of the subducting plate, and the stresses generated by gravitational body forces within the wedge. For a wedge with Mohr Coulomb rheology and constant properties, a single of angle of taper between the top and bottom surfaces, termed the 'critical taper', is established. (A) If shear stress along the base of the wedge is increased, the critical taper is increased, and vice versa. (B) Accretion of material to the toe of the wedge increases wedge width, tending to decrease the critical taper, in response to which (C) the wedge thickens by internal deformation, in order to maintain the critical taper. Sedimentation onto the wedge, erosion, and subcretion (accretion of material to the base of the wedge) similarly induce internal deformation to maintain the critical taper. Copyright Graham Westbrook.

permeability; this favours the build-up of high fluid pressure. Both of these factors reduce the shear stress, leading to low angles of taper. Sands, which are more permeable and have a higher coefficient of friction, would produce a relatively high angle of taper. Several accretionary wedges have angles of taper that are less than 5° and values of the fluid pressure ratio, λ, that are greater than 0.9. The stratigraphy of the trench and minimization of the work required to move the wedge over the subducting plate favour the formation of decollements in clay-rich formations.

At subduction zones, sediments can be become overpressured in three ways:

1. In the trench, on the subducting oceanic plate, fine-grained pelagic and hemipelagic sediments of low permeability become overpressured by the rapid overlying deposition of trench-fill sediment (Figure 3). Deposition rates in trenches, which are as much as a few kilometres per million years, are among the fastest in the world. The greatest degree of overpressure is developed near, but not at, the top of the low-permeability sediment (Figure 4).
2. Sediment accreted to the wedge becomes overpressured by the tectonic thickening of the wedge. The sediment at the base of the wedge is most prone to becoming overpressured, because it has the longest drainage paths and also because low-permeability mud predominates in the lower part of the accreted section.
3. Sediment carried beneath the wedge on the subducting plate becomes overpressured by the weight of the increasing thickness of the wedge above as it passes below. This produces the most rapid increase in load and the highest overpressure.

Wedge Growth

The accretionary wedge grows in a number of ways: by frontal accretion, subcretion, migration into a fore-arc basin, and deposition and deformation of

