Chromates

P A Williams, University of Western Sydney, Penrith South DC, NSW, Australia

Introduction

Naturally occurring chromate minerals are confined to the oxidized zones of base metal orebodies and to extremely oxidizing desert environments. Under such conditions, chromium reaches its highest oxidation state (+6). The only commercially significant ore mineral of chromium is the primary spinel chromite, $FeCr_2O_4$, which contains Cr(III). Chromium (VI) can form under very oxidizing conditions, and nearly all of its minerals contain the simple tetraoxochromate(VI) or chromate ion, CrO_4^{2-} (see Table 1). Two exceptions are chrombismite, $Bi_{16}CrO_{27}$, a complex lattice oxide, and lopezite, naturally occurring potassium dichromate. The anion in the latter is generated reversibly by the acid-assisted dimerization of chromate, as shown in eqn [1]:

$$2CrO_4^{2-}(aq) + 2H^+(aq) \leftrightarrow Cr_2O_7^{2-}(aq) + 2H_2O \quad [1]$$

Geographical Distribution of Chromates

The chromates listed in Table 1 occur in two quite disparate settings: deserts and oxidized zones of a few base metals. Desert environments include those in Jordan (the only known locality for hashemite) and, more spectacularly, the Atacama Desert of Chile. In the latter case, chromates are associated with the caliche nitrate deposits, which besides nitrate contain other highly oxidized species, such as bromate, iodate, periodate, perchlorate, and native iodine. The persistence of highly oxidizing species in this environment is due to the extreme paucity of organic material with

Table 1 Chromate(VI) minerals

Type	*Name*	*Composition*
Simple chromates and dichromates		
	Chromatite	$CaCrO_4$
	Crocoite	$PbCrO_4$
	Hashemite	$BaCrO_4$
	Lopezite	$K_2Cr_2O_7$
	Tarapacaite	K_2CrO_4
Complex chromates		
	Cassedanneite	$Pb_5(CrO_4)(VO_4)_2\ H_2O$
	Deanesmithite	$Hg_5S_2O_2(CrO_4)$
	Edoylerite	$Hg_3S_2(CrO_4)$
	Embreyite	$Pb_5(CrO_4)_2(PO_4)_2\ H_2O$
	Dietzeite	$Ca_2(CrO_4)(IO_4)_2\ H_2O$
	Fornacite	$CuPb_2[(Cr,As,P)O_4]_2OH$
	Hemihedrite	$Pb_{10}Zn(CrO_4)_6(SiO_4)_2F_2$
	Iranite	$Pb_{10}Cu(CrO_4)_6(SiO_4)_2(F,OH)_2$
	Macquartite	$Pb_7Cu_2(CrO_4)_4(SiO_4)_2(OH)_2$
	Phoenicochroite	Pb_2OCrO_4
	Santanaite[a]	$Pb_{11}O_{12}CrO_4$
	Vauquelinite	$Pb_2Cu(CrO_4)(PO_4)(OH)$
	Wattersite	$Hg_5O_2CrO_4$
	Yedlinite	$Pb_6Cl_6O_2CrO_4\ 2H_2O$

[a]Contains both Pb(II) and Pb(IV).

which they would ordinarily react. Dietzeite, chromatite, lopezite, and tarapacaite have all been found in certain of the caliche deposits. These minerals are either freely soluble or decompose in water and they owe their preservation as well to the extreme aridity of the Atacama region.

Chromate minerals that form sparingly in the oxidized zones of base metal deposits form the bulk of the minerals listed in Table 1, and many of these chromate species are involved in complex solid solutions with both constituent cations and anions. Molybdate substitutes for chromate in the fornacite lattice and the alternate end-member molybdofornacite is recognized as a separate species. Nevertheless, all of the chromates are rare and none is a used as a source of chromium. One exception to this is the mineral crocoite, normal lead(II) chromate, which has been used as a paint pigment. The element chromium was first extracted and identified in 1796 by the French chemist Louis Vauquelin in samples of crocoite from Beresov, Russia. Fine specimens of crocoite together with the rarer phase, phoenicochroite, were recovered from Beresov, and the mineral has been found at a number of other localities worldwide. By far the most spectacular specimens have come from the Magnet mine and other deposits in the Dundas area of north-western Tasmania, Australia. Single crystals weighing several hundred grams each were recovered from the Red Lead mine, Dundas, and the neighbouring Adelaide mine has been a prolific producer of fine specimens for several decades. Crocoite in these deposits is formed by the interaction of chromium-bearing solutions derived from weathering serpentinites with oxidized, fault-hosted argentiferous galena ores. Associated with the crocoite is yellow cerussite, $PbCO_3$; the yellow colour is thought to arise from the substitution of minute amounts of chromate in the lattice.

Feldspars

R A Howie, Royal Holloway, University of London, London, UK

The minerals of the feldspar group are the most abundant minerals in the Earth's crust and are also found on the Moon and in meteorites. Their ubiquity and their wide range of chemical composition has led to their use as a primary tool in the classification of the igneous rocks (*see* **Rocks and Their Classification**). In the great majority of these rocks, whether acid, alkaline, intermediate, or basic, the feldspars are the major constituents; they are absent only from some ultrabasic and rare alkaline rocks. They are important constituents of simple pegmatites and are common in mineral veins. Feldspars are major constituents of most gneisses and schists, and occur also in any thermally as well as regionally metamorphosed rocks. Although susceptible to alteration and weathering, the feldspars are second in abundance to quartz in the arenaceous sediments (*see* **Sedimentary Rocks:** Sandstones, Diagenesis and Porosity Evolution), in which they occur as detrital grains. It is only in the pelitic, and to a greater degree in the carbonate rocks that they are of relatively minor importance.

Nomenclature

Most feldspars may be classified chemically as members of the ternary system $NaAlSi_3O_8$ (albite, Ab)–$KAlSiO_8$ (orthoclase, Or)–$CaAl_2Si_2O_8$ (anorthite, An) (*see* **Sedimentary Rocks:** Mineralogy and Classification). Compositions between $NaAlSi_3O_8$ and $KAlSi_3O_8$ are referred to as alkali feldspars and those between $NaAlSi_3O_8$ and $CaAl_2Si_2O_8$ as plagioclase feldspars. These two series each generally contain less than 5–10% of the other. The distinction between alkali and plagioclase feldspars near the $NaAlSi_3O_8$ composition is an arbitrary one.

To achieve a proper understanding of feldspar relationships it is necessary to characterise them not only by chemical composition, but also according to their structural state, the latter depending on the temperature of crystallisation and on subsequent thermal history (*see* **Igneous Processes**). Feldspars that retain a crystal structure appropriate to their high-temperature formation are called high-temperature feldspars; most feldspars in volcanic rocks are of this type. Low-temperature feldspars are those with structures appropriate either to crystallization at lower temperatures, or to slow cooling from elevated temperatures as, for example, in plutonic igneous rocks.

The difference between high- and low-structural state in a feldspar can involve the degree of ordering of Al and Si atoms between distinct tetrahedral sites. Feldspars can thus be classified as:

i. homogeneous high-temperature disordered feldspars; or
ii. ordered feldspars, in most of which phase separation (i.e., phases with appreciably different Na, K, or Ca content) occurs on a macro-, micro- or submicroscopic scale.

The nomenclature of the high-temperature feldspars is based on crystal symmetry. The sanidines (Figure 1A), mostly Or_{50}–Or_{80}, have monoclinic symmetry; the anorthoclase field embraces those feldspars that are triclinic at room temperature but

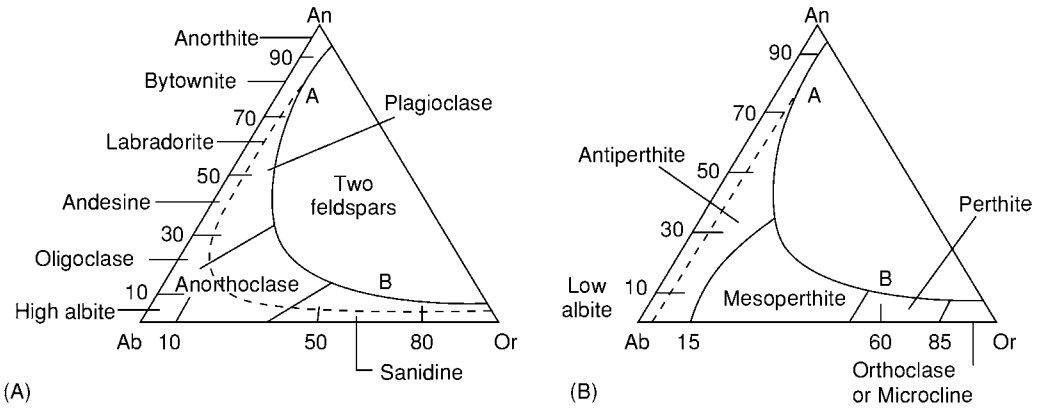

Figure 1 Feldspar nomenclature for (A) disordered ternary feldspars; (B) ordered ternary feldspars in which phase separation is at or below the resolution of the optical microscope. Composition in mol.%. Curve A B limit of ternary solid solution.

which may have possessed monoclinic symmetry at crystallization temperatures. For pure $NaAlSi_3O_8$, both low- and high-temperature forms are triclinic, but the remainder of the plagioclases have triclinic symmetry both at room temperature and at their temperature of crystallization.

In the alkali feldspars Al/Si and Na/K ordering lead to marked changes in symmetry, optics, morphology, and exsolution textures. In the compositional range Or_{15}–Or_{85}, exsolution gives rise to cryptoperthite (in which exsolution is on a submicroscopic scale), or to perthite or microperthite (Figure 1B). Microcline is triclinic, and may show varying degrees of order. The name orthoclase is used to describe intermediately ordered K-rich feldspars. Adularia is a low-temperature ordered potassium feldspar with a characteristic habit (large prism faces) and paragenesis ('alpine' veins).

A purely chemical definition of a plagioclase can be given in terms of Ab–An 'molecular' percentages, but specific names are used to denote the six compositional ranges into which the series has been divided. Thus, albite, oligoclase, andesine, labradorite, bytownite, and anorthite refer to the An percentages 0–10, 10–30, 30–50, 50–70, 70–90 and 90–100, respectively. Position within a chemical range may be further indicated by such terms as sodium-rich (or sodic) oligioclase or calcic labradorite, etc. Many plagioclases consist of a fine lamellar intergrowth of two phases, one more Ca-rich than the other; those within the An_5–An_{20} range are called peristerites and their surfaces may exhibit iridescence. Other ranges for such intergrowths may be found at An_{45}–An_{70} (Bøggild) which shows labradorescence and at An_{75}–An_{85} (Huttenlocher), also with associated iridescence effects.

Most perthites (named from Perth, Quebec, an early locality) are exsolution intergrowths of sodium-rich feldspar in a potassium-rich feldspar host; an intergrowth of K-rich feldspar in a plagioclase host is called antiperthite. The name feldspar as originally given was feldtspat and is believed to be in reference to the presence of this spar (spath) in tilled fields (Swedish: feldt or fält) overlying granite (*see* **Igneous Rocks:** Granite), rather than to the German Fels, meaning rock.

Structure

The feldspars are framework silicates with tetrahedra of $(Si,Al)O_4$ linked to one another (by shared oxygens) in all directions rather than in chains or sheets. Although discrete chains of tetrahedra do not occur in the structure, its nature may be more readily understood by considering the atomic arrangement as the linking of chains in two directions perpendicular to their length. The chains themselves are formed by the linking of horizontal rings of four tetrahedra, as shown in Figure 2. When viewed in the direction of the chain axis, a horizontal ring appears approximately, as shown in Figure 2B, and this can be further simplified by its representation, as in Figure 2C. The configuration shown in Figure 2 is often described as a 'double crankshaft'; the upwards- and downwards-pointing tetrahedra in a horizontal ring are labelled U and D, respectively. In the actual structure, the rings are considerably distorted; successive horizontal rings of a chain are related by vertical glide planes passing through their centres; the view down the chain axis may be idealized, as in Figure 2D, the first, third, fifth, etc. rings being represented by thick and the even number rings by thin lines. At the level of the first ring, a network of oxygen linkages is formed, producing a plane of four-membered and eight-membered rings of tetrahedra. The eight-membered rings are of two kinds, UUUUDDDD and DUUDUDDU, characteristic of feldspars, as distinct from other framework silicates, (*see* **Minerals:** Other Silicates) such as zeolites.

Twinning in feldspars is common and can occur in three different ways: (i) as a primary phenomena during crystal growth; (ii) as glide twinning induced by deformation; or (iii) on thermal transformation to lower symmetry. There are several twin laws shown

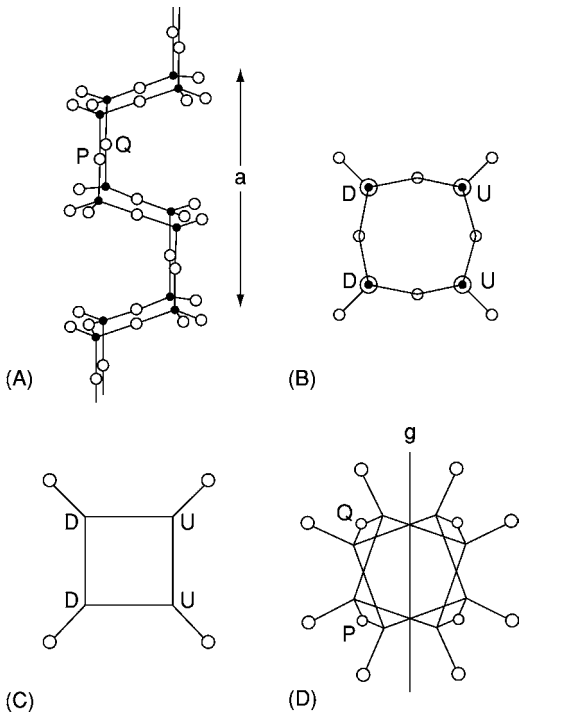

Figure 2 Idealized illustrations of the feldspar 'chain'. In (B) and (C) U and D indicate tetrahedra pointing up and down, respectively.

by feldspars; basically these may appear as single twins or as repeated or polysynthetic twins, an example of the latter being the very frequent twinning on the albite law in triclinic feldspars, giving the characteristic bands of alternating birefringence with an (010) composition plane. Measurement of the positions of optical extinction of these twins in plagioclase can be used to give an indication of the composition of the crystals.

Optical and Physical Properties

All the common members of the feldspars have D 2.55–2.5, with H 6–61/2. They are generally colourless, white or grey, but may be yellow, red, or green; colourless in thin section. Refractive indices are low, alkali feldspars having values <1.54 and plagioclase in the range 1.53–1.59 (the values increasing with increase in An content); the birefringence ranges 0.006–0.013. Single or multiple twins are common.

Alkali Feldspars

(K,Na)[($AlSi_3O_8$]. Monoclinic or triclinic. K-feldspar melts incongruently at ~1150° to leucite ($KAlSi_2O_6$) under anhydrous condition at 1 atm (Figure 3). The eutectic temperature (E) between K-feldspar and tridymite is ~990°C. From a melt of composition A, leucite (B) is the first phase to crystallize, and continues to do so as the liquid composition moves along the liquidus curve to the reaction point (R). At this temperature, the liquid reacts with the leucite transforming it to K-feldspar. As the temperature continues to fall, the composition of the melt moves along the curve RE with K-feldspar continuing to crystallize; at the eutectic (E) crystallization is complete and the whole mass solidifies as a mixture of K-feldspar and tridymite. Later experimental work has shown that at 4 kbar the eutectic point is lowered to ~735°C.

The refractive indices for the alkali feldspar series increase steadily with increasing albite content (Figure 4), values for α and γ in the high-temperature series sanidine–anothoclase–high-albite being marginally lower. Microcline is distinguishable from most other alkali feldspars by its 'tartan' twinning in which two sets of twin lamellae are approximately at right angles to each other.

The K–Na feldspars are essential constituents of alkali and acid igneous rocks and are particularly abundant in syenites, granites, granodiorites, and their volcanic equivalents. In plutonic rocks, the alkali feldspar is usually orthoclase, microcline, microcline microperthite, or microcline perthite, whereas in volcanic rocks it is sanidine, anorthoclase cryptoperthite, or anorthoclase. Granophyric intergrowths, the bulk composition of which is close to the melting minimum in the orthoclase–albite–quartz–H_2O system, consisting of roughly equal amounts of quartz, K-feldspar, and Na-feldspar components, occur in the mesostasis of acid rocks of high-level origin.

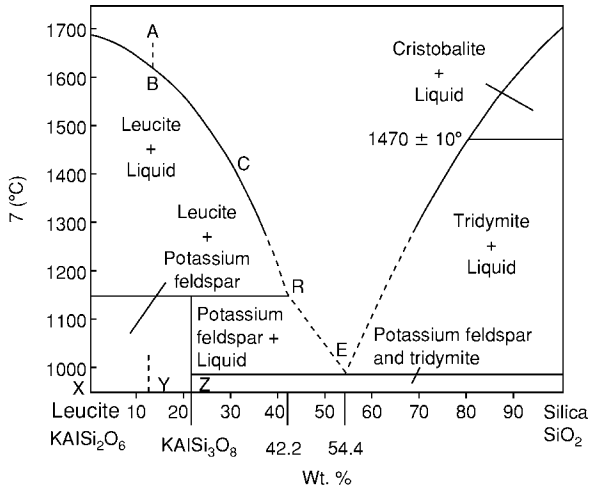

Figure 3 Equilibrium diagram of the binary system $KAlSi_2O_6$ (leucite) SiO_2. Reaction point R represented approximately by $5\,KAlSi_2O_6(\text{leucite}) + 3\,KAlSi_3O_8 + 5\,SiO_2(\text{melt}) \rightarrow 8\,KAlSi_3O_8$.

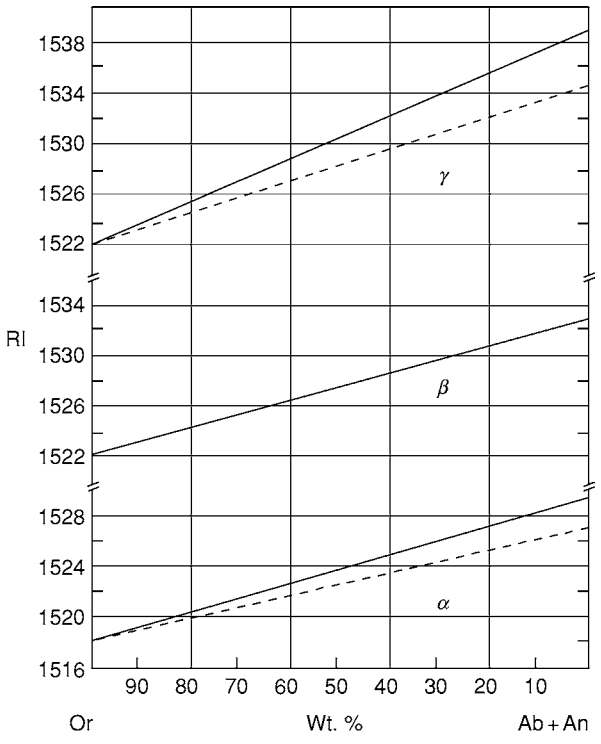

Figure 4 Variation of refractive indices with composition for the alkali feldspars; α and γ for the sanidine anorthoclase high albite series are shown as dashed lines, and those for the ortho clase (microcline) low albite series as full lines. The β index is essentially the same in both series.

K-feldspar is a stable product of both high-grade thermal and regional metamorphism. It is a typical mineral of the sillimanite zone of metamorphism and, in rocks of argillaceous composition, does not appear at lower grades. Where K-feldspars released by weathering of igneous or metamorphic rocks have undergone rapid transportation and burial, they occur as relatively abundant detrital constituents in arkosic sediments. They may also develop as authigenic minerals occurring as rims on detrital feldspar, often in optical continuity.

Plagioclase

$Na[AlSi_3O_8]$—$Ca[Al_2Si_2O_8]$. Triclinic. The phase diagram for the plagioclase series was one of the first to be determined experimentally (Figure 5). It shows a solid solution without maximum or minimum, with the melting point of anorthite at 1550°C and that of albite at ~1100°C at $P = 1$ bar. A liquid of composition $Ab_{50}An_{50}$ (A) begins to crystallize at ~1450°C, the first crystal having the composition of $\sim Ab_{82}An_{18}$(B). With further cooling under equilibrium conditions, both liquid and crystals change their composition along the liquidus and solidus, respectively, until at 1285°C the crystals reach a composition of $Ab_{50}An_{50}$(D) as the last of the liquid now of composition (C) is used up. This continuous change in composition of the plagioclase crystals with falling temperature occurs only if there is sufficient time for the earlier-formed crystals to react with the liquid: if there is insufficient time for this interchange of material, the crystals will be zoned. The resultant product will have an average composition of $Ab_{50}An_{50}$, but the inner core will be more calcic and the outer zones more sodic. With the addition of H_2O to the system, at $P_{H_2O} = 5$ kbar, the liquidus and solidus temperatures are over 300° lower than for the anhydrous system (Figure 5, curve 2). An even greater effect is shown on the addition of SiO_2 to the system at 2 kbar (curve 3).

The optical properties of the plagioclases are directly related to their anorthite content. Both the relief and birefringence are low and similar to quartz. A determinative chart is given in Figure 6; it is important to note that measurement of the refractive indices must be accurate to ±0.001 to obtain an accuracy of ± 2% An. The composition may also be determined by melting a small amount of material, quenching it to a glass and determining the refractive index of the glass, the refractive index for an isotropic glass being more easily determined than for a triclinic mineral and, for the plagioclases, having twice as great a rate of change with composition (Figure 6). This method can give the average composition for plagioclase which is strongly zoned or has exsolution intergrowths; also, the original structural state of the plagioclase is of no consequence.

In the majority of twinned plagioclase crystals, the composition plane is parallel to the crystal length.

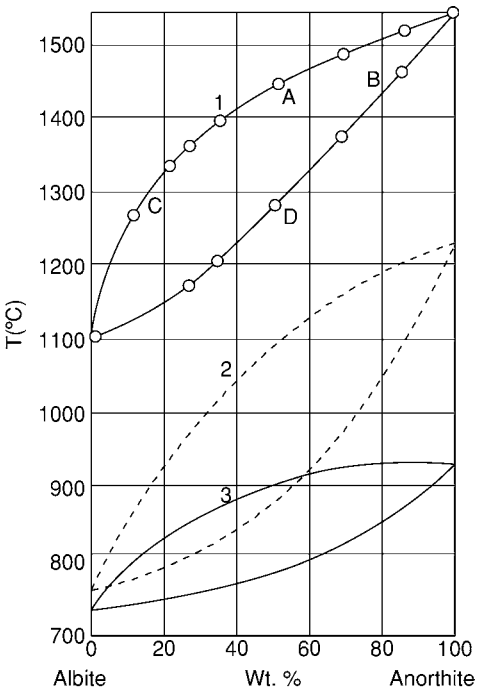

Figure 5 Equilibrium diagram of the plagioclase feldspars: (1) in anhydrous conditions, (2) at 5 kbar water pressure, (3) eutectic liquidus and solvus in the albite anorthite quartz H_2O system at 2 kbar.

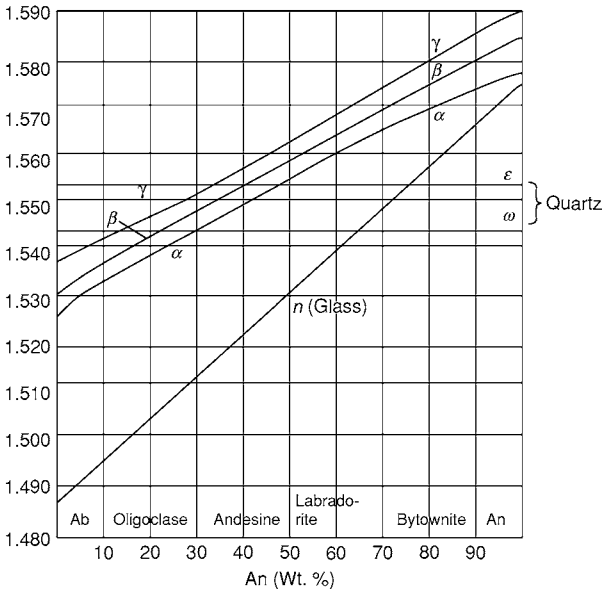

Figure 6 Refractive indices of the plagioclases. Values for glasses of plagioclase composition are also shown.