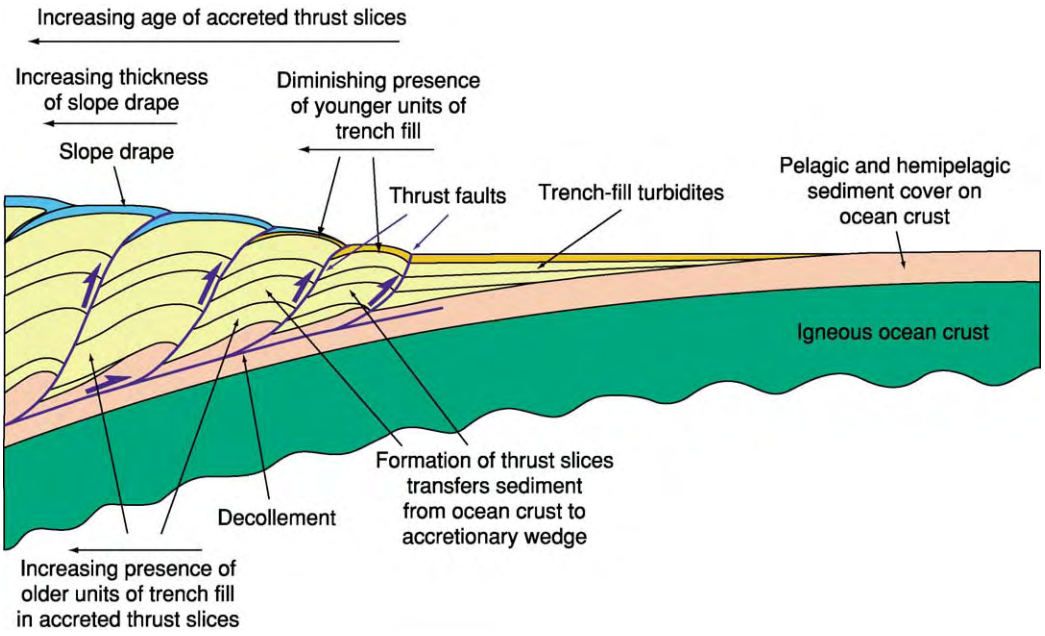

Figure 3 The process of accretion at the toe of an accretionary wedge. Commonly, but not invariably, the turbidites deposited in the trench form most of the accreted material. The accreted materials separate from the overlain pelagic and hemipelagic muddy sediments along a detachment surface (decollement) in the upper part of the sediment cover; the decollement is where loading from turbidite deposition has increased pore fluid pressure to a value nearing that of the lithostatic pressure imposed by the weight of the overlying sediments, weakening them and making them prone to failure by shearing. The thrust faults that detach the individual thrust slices that form the accreted section originate in the decollement, which propagates ahead of the toe of wedge. The accreted section always includes the youngest turbidites; these are deposited in the trench but not on older accreted thrust slices, which have been uplifted out of the zone of deposition. Consequently, the stratigraphy of each successively accreted thrust slice contains younger turbidites. Within each thrust slice, the sediments upward and landward, but the overall stratigraphy of the wedge are younger becomes younger seaward. Superimposed on the accreted sediments of the wedge is a drape of hemipelagic sediment, undiluted by turbidites, and the age of the base of this drape is youngest seaward. The drape is also deformed by the deformation of the wedge as it thickens, with the oldest part of the drape sequence being more deformed than the youngest. Copyright Graham Westbrook.

slope-drape and slope-basin sediments. In frontal accretion, thrusts propagating from a decollement in a weak, overpressured horizon at the toe of the wedge divide the overlying section into thrust slices, which become added to the toe of the wedge (Figure 3). The level of the decollement is commonly in the upper part of the pelagic–hemipelagic sequence on the subducting plate, which has been overpressured by the deposition of turbidites above it in the trench. The age of the accreted sediment changes with time, giving the wedge a characteristic tectonostratigraphy. Each thrust slice is youngest upward and landward, but the sequence of successively accreted thrust slices has the youngest thrust being seaward and downward. It is this characteristic stratigraphy that can be used to identify ancient accretionary wedges, such as the Ordovician–Silurian wedge of the Southern Uplands of Scotland.

In wedge growth by subcretion, sediment is added to the base of the accretionary wedge by the formation of duplexes at a ramp where the decollement changes level. These propagate successively forward because the work required to continue to move the wedge up a ramp becomes greater than that needed to propagate displacement along the lower decollement and generate a new ramp. In the process, the energy in the sediment between the ramps is transferred from the subducting plate to the accretionary wedge (Figure 5). It has also been suggested that the formation of a zone of tectonic melange along the decollement enables material from the subducting plate to be added to the accretionary wedge, but this can also operate in the opposite sense.

Accretionary wedge growth can occur when landward force imparted by the subducting lithosphere increases with increases in wedge width, pushing the wedge backward into the fore-arc basin and forming thrusts that incorporate fore-arc basin sediment into the wedge (Figure 5). In the mechanism involving slope-drape and slope-basin sediments, deposits directly onto the wedge are deformed by the continual deformation of the wedge beneath as it strives to maintain its critical taper. The sediment forming the slope drape is usually hemipelagic, but in some cases,

turbidites derived from erosion of the fore-arc basin or upper part of the wedge are deposited in synclinal troughs to form slope basins, so-called because they occur on the inner trench slope. In foreland fold-and-thrust belts, basins such as these are termed 'piggyback' basins. In the southern part of the Barbados accretionary complex, distributary channels of the Orinoco submarine fan run along synclinal valleys in the accretionary complex, as well as on the ocean floor before it (Figure 5).

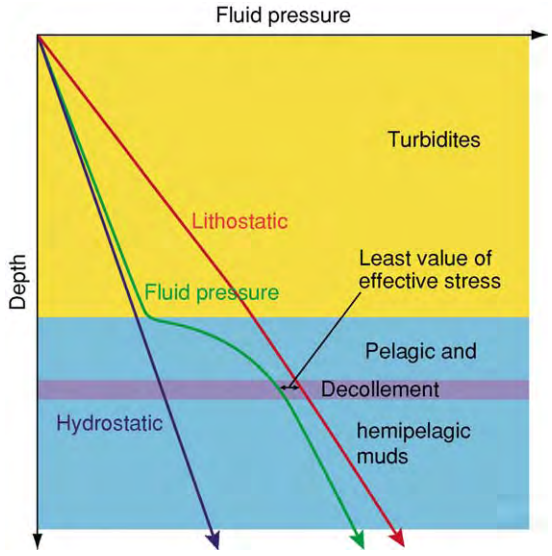

Figure 4 Fluid pressure varies with depth within the sediment in a trench, prior to accretion or subduction. Within the relatively permeable, rapidly deposited, turbidite fill of the trench, fluid pressure is only a little above hydrostatic. Within the low permeability pelagic and hemipelagic sediments, fluid pressure increases towards lithostatic pressure in response to the loading produced by the rapid deposition of the turbidites above the sediments. The depth at which fluid pressure is nearest to lithostatic pressure is favoured for development of the decollement, although local lithologically mediated variations in the coefficient of friction and cohesion may control its actual position. Copyright Graham Westbrook.

Thickening of an accretionary wedge in its frontal part is brought about by continued displacement on the thrusts by which sediment was accreted and by general horizontal shortening, which produces folding of the thrust slices and landward rotation and steepening of structures. The amount of thickening that this can produce is limited by the rotation of the thrust faults away from the optimum angle for thrusting. Consequently, thickening in the more landward parts of the wedge is produced by motion on new, out-of-sequence, thrusts (termed 'out of sequence' because they do not follow the normal sequence of the youngest thrust being the most seaward). Thickening is also produced by subcretion, adding material from below.

The size of an accretionary wedge might be expected to be simply a product of the thickness of sediment on the subducting oceanic crust, the rate of subduction, and the period over which subduction has occurred. It is certainly the case that the really large wedges occur where major submarine fan systems of considerable thickness are being subducted (Figure 6), but the correlation between wedge size and subduction rate is negative. The very large accretionary wedges occur at subduction zones with low rates of convergence. The frictional resistance to motion along the bases of these wide wedges (which, even with a fluid pressure ratio of $\lambda = 0.9$, is a few teranewtons per square metre, per unit length of the

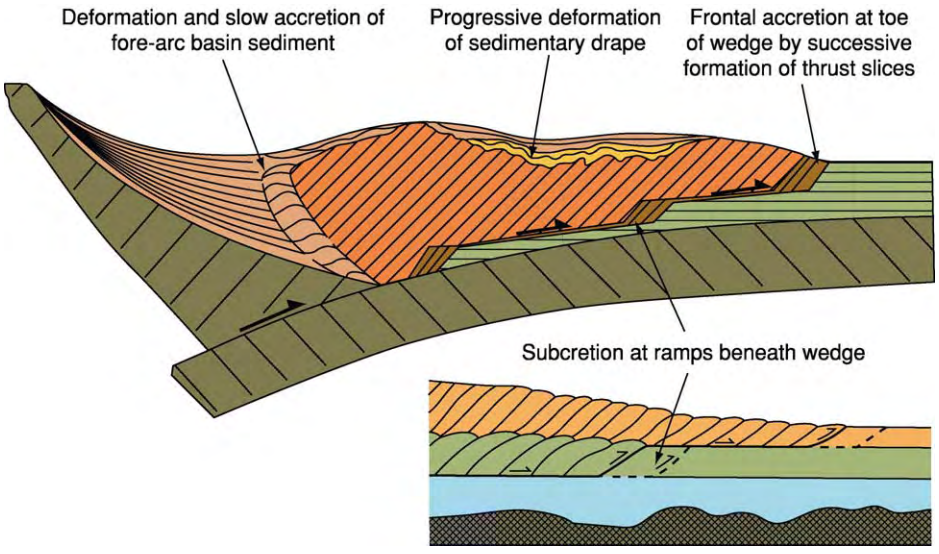

Figure 5 Different modes of accretion of sediment to an accretionary wedge. Copyright Graham Westbrook.