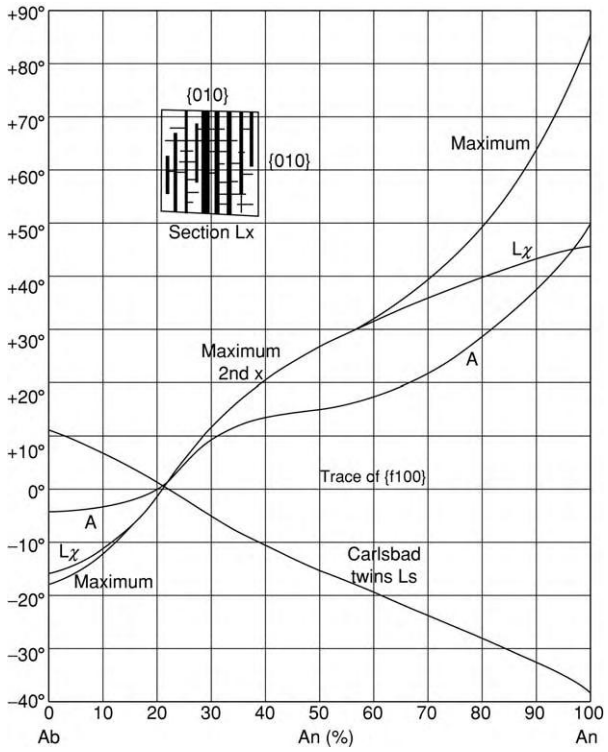

Figure 7 Extinction angles of plagioclase (with respect to α') in the 'symmetrical zone' and in sections normal to *x*.

The maximum extinction angles normal to {010} or in the so-called symmetrical extinction zone are diagnostic (Figure 7). In thin section, the alternate twin lamellae give symmetrical extinction angles on either side of the twin plane. Such sections may be recognised by the sharpness of the composition plane between albite twin lamellae, by the equal interference colours of the twin lamellae when the twin plane is parallel to the vibration direction of the polarizers, and by adjacent twin lamellae giving equal extinction angles on either side of the twin plane. Values which show more than a 5% divergence in the extinction angles for adjacent twin lamellae should be discarded, but lesser variations may be averaged; it is essential to take measurements from several (6–12) suitable grains, and the highest extinction angle must then be used.

Plagioclase is the most abundant mineral in the great majority of basic and intermediate lavas, in which it occurs both as phenocrysts and as a groundmass constituent. In basalts, the plagioclase phenocrysts usually have a wide homogeneous core of bytownite composition surrounded by a narrow zone of more sodic plagioclase. The broad cores of uniform composition indicate slow crystallization and it is clear that the growth of these crystals occurred before extrusion and final consolidation of the magma. Under plutonic conditions the first plagioclase to crystallize from most basic magmas, like that of basalts, has a bytownite composition. In basic igneous intrusions, plagioclase sometimes occurs in feldspar-rich bands formed by the accumulation of the primary precipitate plagioclase (the cumulus phase). In contrast, primary precipitate plagioclase may be absent from the ferromagnesian-rich bands in which the feldspar occurs as a product of the crystallization of intercumulus liquid. In the differentiated basic rocks of layered intrusions, the compositional range of the plagioclase is normally restricted to between An_{85} and An_{30}. In addition to the plagioclase-rich bands of layered intrusions, plagioclase also occurs as the only essential constituent of large masses of anorthosite; in these rocks the plagioclase may be bytownite, labradorite, or andesine in composition. Plagioclase feldspars are the main constituent of dolerites and many other hypabyssal rocks.

In metamorphic rocks, the composition of the plagioclase is generally related to the grade of the host rock. Thus, albite is the stable plagioclase in the chlorite and biotite zones of regional metamorphism, occurring in such rocks as chlorite-biotite-epidote-albite amphibolites and chlorite-albite schists; the anorthite component is not present in notable quantity until the garnet zone. Plagioclase between An_5 and An_{20} in composition is absent in low- to medium-grade schists; this compositional break (the peristerite gap) corresponds with the change in grade between the greenschist and the almandine amphibolite facies. In calc-silicate rocks of the amphibolite facies, clear compositional minima are seen corresponding also with the Bøggild and Huttenlocher gaps (Figure 8). The plagioclase feldspars of the intermediate and acid rocks of the granulite facies commonly are sodic andesines; thus in the rocks of the charnockite series, the majority of the plagioclase is between An_{30} and An_{35} in composition, although labradorite is present in some of the more basic charnockitic rocks. Plagioclase is not stable in the P–T environment of the eclogite facies; under these conditions the albite and anorthite components enter the compositions of omphacite and garnet, respectively. In the thermal metamorphism of calcareous sediments plagioclase again becomes increasingly calcic as the grade increases, with the production of anorthite marking a high grade of metamorphism.

In sedimentary rocks, plagioclase feldspars may occur via a variety of sources, including detrital minerals, authigenic minerals, and the products of volcaniclastic activity. In arkosic sediments, K-feldspar is usually dominant over plagioclase, but this varies according to the source rock and the weathering

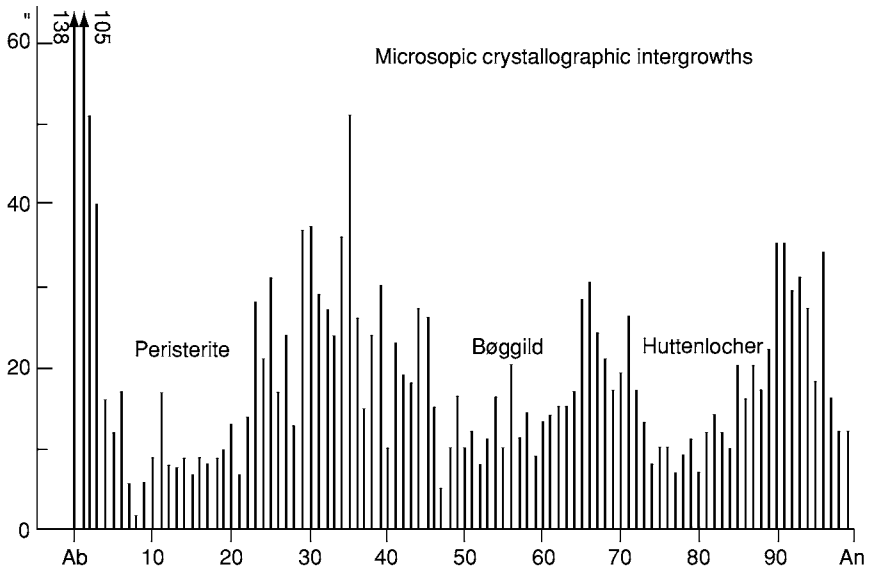

Figure 8 Frequency distribution of plagioclase compositions from 1883 microprobe results from 147 metamorphic calc silicate rocks in the central Alps (after Wenk *et al.* (1991)).

conditions to which they have been subjected. In meteorites, a whole range of plagioclase compositions occur, but there are two main clusters at around An_{90} and An_{15}. In lunar rocks the great majority of feldspars are calcic plagioclase An_{90} to An_{95} representing the lunar anorthosites.

Feldspathoids

M D Welch, The Natural History Museum, London, UK

Structure

Feldspathoid structures consist of rings of AlO_4 and SiO_4 tetrahedra that are connected to form a fully polymerized three-dimensional framework enclosing cavities occupied by large interstitial monovalent or divalent cations (sodium, potassium, calcium, and caesium) and, in some cases, anions (chloride, sulphide, and sulphate). These cavities are aligned to form channels that pass through the structure. Compared with feldspars (*see* **Minerals:** Feldspars), the feldspathoids are silica poor.

Three main tetrahedral-framework topologies are found in the feldspathoid group, and these are represented by the minerals nepheline, leucite, and sodalite. They are distinguished primarily by their different ring types and by how these rings are connected to each other. The nepheline structure consists of rings of six tetrahedra, whereas the structures of leucite and sodalite consist of both four-membered and six-membered rings.

Nepheline Subgroup

Minerals in the nepheline subgroup have the chemical composition ABO_4, where A is Na, K, Ca, or vacant,

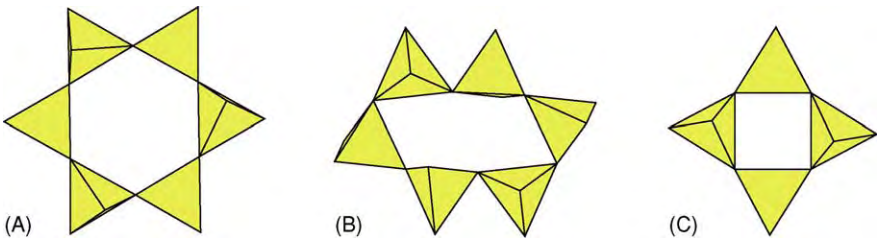

Figure 1 The different tetrahedral rings in feldspathoids. (A) The undistorted six membered rings exhibited by the high temperature form of tridymite. (B) The highly distorted six membered rings exhibited by nepheline and the low temperature form of tridymite. (C) The four membered rings that occur in leucite and sodalite.

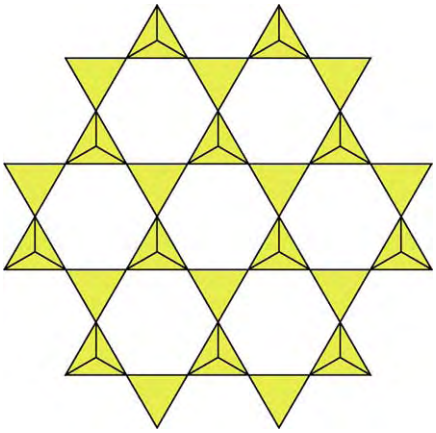

Figure 2 A sheet of undistorted hexagonal rings, as occur in the high temperature form of tridymite.

and B is Al or Si. The tetrahedral framework of nepheline-type structures is related to that of the mineral tridymite (*see* **Minerals:** Quartz), which has two polymorphs: a high-temperature largely undistorted hexagonal framework collapses upon cooling to a low-temperature structure in which all the six-membered rings are highly distorted (Figure 1B). A sheet of undistorted hexagonal rings in the high-temperature form of tridymite is shown in Figure 2. Half the tetrahedra point up; the other half point down. In the nepheline structure these sheets are connected to each other by apical oxygen ions to form cavities that are aligned into channels running parallel to the crystallographic *c*-axis. Insertion of cations into the channels causes distortions of the framework that are similar to those associated with the thermally induced collapse of high-temperature tridymite to low-temperature tridymite. For this reason, minerals of the nepheline group are often referred to as having 'stuffed tridymite' structures. The common stoichiometry of natural nephelines is $Na_3KAl_4Si_4O_{16}$, which arises from the ordering of potassium and sodium in the two different channels (Figure 3).

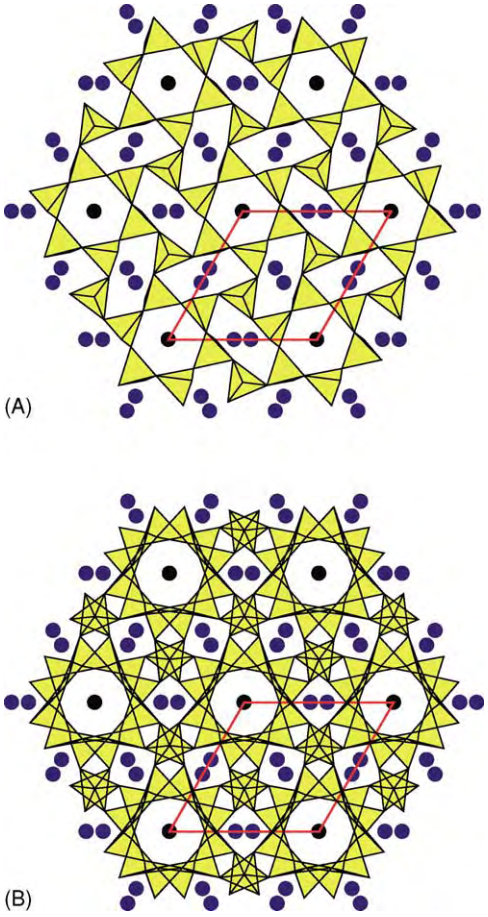

Figure 3 (A) The characteristic sheet of distorted and undistorted six membered rings of AlO_4 and SiO_4 tetrahedra in the nepheline type structure. Blue circles are sodium ions occupying smaller channel sites above and below the sheet, and black circles are potassium ions occupying the larger regular channels. The projection of the unit cell is shown in red. (B) A complete double sheet of the nepheline type structure, showing the two kinds of channel.

Leucite and Sodalite Groups

The leucite and sodalite structures differ from the nepheline structure in that they also contain squares of four tetrahedra (Figure 1C). However, the ways in

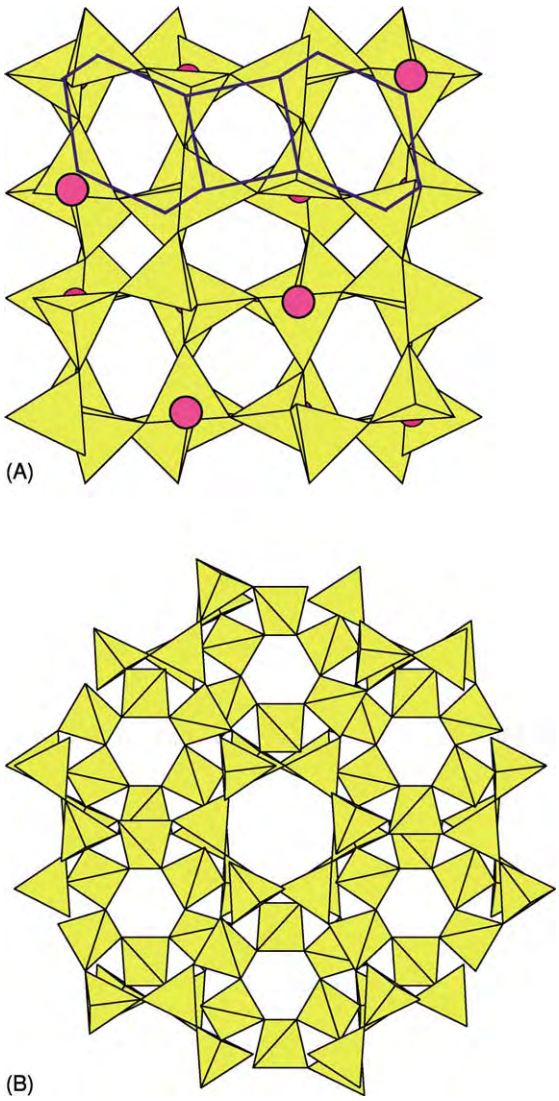

Figure 4 (A) The leucite structure is composed of connected four membered and six membered rings of tetrahedra. Two six membered rings and one four membered ring are shown in blue. Some potassium cations in the channels are shown in pink. (B) A view of the high temperature cubic leucite structure looking down the <111> channels. Channel cations are omitted for clarity. In leucite these channels do not intersect, but in sodalite they do.

which the six-membered and four-membered rings are connected to each other differ in the leucite and sodalite structures. In leucite, the hexagonal rings are aligned to form a set of non-intersecting channels in four orientations corresponding to the triad axes of the cubic high-temperature phase. In sodalite, these channels intersect to form very large cavities. Figure 4 shows the structure of leucite, in which the four-membered and six-membered rings are connected and potassium ions occupy the channels. Natural leucites are usually extensively twinned as a result of a reduction in symmetry upon cooling from the high-temperature cubic polymorph to a tetragonal structure. In end-member leucite, $KAlSi_2O_6$, this transition occurs at about 625°C.

The leucite group has the general chemical formula $AB_3O_6 \cdot xH_2O$, where A is K, Na, or Cs, B is Al or Si, and x is between zero and one. The three main minerals of the group are leucite ($KAlSi_2O_6$), analcite ($NaAlSi_2O_6 \cdot H_2O$), and pollucite ($CsAlSi_2O_6 \cdot xH_2O$, where $x = 0$ to 1). Water molecules occur in the larger channels.

The structure of the sodalite group differs from the leucite structure primarily in that the channels intersect to form large cavities, which are occupied by chloride, sulphide, and sulphate anions. The hexagonal channels are occupied by sodium or calcium ions. The sodalite group has three main mineral types: sodalite (*sensu stricto*) ($Na_8Al_6Si_6O_{24}Cl_2$), nosean ($Na_8Al_6Si_6O_{24}SO_4$), and häuyne ($(Na,Ca)_{4-8}Al_6Si_6O_{24}(SO_4,S)_{1-2}$).

Natural Occurrences of Feldspathoids

Nepheline-group feldspathoids occur predominantly in silica-undersaturated igneous rocks such as syenites and phonolites, of which they are major diagnostic minerals. More rarely, nepheline can occur as a metasomatic alteration product in metamorphosed sedimentary rocks. Nepheline is used in the manufacture of ceramics and glasses.

Leucite-group and sodalite-group minerals occur only in alkaline volcanic rocks that are more siliceous than syenites and phonolites. Leucite itself is unstable and, upon slow cooling, can transform to pseudomorphs of potassium feldspar and nepheline.

Glauconites

J M Huggett, Petroclays, Ashtead, UK and The Natural History Museum, London, UK

Green clay can be Fe smectite, glauconitic-smectite, smectitic-glauconite, berthierine, odinite (formerly phyllite v), a ferric chlorite (phyllite c), chamosite, ferric illite, or celadonite. Although the environment of deposition can be a guide to identification, careful chemical and mineralogical analysis is required to unequivocally identify green clay minerals. The green granule-forming clays are glauconitic, odinite, berthierine, or rarely chamosite, all forming where the rate of deposition is slow. Glauconite is a green, ferric iron-rich micaceous mineral that forms in marine sediments. Odinite and ferric chlorite are the ferric iron-rich precursors of the ferrous iron-rich clays berthierine and chamosite. Together odinite and ferric chlorite comprise the verdine facies in recent sediments. Odinite is only known from marine sediments, but berthierine and chamosite can be non-marine. An assemblage of mainly glauconitic granules is referred to as the glaucony facies, whereas an assemblage of mainly iron-rich 7-Å granules is called the verdine facies (although the latter term is used for recent assemblages rather than ancient ones).

Composition

Glauconite (*sensu strictu*) is an Fe-rich, K-rich dioctahedral mica with tetrahedral Al (or Fe^{3+}) usually >0.2 atom per formula unit and octahedral R^{3+} correspondingly >1.2 atoms. Typically 5–12% of the total iron is ferrous (Table 1). The structural formula may be written as

$$K_{(x+y)}(Si_{4-x}, Al_x)_{\sim 4}(Fe^{3+}, Al, Mg, Fe^{2+})_{\sim 2} O_{10}(OH)_2$$

where x is 0.2–0.6 and y (the sum of the divalent octahedral cations) is 0.4–0.6.

It is distinguished chemically from ferric illite in having more total iron, and from celadonite in having greater substitution of aluminium for silicon in the tetrahedral layer and a higher octahedral charge (Table 1). Glauconitic granules that have replaced faecal pellets are almost always inhomogeneous, with inclusions of common detrital minerals: clays, quartz, feldspars, carbonates, or apatite. Glauconitic-smectite is a mixed layer clay that is less potassic than glauconite and which characterizes immature glauconitic granules. Fe smectite is a ferrous iron-bearing dioctahedral smectite, half way between montmorillonite and nontronite (iron-rich smectite). Odinite is a poorly ordered, ferric iron-rich, 7-Å 1:1 green clay with ~0.8 $Fe^{3+}/Fe^{2+} + Fe^3$ and low tetrahedra substitution of Al_2O_3 for SiO_2. It is believed to be the precursor of the poorly – ordered, ferrous iron-rich, 7-Å green clay berthierine, which has ≤0.2 $Fe^{3+}/Fe^{2+} + Fe^3$ and less Mg than odinite. Phyllite C has

1 Shallow water glauconite (Pliocene) from ODP leg 174 A,
2 deep water glauconite (Oligocene) from ODP leg 174 A,
3 smectitic glacuonite from the Weches Formation (Eocene, Texas),
4 smectitic glauconite from the Karai Formation (Cretaceous, India).
5 odinite from Weches Formation (Eocene, Texas),
6 berthierine. Interlayercations in berthierine are due to contamination by micaceous minerals. Number of cations are on the basis of O20(OH)4 for glauconitic clays and O10(OH)8 for odinite and berthierine.

[a]FeO is assumed to be 10% of the total iron for glauconite, the odinite FeO is <5% of total Fe (analysed by EELS).

chemistry similar to that of odinite but a 14-Å 2:1 lattice structure similar to that of chlorite; it is only found in recent verdine granules. Chamosite is chemically similar to berthierine, but has a 14-Å 2:1 clay structure; some chamosite forms by the replacement of berthierine.

Formation

Granules formed from faecal pellets are often referred to as pellets; where the origin is not clear, the term peloid may be used. Faecal pellets are the main substrate for glaucony formation in both ancient and recent sediments. For iron-rich, 7-Å clay they are the main substrate only in recent sediment; most ancient berthierine (and some chamosite) occurs as ooids or pore-lining or pore-filling clay. Other modes of occurrence are replacement of mica, quartz, chert, feldspar, calcite, dolomite, phosphate, and volcanic rock, cementation of microfossil cavities, and formation of thin films on limestone hardgrounds, quartz grains, and flint pebbles. The current consensus on the origin of iron-rich clays is that they form by direct precipitation, close to the sediment–water interface. The crucial component of the faecal pellets and microfossil cavities that predisposed them to replacement by iron-rich clay is the presence of labile organic matter, the composition of the clay-rich clastic component apparently having little if any affect upon the mineralization process. It is likely that microbial oxidation of the organic matter may be critical in creating redox conditions favourable to iron fixation and detrital clay dissolution. The formation of glaucony and iron-rich, 7-Å clays (verdine) is favoured by a semiconfined oxic microenvironment. This is indicated by the following observations:

1. Green clays form in microfossil tests.
2. Grains $<100\,\mu$m are commonly only slightly glauconitized, whereas grains of 100–500 μm are typically homogeneously glauconitized. Grains >1 mm have a zone of most intense glauconitization just inside the margin.
3. There is an absence of diffuse glaucony or iron-rich, 7-Å clay layers from sediment.
4. There is a concentration of green granules in invertebrate burrows.

Glauconitization

The iron in glauconite and its precursors is mainly ferric (unusual for a sedimentary silicate), but mobile iron is ferrous; hence, it is believed to form close to the redox boundary. The first stage in glauconitization of faecal pellets is the dissolution of carbonate, detrital clay and formation of Fe(III) smectite, while the organic matter content decreases. The overall Fe, and to a lesser extent K_2O (2–4%), content of the faecal pellets increases while the Al content decreases. At this stage the granules have the particulate or vermiform fabric of the detrital faecal pellets are ochre to light green in colour and soft; i.e., reworking will disperse them. This is the 'nascent' stage in the classification of Odin (see Further Reading). The 'slightly evolved stage' is characterized by the almost complete disappearance of detrital minerals (nonclay, noncarbonate minerals are the most resistant to replacement). Fe and K uptake continues through this phase, which is characterized by 4–6% K_2O, 20–28% Fe oxides, and a mixed layer expandable/10-Å clay composition. At this stage the pellets are olive green, and in backscatter SEM images still have a particulate or vermiform appearance (**Figure 1**). The 'evolved stage' is the result of recrystallization where dense, indurated dark green pellets, frequently cracked at the margins, are formed. The original fabric is destroyed and X-ray diffraction spectra show a strong reflection at 10 Å (diagnostic of potassium-bearing micas, including glauconite). At this stage there are few expandable layers remaining, K_2O content is 6–8%, and the iron content is no higher than that for the slightly evolved stage. In-filling of fractures with glauconite represents the highly evolved stage. By this stage the granule is made of end-member, *sensu strictu* glauconite with $>8\%$ K_2O. Note that iron is fixed in the octahedral layer before potassium fixation is complete. It is also potassium content that increases as the layer charge increases (due to loss of swelling layers and

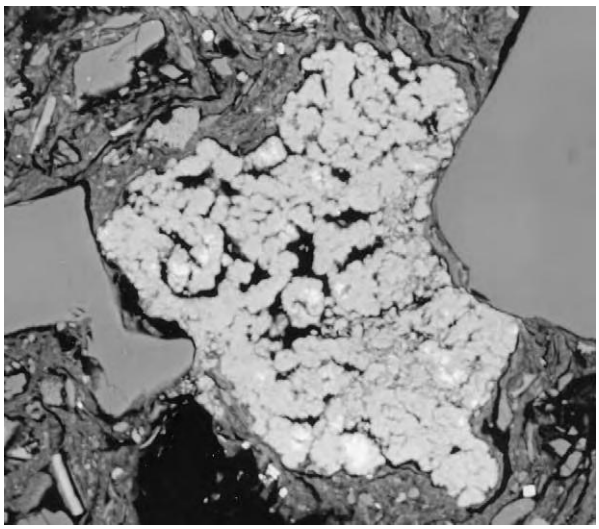

Figure 1 Thin section of vermiform (white in this picture) glauconite pellets in the ''slightly evolved'' stage of glauconization.

reduction of octahedral iron), and is consequently the only reliable chemical indicator of glaucony maturity. If glauconitic clay is not buried, it will remain stable so long as there is not a major sea-level fall. In a very shallow marine, fluvial, or palaeosol environment, glauconite will oxidize to kaolinite and goethite. Recently it has been found that tunnelling into glauconitic sand can result in a sudden (and harmful to life) drop in oxygen level, due to oxidation of the ferrous iron in glauconitic clay to ferric oxides or hydroxides. This instability only affects incompletely evolved glaucony; the use of sandstone containing highly evolved glauconite as building stone that has remained green over several centuries demonstrates this. In a reducing environment glauconite may be replaced by phosphate. Burial to more than a few decimetres halts the glauconitization process. Hence, burial prior to the glaucony attaining the fully mature state will preserve the immature state. Burial diagenesis results in increasing substitution of Al for Si, a decrease in swelling (smectite) layers, and an increase in crystallinity; hence, the chemistry of ancient glauconite differs slightly from that of Recent and Quaternary glauconite.