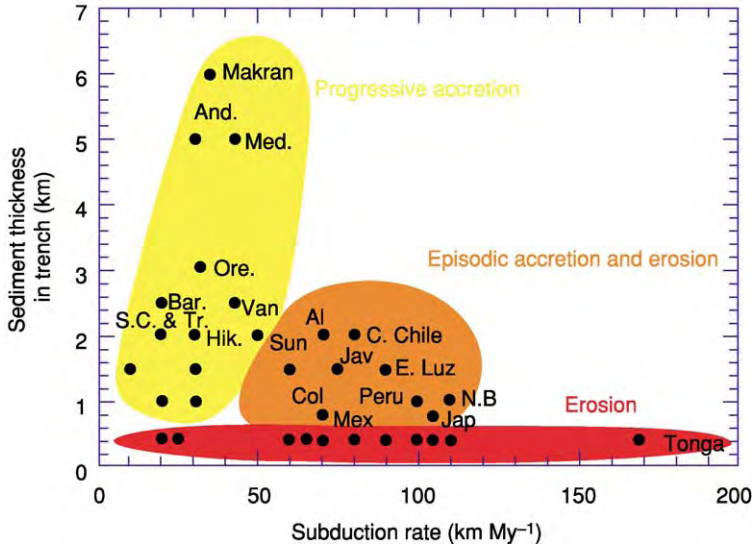

Figure 6 Thickness of sediment on a subducting plate in the trench at a subduction zone, plotted against the rate of subduction. Three discrete groups of subduction zones are identified worldwide: those that have large accretionary wedges with a history of near continuous growth (yellow), those that have accretionary wedges of small or moderate size in relation to their budget of sediment input and history and that have undergone episodes of tectonic erosion (orange shading), and those that have no, or insignificant, accretionary wedges and are dominated by tectonic erosion (red shading). The last category is typified by very thin sediment fill in the trench, irrespective of subduction rate, and tectonic erosion by basement relief is predominant. Copyright Graham Westbrook.

plate boundary, comparable to the net plate driving forces from ridge push and subduction pull) may be a contributory cause of the low convergence rates. A crucial aspect of the accretion process is the separation of accreted from subducted sediment. Off the coast of Costa Rica, all of the sediment in the trench, which has no cover of turbidites, is subducted. Lower permeability and a higher rate of loading, which correlates with faster subduction, develop higher fluid pressure in the sediments, which favours their subduction because the decollement surface can form at a shallow level. Studies of the global budget of material accreted at convergent plate boundaries, in comparison with material supplied by subducting plate and sedimentation in the trench, have shown that there is a net loss of material. Globally, sediment subduction and tectonic erosion (see below) predominate over accretion.

Fluid Flow, Seeps, and Methane Hydrate

As the sediment incorporated into an accretionary wedge and subducted beneath the wedge compacts, it expels water. Also, the dehydration of minerals in the sediment with increasing temperature and pressure, such the transformation of smectite to illite, releases water. This water flows through the wedge and subducting crust as it escapes to the ocean, carrying with it heat, solutes, and gases (Figure 7). The permeability of the mud-rich sediments that are subducted is generally too low for the water to escape along the subduction zone. The rate of flow of the water through the sediment is less than the rate of subduction. So, the water migrates into and then through high-permeability pathways, such as faults and permeable sediments such as sands, or even the igneous ocean crust, which is about a thousand times more permeable than compacted clay-rich mud deposited on the ocean floor. The warm water expelled beneath the trench increases the heat flow from the trench. Water driven into trench sediments or expelled along faults through the wedge can contain methane that was generated by methanogenic bacteria and other hydrocarbon gases that were created in conditions of higher temperature beneath the wedge. The methane and hydrogen sulphide expelled at seeps and vents sustain chemosynthetic communities of biota. (In this setting, the hydrogen sulphide is a product of anaerobic oxidation of methane by symbiotic communities of aquatic bacteria and archaea.) The seeps and vents are usually located along faults or in mud volcanoes, which occur on the accretionary wedge and on the ocean floor in front of the wedge. Mud volcanoes are created by mud diapirism, in which the tensional stresses at the top of a body of low-density mud are sufficient to create a pathway for the mud to rise buoyantly to the seabed, where it erupts. The diapiric bodies are initially created by deformation of underconsolidated