Glauconite forms coatings on particles and as laterally extensive (many squared kilometres) surfaces on hardground. Coatings of glauconite on particles are most frequent on flint pebbles in chalk and on bioclasts. Thin section study of these films shows that the clay mainly develops along fissures, biogenic borings, and any other void of suitable size to provide the semiconfined microenvironment necessary to glauconite formation. The thickness of the film depends upon the substrate and extent of alteration: on silicates it is $\leq$3 mm for silicates and $\leq$1 cm for carbonates. Film glaucony is commonly present in Jurassic limestone and Late Cretaceous chalk and provides useful stratigraphic markers.

The origin of the elements necessary for the formation of glauconite has been the subject of much discussion. Experimental work has indicated that a high silica concentration is necessary for glauconite and iron-rich smectite formation, as at low silica concentration iron-rich, 7-Å clays will form instead. This may link glaucony formation to the presence of biogenic silica.

The concentrations of Fe, Al, and K in normal seawater are also too low for direct precipitation of glaucony, although in river water the concentrations of Fe and Si are sufficient. Reducing conditions develop as soon as all dissolved oxygen in the pore fluid is used up in microbial oxidation of organic matter. Subsequently iron-reducing bacteria become the major consumers of organic matter until the sediment is buried sufficiently deep for sulphate-reducing bacteria to become active. In this narrow depth zone, just below the sediment–water interface in oxic sediments, the concentration of dissolved (ferrous) iron increases. Where there is a low sedimentation rate, intraformational reworking, or winnowing, much of the dissolved iron will diffuse towards the oxic zone and be precipitated as ferric iron hydroxides. Such precipitates can sorb silica, Fe^{2+}, Al, K, Mg, B, and other ions from solution. Experimental work has shown that these poorly crystalline materials can reprecipitate as iron-rich smectite. Glauconite cannot be directly precipitated at the low K concentrations in natural pore water, but evolves gradually through increased interlayer charge and K fixation.

Studies of recent glaucony have provided information on the rate of glauconitization. On the Congolese continental shelf glaucony from depths $<$110 m is younger than 20 000 years and has an average K_2O content of 5%, indicating that it is slightly evolved, whereas the age of recent glaucony off Vancouver Island is estimated to be $<$3000 years. Exceptionally, very small mica grains in nonevolved faecal pellets may undergo K and Fe enrichment in less than 10 years. In general it is thought that a slightly evolved granule typically takes the order of 10^4 years to form, and a mature pellet 10^5–10^6 years. However, laser-argon probe dating suggests that the period of genesis may be as long as $\sim$5 million years. It is therefore possible to use glaucony maturity as an indication as to the length of a hiatus. However, the extent and intensity of glauconitization appears to depend upon the size of the host material.

Verdinization

Verdine granules are mostly odinite, with minor ferric chlorite and detrital minerals; they occur only in recent sediments and have never been buried. Also referred to as the process of *verdissement*, the replacement of faecal pellets by iron-rich, 7- and 14-Å minerals follows a maturation process similar to that for glauconite, although without the interlayer K it is less easy to monitor the degree of chemical evolution. Verdine formation requires oxic pore waters because both odinite and the less frequent ferric chlorite are rich in ferric iron. The formation of verdine is less well known than that of glauconite. It follows a similar morphological transformation from nascent to evolved, though detrital minerals may be more persistent (Figure 2). It has been suggested that the first part of the process is odinite formation, followed by formation of ferric chlorite, and finally replacement by ferrous iron-rich clays. However, as very few intermediate stages between recent odinite and diagenetically modified chlorite and berthierine deposits have

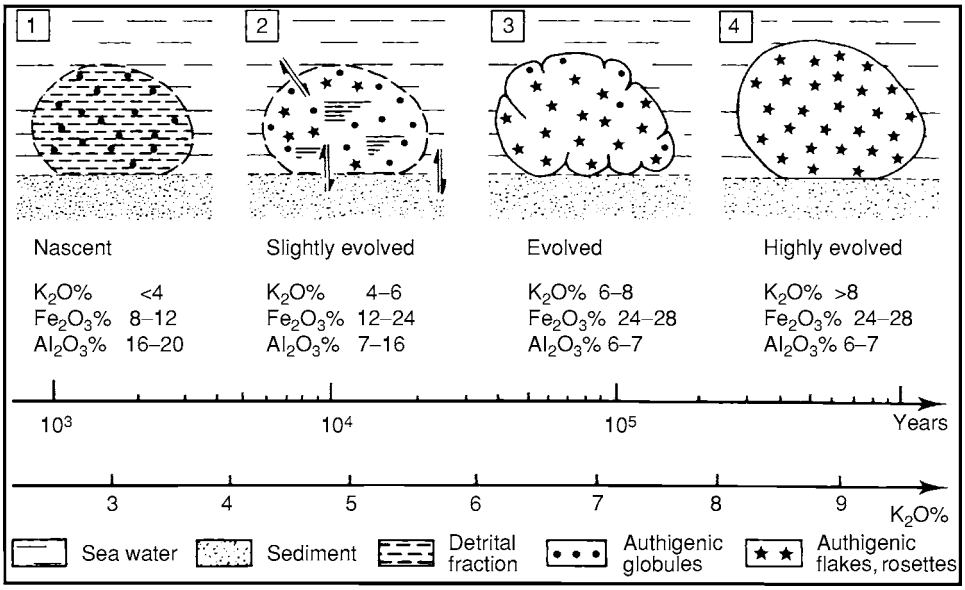

Figure 2 Morphological transformation from nascent to highly evolved glauconite.

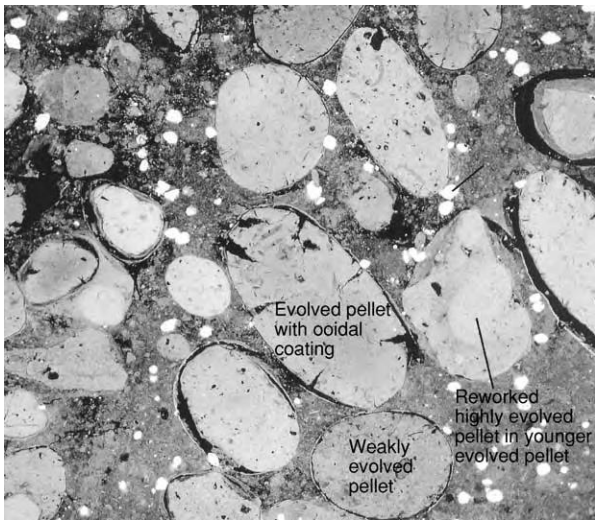

Figure 3 Thin section of faecal pellets with different stages of maturation towards full glauconization.

yet to be identified, the reaction pathway or pathways is not known with certainty. In some of the older literature it is suggested that berthierine forms by reaction of goethite and kaolinite. Although this may be true in some instances, it seems more likely that, like glaucony, formation of 7-Å, iron-rich clays is substrate independent. Verdinization may, like glaucony formation, follow a general pattern of iron-rich smectite formation followed by iron-rich, 7- and 14-Å clay formation (an example is the Claibourne Group of Texas, rich in pellets of an odinite-like mineral). Before it was realized that ferric iron-rich clays can be precursors of chlorite and berthierine it was commonly argued that these clays are indicative of a reducing environment at the time of sedimentation, rather than during diagenesis. It is possible to find many examples of this often-erroneous view in the literature.

Verdine is known only as granules and microfossil test in-fills. In contrast chamosite chlorite and berthierine frequently occur as ooidal coatings on grains, as pore-linings, replacement of detrital chlorite or discrete 'cryptocrystalline' clay, and only rarely as granules. This discrepancy has not been explained, although it might in part be due a widespread presumption that green granules are glauconitic. The odinite-like mineral found in the Claibourne Group of Texas does occur as ooidal coatings, but only rarely (Figure 3).

X-Ray Diffraction Identification of Green Clays

Optically the two various green granules are indistinguishable; hence, X-ray diffraction can assist in identifying the composition and purity of such granules. Due to their much higher Fe content, glauconite and ferric illite have a 002 (~5 Å) reflection much weaker than that of illite. Additionally, the iron-rich clays have a diagnostic 060 reflection at 1.51 Å. However, where both Fe-rich and-poor, 10-Å clays are present, this will not be so pronounced as that for the pure clays. All except the most evolved glauconitic clay will typically have some swelling clay layers, which can be identified by the broad area of reflection intensity between 10 and 14 Å and its shift to $\leq$17 Å

upon treatment with glycol and collapse to 10 Å upon heating at >400°C. Verdine granules yield a broad 001 reflection at ~7.2 Å, which is the strongest reflection of odinite, and also of berthierine, but the latter has a slightly smaller 002 reflection. Chlorites (both ferrous and ferric) are distinguished from other green clays by their 001 reflection at ~14 Å, which is unaffected by glycol treatment but shifts to a slightly smaller spacing upon heating at >500°C.

Distribution

In Time

Glaucony is absent from Precambrian sediments, but two major episodes of glauconite (and chamosite/berthierine) formation occurred during Phanerozoic time, the first in the Early Palaeozoic, and the second in the Middle-Late Mesozoic. Both episodes were characterized by temperate to subtropical climates, dispersed cratonic blocks, global sea-level rise (transgressive sediments), and periods of low shelf sedimentation. After the break-up of the Precambrian supercontinent about 600 My ago, glauconite became increasingly common through the Cambrian as cratonic blocks were rifted and dispersed from the Late Proterozoic supercontinent, the sea-level rose, and invertebrate faecal pellet makers became abundant. Glauconite formation in the Palaeozoic peaked in the Late Cambrian–Early Ordovician (*see* **Palaeozoic:** Ordovician). From then until the Cretaceous glauconite is relatively uncommon. The greatest period of glauconite formation occurred in the Cretaceous, notably along the continental margins of the widening North Atlantic Ocean, when global sea-level was again high (*see* **Mesozoic:** Cretaceous). Abundant glaucony continued until the Middle Cainozoic.

The earliest chamositic granules formed in the Early Proterozoic in association with greenalite. Chamosite ooids are not known until the Phanerozoic, and berthierine is only known from a few banded iron formations prior to the Mesozoic, whereas ancient odinite-like minerals are recorded only from the Eocene and younger rocks. The formation of ferrous clays in the Proterozoic was probably favoured by the lack of atmospheric oxygen. The major periods of chamosite/berthierine formation occurred when cratonic blocks were dispersed during the Ordovician, Devonian, and Jurassic–Cretaceous eras. Also global temperature may have effected the variation in abundance of chamosite and berthierine. In the Eocene a decrease in maturity of odinite-like mineral granules and an increase in Fe smectite may be linked to global cooling.

In Space

Recent glaucony apparently forms principally on the outer shelf at a water depth of 100–300 m, at a temperature of <20°C (possibly <13°C) and between 50° N and 50°S, although the true depth and latitude range may be masked by Late Pleistocene and Holocene sea-level fluctuations. Glaucony occurs where there are bottom currents that cause constant remobilization of sediment and winnowing. This association occurs because the intraformational reworking results in grains being exposed at the seafloor for sufficient time to permit glauconitization. Most recent glaucony occurs around the margins of the North and South Atlantic, and the Pacific west coast of the Americas, with smaller occurrences around the Mediterranean Sea and the Gulf of Oman. Glaucony is particularly abundant (up to 90% of the sediment) at the shelf-slope transition; however, apparently *in situ*, unweathered glauconite has been reported from ancient marine sediments deposited beneath 10–30 m water (e.g., in marginal marine to estuarine Tertiary sediments of the Hampshire basin, UK) and from clinoform toe sediments that must have been deposited beneath at least 600 m water. Very deep water glaucony (2000–3000 m) occurs in some recent sediments, as on the Chatham Rise, on the Scotia Ridge, and on both sides of Japan. The glauconite in the Chatham Rise and the Scotia Ridge sediments has not been investigated in detail, whereas that around Japan is associated with a fauna indicative of water shallower than the present depth. This could be due to either redeposition or rapid subsidence in this tectonically active area. Examples of ancient deep-water glauconitic sediments are the Miocene turbidites south-west of the Rockall Plateau (North Atlantic) and in Cretaceous turbidites in south-east France, e.g., the 'Petit Verolles'. The Petit Verolles is concentrated in coarser laminae, which suggests it was redeposited by turbidity currents along with the rest of the sediment with which it occurs. Glaucony in turbidites typically comprises fragments of mature pellets, because immature pellets are relatively soft and so become disaggregated during transport. It is likely that the precipitation temperature (which is reflected in the latitudinal constraints) and the availability of iron and potassium are ultimately more important than water depth. The importance of temperature is illustrated by the decrease in neoformed glaucony throughout the period of shallow marine sedimentation in the Eocene of the Hampshire basin (UK). This decrease coincides with a period of global

temperature decrease, whereas all other factors for glauconitization remained favourable. Indeed, the presence of the appropriate bacteria (which may be temperature-controlled) for organic matter degradation and iron reduction, plus faecal pellets (which are most abundant on the continental shelf in water <100 m deep), may prove to be the ultimate controls on glauconite formation.

Verdine in recent sediments is much more restricted than is glaucony. Its formation requires water temperatures >20°C; hence it is only known from the tropics. Verdine preferentially forms where the water depth is 20–60 m (but <5 m in the Casamance Estuary, Senegal, and up to 200 m elsewhere), where large amounts of land-derived iron compounds have been deposited in shallow marine sediments. Major recent examples are seaward of the Congo River, the Niger Delta, and between the mouths of the Amazon and Orinoco rivers. Recent verdine is also associated with iron derived from volcanic rocks, as in the case of offshore from New Caledonia. Berthierine, which in some instances has probably replaced odinite as the principal component of verdine, apparently precipitates over a much wider temperature range. For example, it is known from Arctic palaeosols and estuarine sediments of western Scotland. However, like glaucony, berthierine can be an indicator of hiatus, and in the case of the latter mineral this applies to nonmarine as well as to marine sediments. Hence berthierine and chamosite may be of use for onshore sequence stratigraphic interpretation.

The different types of substrate for replacement by green clays in a marine environment are typically found at different water depths. For example, on the Western African margin there is a succession of substrates from planktonic foraminiferans on the outer shelf margin, to benthic bioclasts, faecal pellets, mineral grains, and shell bioclasts in water <5 m deep. Of these the deeper water substrates are glauconitized, and the shallower ones are replaced by verdine. Such a succession is only possible in a period of stable sea-level. During a transgression, successive substrates will be glauconitized. Note that this produces a glauconitic sediment that may be used for facies correlation, although the age of the sediment will decrease up-dip.

Because green clay granules are slow to form, they are favoured by a low sedimentation rate, which may partially explain the depth constraint. The slow rate of formation also explains the common association of abundant glaucony with transgressive sediments. The frequent association of glaucony with transgressions and condensed sections predisposes it to reworking. Indeed, any glaucony found outside the range suggested above should be checked carefully for evidence of reworking. There have been several reports of nonmarine glauconite but detailed investigation has shown that it was reworked from underlying marine deposits.

The principal criteria for evidence of *in situ* granules are:

1. Concentration of glaucony in burrows rather than the host sediment; and
2. The presence of immature granules, which are soft and unlikely to withstand transport over more than a few metres; and
3. Deeply fractured mature granules (e.g., Plate), which would not survive transport without breaking up.

However, for reworked granules one or more of the following criteria may apply:

1. Fragments of granules;
2. Sand-size green granules in silt- or clay-dominated sediment;
3. Cross-bedding (which implies a high-energy environment), especially with laminae of green granules, whereas green clays are associated with slow sedimentation; and
4. Inclusions of material not representative of the host sediment; at the immature stage glaucony or verdine has a mineralogy similar to that of the enclosing sediment.

Age Dating

Potassium-rich glaucony provides ~40% of the absolute age dates for the geological time-scale of the past 250 million years. However, there are potential problems with this method of K/Ar radiogenic isotopic age dating:

1. Argon loss.
2. Residual detrital illite or K feldspar will result in incorrect (too old) dates. Both K/Ar and Rb–Sr apparent ages progressively decrease as glauconitization proceeds, but even the most evolved grains may retain around 10% of the initial substrate, which may affect the apparent age, depending upon its mineralogy. This is true for both ancient and recent glaucony.
3. Potassium-rich glaucony, being the most resistant to weathering, is the most likely to survive reworking; hence, ages greater than time of sedimentation may be measured.

4. A single glaucony assemblage may represent a cluster of glauconitization events; hence, the bulk age will be an average of these.

To get a meaningful, if not completely accurate date, the glauconite should be *in situ*, then sieved, mixed with distilled water, and subjected to one hour in an ultrasonic bath to break up the less-evolved granules. The remaining intact granules can then be separated off by washing, and if necessary any feldspar can be separated by magnetic separation. *In situ* glaucony with >7% K_2O gives the most reliable dates. Argon loss can be avoided by the microencapsulation technique. And clustered glauconitization events can be individually identified by single-grain age dating.

Ferric Illite

Ferric illite (sometimes misleadingly called nonmarine glauconite) most often forms green illite-rich claystones rather than granules. The iron content is much less, and the aluminium content is higher than that in marine glauconitic minerals. It forms in palaeosols and hypersaline lacustrine environments, but is not known to originate from marine environments. In lacustrine environments it is often associated with limestone and evaporite minerals, where alkaline, potassium-rich pore water favours illite precipitation. In palaeosols illite forms by the wetting and drying of smectite. Ferric iron in the smectite is reduced while the clay is wet, resulting in increased layer charge, loss of swelling capacity, and K fixation in the interlayer sites. Note that green clay in palaeosols can also be berthierine, but the latter is not associated with wetting and drying.

Micas

R A Howie, Royal Holloway, University of London, London, UK

Introduction

The minerals of the mica group show considerable variation in their chemical and physical properties, but all are characterized by a platy morphology and perfect basal cleavage which is a consequence of their layered atomic structure. They all have a negative optic sign and have the optic direction α approximately perpendicular to their perfect cleavage. The most common micas are muscovite (or white mica), the phlogopite-biotite series (brown or black mica), and lepidolite (lithium mica), of which muscovite, phlogopite, and lepidolite are of economic importance. The classification of

micas has been reviewed recently by an international committee.

Crystal structure

The basic structural feature of mica is a composite sheet in which a layer of octahedrally coordinated *Y* cations is sandwiched between two identical layers of linked $(Si,Al)O_4$ tetrahedra. Two of these tetrahedral sheets, with a composition $(Si,Al)_2O_5$, are illustrated in Figure 1. On the left is a sheet in which all tetrahedra are pointing upwards (see the elevation view), and on the right is a sheet of tetrahedra which all point downwards. These two sheets are superimposed and are linked by a plane of octahedrally coordinated cations (Figure 2). Additional hydroxyl ions, together with the apical oxygens of the inward-pointing tetrahedra, complete the octahedral coordination of the sandwiched cations. The central *Y* ions determine the positions of the two tetrahedral sheets so that they are displaced relative to one another by *a*/3 in the [001] direction. Thus the micas, although superficially hexagonal, have a monoclinic unit cell (outlined in Figure 2). The perfect cleavage is along the weakly bound sheet of *X* ions (K, Na, etc.) lying between the tetrahedral layers.

The tetrahedral hexagons may be superimposed in six different ways. Thus one hexagon may be related to the next by rotation through 0° or by multiples of 60°; this, in combination with the stagger of *a*/3 introduced by the *Y* layer (Figure 2), determines the location of corresponding atoms in successive cells. Various sequences of layer rotations are possible, and when repeated regularly these build up unit cells with one, two, three, or more layers. The commonest stacking sequences lead to either one- or two-layered monoclinic polytypes (symbols 1M, $2M_1$), a different two-layered monoclinic ($2M_2$) or a three-layered trigonal (3T) polytype.

Chemistry

The general formula, which may be used to describe the chemical composition of micas, is $X_2Y_{4-6}Z_8O_{20}(OH,F)_4$, where:

X is mainly K, Na or Ca, but also Ba, Rb, Cs, etc.
Y is mainly Al, Mg or Fe, but also Mn, Cr, Ti, Li, etc.
Z is mainly Si or Al, but perhaps also Fe^{3+} and Ti

The micas can be subdivided into di-octahedral and tri-octahedral classes in which the number of *Y* ions is 4 and 6, respectively. Thus muscovite $K_2Al_4[Si_6Al_2O_{20}(OH,F)_4$ is di-octahedral whereas phlogopite $K_2(Mg,Fe^{2+})_6[Si_6Al_2O_{20}](OH,F)_4$ is tri-octahedral.

Di octahedral			
	X	*Y*	*Z*
Muscovite	K_2	Al_4	Si_6Al_2
Paragonite	Na_2	Al_4	Si_6Al_2
Glauconite	$(K,Na)_{1\ 2-2\ 0}$	$(Fe,Mg,Al)_4$	$Si_{7-7\ 6}Al_{1\ 0-0\ 4}$
Tri octahedral			
	X	*Y*	*Z*
Phlogopite	K_2	$(Mg,Fe^{2+})_6$	Si_6Al_2
Biotite	K_2	$(Mg,Fe^{2+},Al)_6$	$Si_{6-8}Al_{2-3}$
Zinwaldite	K_2	$(Fe, Li,Al)_6$	$Si_{6-7}Al_{2-1}$
Lepidolite	K_2	$(Li,Al)_6$	$Si_{6-5}Al_{2-3}$

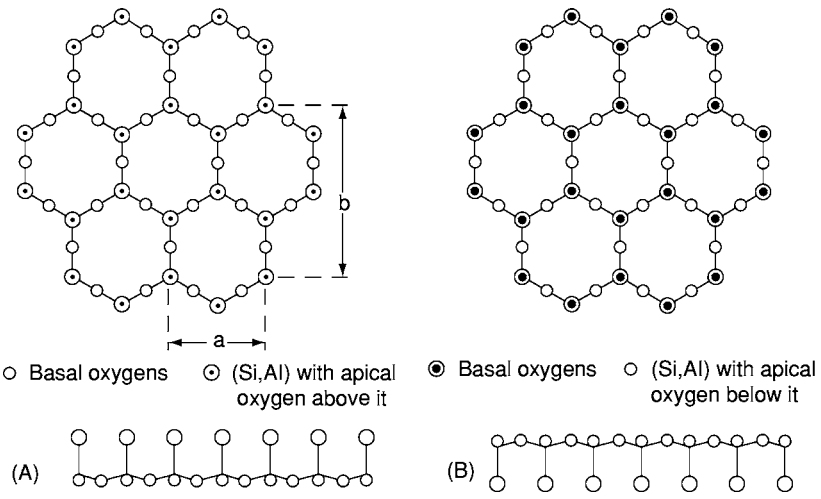

Figure 1 Tetrahedral layer $[(Si,Al)_4O_{10}]$ in an ideal mica structure viewed in *z* and *y* axis projection with tetrahedra pointing (A) upwards and (B) downwards. (After Deer *et al.* (1992).)

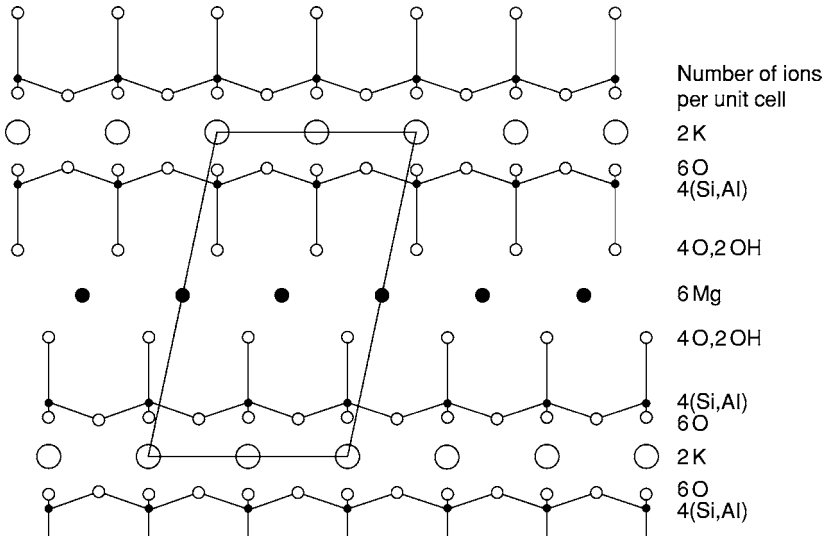

Figure 2 The crystal structure of phlogopite [$KMg_3AlSi_3O_{10}(OH)_2$] viewed in *y* axis projection, highlighting the three layer (tetrahe dral octahedral octahedral [*t o t*] sandwich unit, and the layer of interlayer cations (K^+). (After Deer *et al.* (1992).)