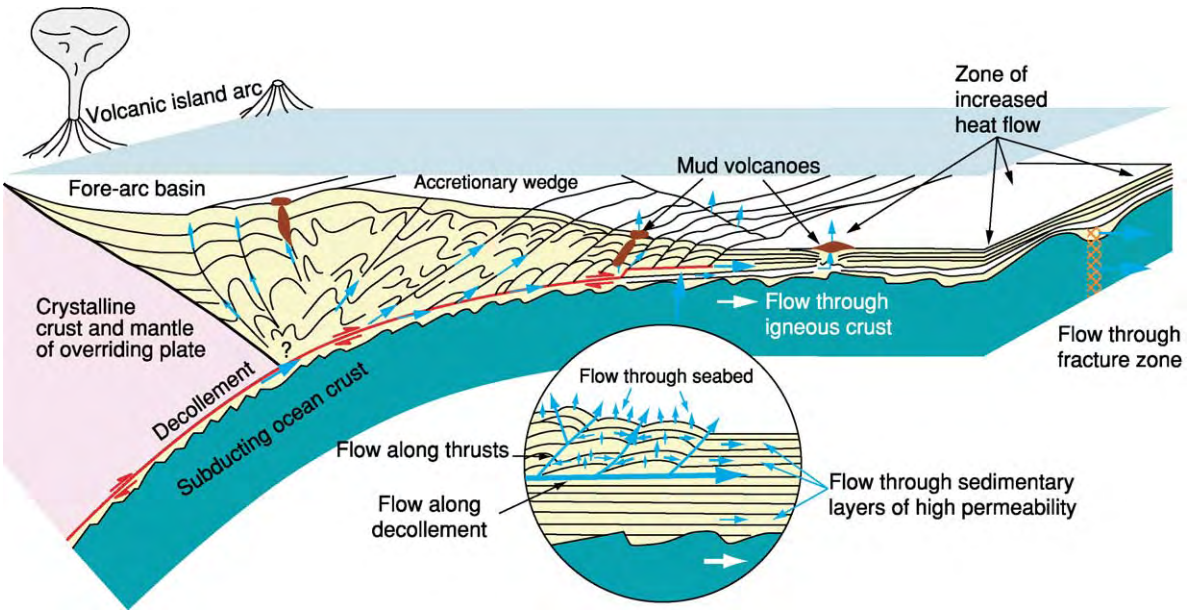

Figure 7 Fluid flow and modes of expulsion of fluid from an accretionary wedge. The sources of fluid are pore water expelled by compaction from sediment subducted beneath the accretionary wedge and sediment accreted to the wedge, and dehydration of hydrous minerals such as smectite, as temperature increases with increasing depth of subduction. Copyright Graham Westbrook.

mud-rich layers that are accreted into the wedge or subcreted beneath it. Mud volcanoes also appear to be created by the fluidization and entrainment of mud by water driven to the surface by tectonic expulsion, and this mode of formation is characteristic of mud volcanoes created in front of accretionary wedges on the ocean floor, or behind them in fore-arc basins.

The migration of methane-containing pore water through the sediments of an accretionary wedge as it compacts creates methane hydrate in the sediments occupying the first few hundred metres depth range beneath the seabed (*see* **Petroleum Geology:** Gas Hydrates). This occurs because this region lies within the stability field for methane hydrate (which is a solid clathrate formed from water and methane, in which the methane molecules are held within a cage of water molecules in an approximately 1:6 ratio). The hydrate stability field generally exists in Earth's major oceans in water depths greater than about 300 m, and is favoured by increasing pressure and decreasing temperature. Consequently, most of the sediments beneath continental margins are in the hydrate stability field down to the depth at which, because of the increase of temperature with depth, the geotherm crosses the stability boundary for hydrate. Beneath this boundary, methane can be present as free gas, in which case the boundary creates a seismic reflection because the presence of only a very small amount of free gas (less than 1% of the pore space is enough) reduces the seismic velocity of P waves significantly. The polarity of the reflection is negative, opposite to that of the seabed, because of the decrease in velocity beneath it, and is most clearly visible on seismic reflection sections where it cuts across the reflections produced by sedimentary bedding (Figure 8). This reflection is widespread in accretionary wedges, and is usually termed a bottom-simulating reflection (BSR) because its shape, to the first order, mimics that of the seabed, which, because of its nearly uniform temperature, controls the shape of the isotherms beneath it.

Uplift of the seabed produced by the thickening of the wedge continually moves the base of the zone containing hydrate upward out of hydrate stability field, causing hydrate to dissociate and release free gas that produces the BSR. Because the depth of the BSR below the seabed is controlled by the geothermal gradient, mapping the depth of the BSR has been used to map variations in heat flow from accretionary wedges, which is influenced by tectonic thickening and fluid flow. The tectonic expulsion of methane-rich pore water and the dissociation of hydrate to free gas caused by uplift results in methane hydrate and BSRs being widespread in accretionary wedges, whereas they occur only rarely in the sediments of passive continental margins.

Tectonic Erosion at Subduction Zones

The inner walls of trenches of arcs (e.g., the Mariana arc, Tonga arc, and South Sandwich arc) do not have significant accretionary wedges. Those that do occur

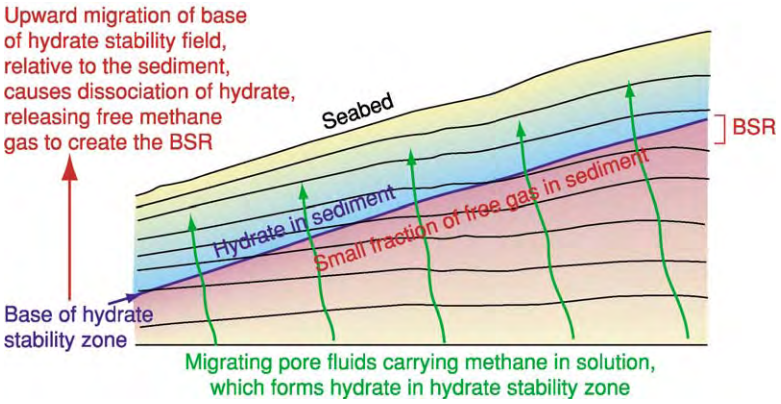

Figure 8 Model for the growth of methane hydrate within sediments in the uppermost part of an accretionary wedge, and for the formation of a bottom simulating seismic reflection (BSR). Methane, dissolved in pore water expelled from sediment by compaction within and beneath the wedge, is carried upward into the hydrate stability field, where it forms hydrate. Uplift of the seabed, caused by the thickening of the wedge with continuing growth, destabilizes the base of the hydrate stability zone, releasing methane gas and water from dissociated hydrate. The presence of free gas is the principal cause of the BSR. Copyright Graham Westbrook.

are very small and transitory. Most of the evidence suggests that material from the inner trench wall is being removed and subducted. The budgets of sediment available to be added to accretionary wedges in comparison with the mass of sediment in wedges indicate that many have lost sediment or have undergone periods when none was accreted. For example, the accretionary wedge off the coast of Honshu, Japan, is composed mainly of Cretaceous sediment, with only a very little Neogene sediment and no Paleogene sediment. This suggests that there is a process that removes material from the overriding plate at subduction zones. This process, or group of processes, is referred to collectively as tectonic erosion or subduction erosion.

What is the evidence for tectonic erosion? The absence of accretionary wedges from arcs such as Tonga might be explained if all of the sediment in the trench was subducted. Fore-arc subsidence such as that off the coast of Peru, where there has been 4 km of subsidence over a 100-km width of fore arc since the late Miocene, is difficult to explain other than by the removal of material from the base of the fore arc. The landward migration of the volcanic arc across the overriding plate, as exemplified by the Andes and by island arcs such as the South Sandwich or the northern end of the Lesser Antilles, although explicable in specific instances by a reduction in the angle of dip of the subducted lithosphere, can only be generally explained by removal of crust from the leading edge of the overriding plate. The mechanisms proposed for tectonic erosion are of two principal types: erosion by basement topography and erosion from the effects of high fluid pressure.