Some 40 mica species are recognized, but the more common micas are be listed as below. For muscovite and paragonite, a Si/Al ratio greater than 6:2 can be balanced by equivalent substitution of divalent ions for Al in the *Y* sites.

A chemical feature in most micas is their water content, which is generally around 4–5 wt% H_2O^+, except for those with a high fluorine content. The F/(F + OH) ratio rises in acid rocks, particularly in late-stage granites (*see* **Igneous Rocks:** Granite) and in the micas of pegmatites.

Optical and physical properties

The optical properties of micas cover a wide range but all have negative optic sign, low 2V, and have the α optic direction approximately perpendicular to their perfect cleavage. Birefringence is generally very weak in the plane of cleavage flakes but strong in transverse sections. Pleochroism is strong in coloured micas such as biotite, where it may range from yellow in the α direction to dark reddish-brown perpendicular to this direction. The perfect {001} cleavage of all micas is a useful characteristic. The sheet-like nature of the micas makes muscovite and phlogopite of economic interest in electrical insulation applications

Paragenesis

Minerals of the mica group occur in igneous, metamorphic, and sedimentary rocks. The principal occurrences are as follows:

i. *Igneous rocks*
   - Muscovite: granites, granitic pegmatites, and aplites.
   - Phlogopite: peridotites and kimberlites.
   - Biotite: gabbros, norites, diorites, syenites, granites, and pegmatites.
   - Lepidolite and zinnwaldite: pegmatites and high-temperature veins.

ii. *Metamorphic rocks*
   - Muscovite, paragonite, and biotite: phyllites, schists, and gneisses.
   - Phlogopite: metamorphosed limestones and dolomites.

iii. *Sedimentary rocks*
   - Muscovite and paragonite: detrital and authigenic sediments.
   - Glauconite: greensands.

Molybdates

P A Williams, University of Western Sydney, Penrith South DC, NSW, Australia

Inroduction

Molybdates are compounds containing negatively charged oxymolybdenum ions. For the most part, mineralogically, the simple tetraoxomolybdate(VI), or molybdate ion, MoO_4^{2} , is present. Under acid conditions, molybdate ions polymerize and this process can incorporate other chemical entities. Resulting heteropolymolybdates are represented in the mineral kingdom, but are rare. Indeed, only a few minerals containing essential molybdate are known, and overwhelmingly, molybdate minerals contain the simple molybdate ion. In this connection, the chemistry of molybdenum displays some differences compared to that of its congeners, chromium and tungsten. The former does not polymerize to any significant extent in its highest oxidation state, aside from the formation of dichromate(VI), $Cr_2O_7^{2}$, and tungsten and molybdenum minerals in the primary zones of deposits are markedly differentiated by virtue of redox differences. Standard potentials at 25°C are –0.78 and –1.26 V for eqns [1] and [2], respectively. This accounts for the fact that tungstates are favoured even in the primary environment; tungstenite, WS_2, is an extremely rare species.

$$MoO_4^{2} + 2H_2O + 2e \rightarrow MoO_2 + 4OH \quad [1]$$

$$WO_4^{2} + 2H_2O + 2e \rightarrow WO_2 + 4OH \quad [2]$$

Primary Molybdates

The primary mineralogy of molybdenum is dominated by molybdenite, MoS_2. Aside from the substitution of molybdate in primary scheelite, $CaWO_4$, molybdates are generally confined to the supergene environment. A remarkable exception to this pattern of paragenesis concerns the rare occurrence of primary powellite, $CaMoO_4$, in centimetre-sized crystals from basalt-hosted deposits of the Deccan Trap in India. In primary or other reducing environments, lower molybdenum valencies are stabilized in various complex oxides. Some molybdenum oxides are termed 'fumarolic condensates', and the more complex mineral, kamiokite, $Fe_2Mo_3O_8$, found in such settings contains Mo(IV). Sedovite is thought to be a U(IV) molybdate, and mourite, $UMo_5O_{12}(OH)_{10}$, may also contain U(IV). Alternatively, it may be a mixed-valency Mo(V,VI) molybdate or polymolybdate of the uranyl ion, but further studies are required to characterize this species fully.

Secondary Molybdates

Apart from the preceding examples, molybdates are mostly confined to the oxidized zones of base metal orebodies. Here molybdate is derived from the oxidation of molybdenite. In such environments, a number of simple salts are found, together with rarer double salts and polymolybdates, as listed in Table 1. For simple salts such as powellite, substitution by tungstate is common and solid solution over the full range of compositions to scheelite is known. The end-member composition is shown in Table 1, as is the case with other examples (aspects of solid solution are dealt with later, where they are significant). Where solid solution is more complex, stoichiometries reflect compositions of known materials.

In similar fashion to the case with the powellite–scheelite pair, complete solid solution between wulfenite, $PbMoO_4$, and stolzite, $PbWO_4$, can occur, although most naturally occurring material contains minor tungstate. Other ions substitute in the lattice as well, including chromate, arsenate, and vanadate, the latter involving some other charge compensation mechanism. Molybdofornacite, $CuPb_2[(Mo,Cr)O_4][(As,P)O_4]OH$, is structurally related to the brackebuschite group of monoclinic arsenates, phosphates, sulphates, and vanadates of general formula $AB_2(XO_4)_2(OH,H_2O)$; A = Al, Cu, Fe, Mn, Zn; B = Ba, Ca, Pb, Sr; X = As, P, S, V. Chromate substitution is pronounced in this species. However, not all of the species in Table 1, even those of comparatively simple stoichiometry, contain isolated molybdate ions. Koechlinite is an example of a layered-structure compound; this type of chemical and structural feature is more pronounced in related minerals of W(VI). For example, there is no Mo(VI) analogue of the dimorph of stolzite, raspite, that contains chains of edge-linked WO_6 octahedra (*see* **Minerals:** Tungstates). The heteropolymolybdates betpakdalite, sodium betpakdalite, and mendozavilite are all rare minerals, although betpakdalite is commonly found in small amounts in the oxidized zones of molybdenite deposits. It is possible that the very rare minerals

Table 1 Molybdate(VI) minerals

Mineral	*Chemical composition*
Simple molybdates

Sodium betpakdalite	$MgCa_2[Mo_8As_2Fe_3O_{36}(OH)](H_2O)_{23}$
Mendozavilite	$Na(Ca,Mg)_2Fe_6(PO_4)_2(PMo_{11}O_{39})(OH,Cl)_{10}\ 33H_2O$
Other complex species	
Obradovicite	$H_4(K,Na)CuFe_2AsO_4(MoO_4)_5\ 12H_2O$
Melkovite	$CaFeH_6PO_4(MoO_4)_4\ 6H_2O$
Chiluite	$Bi_6(TeO_4)_2(MoO_4)_2O_5$

obradovicite, melkovite, and chiluite also belong to this class of heteropolymolybdate.

Molybdate minerals have little commercial significance, although wulfenite assumed an important role in this regard between the two World Wars. The Mammoth–St Anthony mine at Tiger, Arizona, USA, was the principal producer of molybdenum during this period, all from oxidized ores carrying wulfenite. Today, however, the mineral is of interest only to collectors. Nevertheless, it is a common mineral in many deposits, the most noteworthy of which are found in the south-western states of the United States and in Mexico.

Native Elements

P A Williams, University of Western Sydney, Parramata, Australia

Introduction

A surprising number of the elements of the Periodic Table occur naturally, in the so-called native state. These range from the familiar coinage metals – copper, silver, and gold – to quite reactive metals, such as iron, zinc, and perhaps aluminium. Non-metallic elements such as sulphur and carbon are also well represented in the mineral kingdom (Table 1). The amounts of native elements present in rocks and ores vary widely, from minute grains to bodies weighing millions of tonnes. A number of these occurrences play extremely important economic roles, yet others are no more than mineralogical curiosities. The elements and their associations in widely disparate environments are reviewed, but ordered intermetallic species are not included.

Gases and Liquids

The majority of the atmosphere is made up of two gaseous elements, nitrogen and oxygen. Traces of hydrogen are known to be present. All of the noble gases – helium, neon, argon, krypton, xenon, and radon – are present in the atmosphere, the latter in small amounts, particularly in soil gas, where it is produced as the result of the radioactive decay of certain elements. No doubt other elements, including astatine, not considered in detail below, exist transiently in the free state as members of various radioactive decay series, but this aspect of the existence of the elements is rather arcane and is beyond the scope of this article. The third most abundant gas in the atmosphere is argon. Its apparently abnormal distribution is due to ^{40}Ar being a stable decay product of ^{40}K. While these gaseous elements are ubiquitous on Earth, albeit in highly variable amounts, they are not considered to be minerals. Another element present in volcanic gases is chlorine.

Under ambient conditions, only one element is found on Earth as a liquid. Native mercury is widespread, usually in small amounts, in low-temperature hydrothermal deposits and in hot springs. One exceptional occurrence is in the celebrated mercury deposits of Almadén, Spain, where it occurs in sufficient amounts to make it an economic mineral.

Solid Metals

The frequent occurrence of the coinage metals – copper, silver, and gold – gave rise to their use from early times. Native gold (*see* **Gold**) is overwhelmingly the commonest mineral form of the element and

remains its economically most important ore mineral. It is frequently alloyed with silver (electrum) or mercury (an amalgam) and usually contains small amounts of other alloyed elements. While silver and gold form a continuous solid solution, the mutual solubilities of copper and silver are quite restricted. Gold of very high fineness is known from supergene deposits. Silver is a comparatively common native element, forming a range of solid solutions with other elements. It also is known to occur as ordered alloys and intermetallic compounds, which are not considered here. Allargentum is a hexagonal mineral that may be considered to be the hexagonal form of silver, at least in part. Native silver is present in both primary and secondary ores, but it is now chiefly produced by the refining of other metals or concentrates, especially those of copper, lead, and zinc. Native copper is a very common mineral in the oxidized zone of base metal ore bodies. It is also found in the form of masses amounting to many tonnes in weight in the famous Keweenaw Peninsula of northern Michigan, USA. Native copper remains a significant ore mineral, especially in the oxidized zones of base metal deposits.

The other precious metals – iridium, osmium, palladium, platinum, rhodium, and ruthenium – are well known minerals in primary and placer deposits. They also form alloys with each other and with base and noble metals. They remain economically important species in layered deposits of platinum-group elements such as those in the Bushveldt (South Africa), Stillwater (Montana, USA), and related igneous complexes. Platinum was originally extracted from extensive placer and alluvial deposits in South America, the Urals, and elsewhere, but these are not now important sources of the element.

Many other metallic elements are known to exist in the natural environment in amounts varying from isolated grains to large masses. Native iron is a frequent accessory mineral of basic rocks, and masses weighing many tonnes have been recovered from weathering basalts on Disko Island, Greenland. It is also found in meteoritic materials, alloyed with nickel and small amounts of cobalt and other elements. Native nickel is a minor component of nickel-rich ultramafic rocks. Taenite (Ni, Fe) and kamacite (Ni Fe) are ordered and disordered cubic minerals that have been recovered from Ni–Fe meteorites, and a third tetragonal phase is known. Elemental chromium has been reported from unspecified localities in Russia and China. A number of high- and low-temperature hydrothermal deposits are known to host native antimony, arsenic, and bismuth. The last is a significant ore mineral in some deposits. The intermetallic compound stibarsen (SbAs) is known to occur naturally, and both native selenium and tellurium, included here with the metals, are frequent accessories in certain epithermal deposits. Native indium has been reported to occur in several unspecified Russian deposits.

Very rarely, metals whose natural existence would be unexpected because of their redox potentials have been found in small amounts. Aluminium, zinc, and cadmium have been found in highly reduced skarn and intrusive igneous deposits. Native zinc is the most common of these and has been found in other settings. Elemental tin has been found in a number of igneous deposits. Grains of tin have also been recovered from placer deposits in northern New South Wales, Australia. It is thought that these may be the result of the reduction of cassiterite, SnO_2, by carbon during bush fires. Some doubt has attended many reports of native lead because a number of cases may be due to the recovery of shot or other human artefacts. However, it has been reliably reported from a dozen or so deposits, and fine crystal groups have been found at Långbarn and the Harstigen mine, Sweden.