Erosion by Basement Topography

Tectonic erosion may occur when the basement topography physically breaks off and displaces parts of the fore arc, carrying it deeper into the subduction zone; this steepens the trench slope locally, causing submarine slides into the trench. The material from the slides may then also be subducted (see **Figure 9**). The mechanism depends on the basement of the subducting plate being stronger than the material in the tip of the overriding plate. Where an accretionary wedge, composed of sediment or metamorphosed sediment, forms the leading edge of the overriding plate, this is normally the case, but where the edge of the overriding plate is composed of igneous or high-grade metamorphic rocks, the situation can be reversed, resulting in the accretion/obduction of the basement feature on the subducting plate. There are two broad categories of basement topography. The first is general basement relief inherited from a mid-ocean ridge and accentuated by normal faulting in the outer trench slope. This is ineffective if sediment cover is more than several hundred metres thick, because the decollement forms well above the basement and the accretionary wedge rides over the relief, undisturbed. The second category comprises discrete features of high relief, such as seamounts, transform ridges and troughs, and hotspot ridges. These are more severe in their effects, but are not present everywhere, and so they produce spatially and temporally limited episodes of tectonic erosion, of which a good example is provided by the subduction of seamounts on the Cocos plate beneath the convergent margin of Costa Rica.

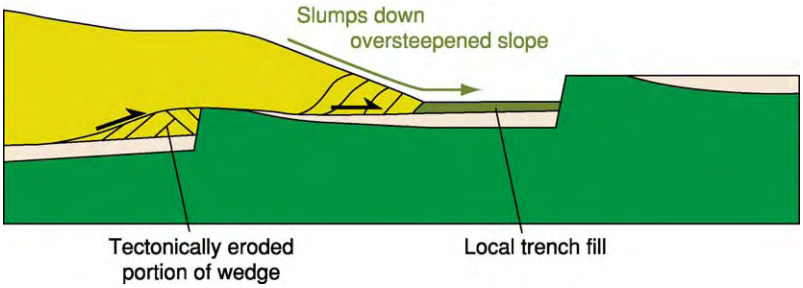

Figure 9 Tectonic erosion by the relief of the oceanic basement is a common process where sediment cover on the subducting plate is thin. Scarps originally formed by normal faulting at the mid ocean ridge are enhanced, or a new one is created by normal faulting in the outer part of the trench as the oceanic lithosphere flexes downward into the subduction zone. The tops of these scarps collide with the toe of the accretionary wedge or with the leading edge of the crystalline fore arc of the overriding plate, forcing the decollement to jump upward to the level of the top of the scarp, thereby transferring some of the material that was in the wedge to the subducting plate. The surface of the wedge is steepened by the removal of material from its toe, inducing slumps into the trench of material that is subsequently accreted and swept into the subduction zone by the basement scarps. The subduction of seamounts produces a similar, although more severe, process of tectonic erosion that is effective in thicker sediment cover, but is geographically more localized. Erosion from the Effects of High Fluid Pressure

The need to invoke this second type of mechanism is presented by those subduction zones where it is clear that tectonic erosion is or has been active, yet no features of basement topography appear to be responsible. The fluid pressure ratio, λ, is greatest at the top of any body of rock in which pore water is connected. This makes the uppermost rocks weakest and most liable to failure and displacement. As zones of high pressure are driven to migrate upward, progressive failure and displacement remove material from (tectonically erode) the section through which the high-pressure pore fluid migrates, until it dissipates or escapes to the surface. As subduction is continually feeding sediments with a high water content beneath wedges of accreted sediment or the basement of the overriding plate, the potential for this type of mechanism to operate is always present, if pore water expelled from the sediment cannot escape easily through the overlying wedge. There is evidence for two possible variants of this process, the first more general, the second more specific:

1. In 'stoping', high-pressure fluid causes disaggregation of the base of the wedge. The disaggregated rock is incorporated into a shear zone melange and is subducted (Figure 10). Shear zone melanges are exhibited by the exhumed deeper parts of old accretionary wedges that can be observed on land, such as the Franciscan wedge in California.
2. In the process of reactivation and upward migration of detachment surfaces, high-pressure fluid weakens the upper surfaces more than the lower ones. Rock beneath the reactivated surfaces is subducted (Figure 10). Seismic images of duplexes within the subducting section have provided the indication that this process occurs.

Obduction