Solid Non-Metals

Only four solid non-metals, other than perhaps selenium, occur naturally as elements. These are carbon, sulphur, phosphorus, and iodine. Two allotropes of carbon – diamond and graphite – are recognized as minerals. No doubt the buckminsterfullerines and related compounds occur in nature as well, but they have not yet been formally described. Deposits of millions of tonnes of α-sulphur (the mineral sulphur) occur in so-called 'salt dome' deposits, and these are the most important commercial source of the element, which is recovered by the Frasch process. Sulphur is found in other sedimentary rocks, in the oxidized zones of many sulphide ore bodies, as a product of various micro-organisms, and very frequently as a sublimate associated with volcanic fumaroles, where it is sometimes associated with selenium. Two further modifications of sulphur have been reported to occur as minerals. Rosickýite is the natural counterpart of the well-known allotrope γ-sulphur. It occurs as a volcanic sublimate at Vulcano in the Mediterranean Sea and in sediments in Czechoslovakia and the USA. Naturally occurring β-sulphur has been reported from volcanic fumaroles on Vulcano and Mount Vesuvius, Italy. Amorphous or 'plastic' sulphur occurs in the Kobui sulphur mine, Japan, but it crystallizes over time to α-sulphur. Native phosphorus has been found in the Saline Township meteorite from Kansas, USA. Finally, the occurrence of elemental iodine is worthy of note. Iodine-rich caliche from certain

deposits of the Atacama Desert, Chile, is coloured blue-purple by elemental iodine. In addition, specimens of marshite (CuI) frequently possess the characteristic odour of iodine. This is perhaps not surprising given the mode of formation of marshite by the interaction of aqueous solutions carrying Cu^{2+} and I^- ions:

$$Cu^{2+}(aq) + 2I^-(aq) \rightarrow CuI(s) + 0.5I_2(s)$$

Nitrates

P A Williams, University of Western Sydney, Penrith South DC, NSW, Australia

Introduction

Naturally occurring nitrate mineral deposits are found in a number of different environments, but most are found in arid climates or in areas in which evaporation rates are high. This is because nitrate salts are generally highly soluble in water; exceptions are the metastable nitrate-bearing members of the hydrotalcite groups and certain basic copper salts.

Geographical Distribution of Nitrate Minerals

Despite the high degree of solubility of most nitrates in water, aside from basic salts, they are quite widely distributed in the natural environment, given appropriate conditions for their crystallization. Simple nitrates (Table 1), including gwihabaite, nitratine, niter, nitrobarite, nitrocalcite, and nitromagnesite, are found in quantities ranging up to thousands of tonnes in dry caves, where rates of evaporation are significant. The nitrate in this case (together with the ammonium ion in the case of gwihabaite) is usually derived from the decomposition of bat guano or is derived from the leaching of nitrate-bearing volcanic or sedimentary rocks. Some of the simple anhydrous species are also formed as ephemeral efflorescences on rock faces and in playa lakes in arid climates. Aside from this, both simple and complex nitrates (again, excluding the basic salts) are present in quantities amounting to millions of tonnes in the celebrated Chilean nitrate deposits of the Atacama Desert. These represent a significant source of nitrate fertilizer and have been mined as such for centuries. The rare mineral ungemachite was first found in during mining operations in the oxidized zone of the Chuquicamata copper deposit together with clinoungemachite; the mine is located in the Atacama region and ungemachite has been identified elsewhere only in a single specimen from the oxidized zone of the New Cobar copper–gold deposit near Cobar, New South Wales, Australia. The caliche-hosted nitrate deposits of the Atacama Desert contain other highly oxidized species (besides nitrate, with nitrogen in its highest oxidation state), including bromate, iodate, periodate, perchlorate, and native iodine.

Three nitrate-bearing members of the hydrotalcite group containing nickel are confined to a single locality, the Mbobo Mkulu cave in South Africa. Nitrate is formed from the leaching of nitrate-bearing volcanic or sedimentary rocks, and nickel and copper are

	Likasite	$Cu_3NO_3(OH)_5\ 2H_2O$
	Buttgenbachite	ca $Cu_{36}(NO_3)_2Cl_8(OH)_{62}\ 4\ 10H_2O$

derived from oxidizing sulphide minerals in associated shale horizons. Sveite is also a cave mineral; it has been found in the Autana cave, Venezuela, and has been reported as a coating on rock faces at an unspecified California locality. All of these minerals are exceptionally rare and are based on the hydrotalcite structure, $Mg_6Al_2CO_3(OH)_{16} \cdot 4H_2O$, consisting of an $M(OH)_2$ layer that sandwiches layers containing anions, metal ions, and water molecules. The minerals are metastable phases with respect to Al(III) oxyhydroxides and other soluble components.

The basic copper(II) nitrates of Table 1 are an exception to the pattern of nitrate mineral distribution in arid regions in that they are found sparingly in the oxidized zones of a number of copper orebodies. Perhaps the most common of the minerals is buttgenbachite. The composition of this mineral is complicated by the fact that it is involved in a complex solid-solution series involving the sulphate-chloride analogue, connellite. Various amounts of chloride and hydroxide ions are found in the lattice, depending on the composition of the solution from which the mineral crystallizes and with respect to requirements for charge compensation. Connellite, the sulphate-dominant analogue, almost invariably carries some nitrate, although the nitrate-free end-member can be synthesized.

The origin and persistence of nitrate in the natural environment are both complex phenomena. Biological activity serves both to produce and to consume nitrate, depending on the micro-organisms involved. The accumulation of vast amounts of nitrate in the Chilean deposits is due to the extreme paucity of living matter that would ordinarily consume it. Large amounts of nitrate minerals can accumulate only in the absence of significant biological activity or in a steady-state environment when losses due to metabolic processes are balanced by biological nitrate production or inputs from other sources. In this connection, aside from contributions from leaching of rocks, nitrate is formed in significant amounts by electrical discharge in the atmosphere during thunderstorm activity.

Despite the large quantities of some of the world's nitrate deposits, including those found in caves, nitrates generally are rare minerals and are confined to special environments. Aside from the few simple minerals that dominate the exploitable resources, nitrate minerals are of interest only in the academic sense or to collectors.

Olivines

G Cressey, The Natural History Museum, London, UK
R A Howie, Royal Holloway, University of London, London, UK

Introduction

Olivine is an important rock-forming mineral and occurs in mafic igneous rocks such as peridotite, gabbro, and basalt, along with pyroxene and plagioclase. The ultramafic rock dunite consists almost entirely of olivine, and is the result of the fractional crystallisation of peridotite-composition melts to form cumulate olivine. Magnesium-rich olivine is abundant in the majority of mantle-derived ultramafic nodules in kimberlite pipes. Olivine is common in the Earth, Moon, (*see* **Solar System:** Moon) and in the stony meteorites, and much research is conducted into the physical, chemical, and mechanical properties of olivine in order to understand the physical state of the interior of the Earth, the origin of meteorites, and the history and processes on planetary bodies (*see* **Solar System:** Mars).

Crystal Chemistry of the Olivine Group

Crystals of olivine possess orthorhombic symmetry and have a structure consisting of an array of individual (SiO_4) tetrahedral units that do not share linking oxygen atoms (unlike the pyroxenes, amphiboles, or feldspars which form linked SiO_4 polymers). The oxygen atoms that form the individual tetrahedral units of the olivine structure are arranged in planes perpendicular to the x-axis; in each plane the oxygen atoms are in approximate hexagonal array, but they are not touching. The tetrahedra point alternately up and down in the x and y directions of the unit cell, and there are two non-equivalent sets of cation sites linking the tetrahedra. Half of the cation sites lie on a centre of symmetry between the tetrahedral bases (M1 sites), and half lie on mirror planes between edges and bases of tetrahedra (M2 sites). Although in each of these sites the cations are in six-coordination with oxygen atoms of neighbouring SiO_4 tetrahedra, the cation sites are geometrically distinct (**Figure 1**). At elevated temperatures, the cation–oxygen bond lengths of both M1 and M2 sites increase, but the SiO_4 tetrahedra remain the same, thus reflecting the greater bond strength of Si–O compared with that between other cations and oxygen. In most natural olivines, Mg^{2+} or Fe^{2+} occupy the cation sites. Because of their similar ionic size, Mg^{2+} (ionic radius 0.72 Å in 6-coordination with oxygen) or Fe^{2+} (ionic radius 0.78 Å) can be accommodated in either cation site, and there exists a complete solid solution series between these two end-members having compositions Mg_2SiO_4 (forsterite) and Fe_2SiO_4 (fayalite). Almost all natural olivines have compositions intermediate between these two extremes, the exact composition reflecting the availability of Mg and Fe during crystallisation. Mg^{2+} and Fe^{2+} can occupy M1 and M2 with almost equal preference, so Mg^{2+} and Fe^{2+} remain disordered over these two sites down to low temperatures, and the solid solution is close to ideal with no tendency for ordering or exsolution to occur. However, it has been established that there is a slight tendency for Fe^{2+} to occupy the M1 site rather than the M2 site (this is paradoxical since M1 is the smaller site and Fe^{2+} the larger cation), therefore the Mg–Fe distribution is not completely random, but this effect is only slight.

Larnite, Ca_2SiO_4, does not have an olivine-type structure, but Ca^{2+} ions can be accommodated in the olivine structure on half the cation sites, i.e.,

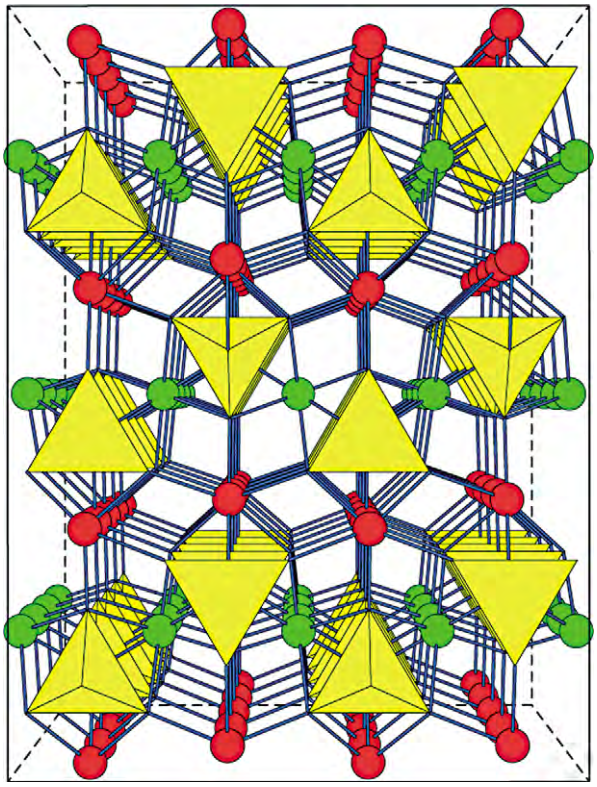

Figure 1 The olivine structure (view looking down the *x* axis of the unit cell): SiO_4 tetrahedral units (yellow) point alternately either way in both the *x* and *y* directions, and there are two different cation sites, M1 (green) and M2 (red).

$CaMgSiO_4$, forming the mineral monticellite. The Fe analogue, $CaFeSiO_4$ (kirschsteinite) is known only in synthetic systems, but complete solid solution is possible between montcellite and kirschsteinite as Fe replaces Mg in the structure. The most iron-rich naturally occurring examples in the $CaMgSiO_4$–$CaFeSiO_4$ series contain about 70% $CaFeSiO_4$ component. However, there is very limited solid solution between the montcellite-kirschsteinite series and the forsterite-fayalite series, because the size of the Ca^{2+} ion (ionic radius 1.00 Å) is substantially larger than Mg^{2+} and Fe^{2+} ions. Substitution of the large Ca^{2+} ion into the olivine structure causes strain that distorts the SiO_4 tetrahedra.

The olivine structure cannot tolerate the degree of distortion that would be produced by a random occupation of the cation sites by ions of such different sizes, so very little solid solution can exist between the Ca-olivines and the Mg, Fe-olivines, even at high temperatures. In the Ca-bearing olivines, the Ca and Mg, Fe ions are completely ordered in the structure; Ca^{2+} occupies the (larger) M2 site, while Mg^{2+} and Fe^{2+} are randomly distributed on the M1 sites. In many natural Mg-Fe olivines, particularly those rich in Fe, there is often a small proportion of Ca and Mn present in the structure. The substitution of Mn^{2+} (ionic radius 0.83 in 6-coordination) for Fe^{2+} in fayalite also occurs when Mn is present during crystallization, and a complete solid solution series exists between Fe_2SiO_4 (fayalite) and Mn_2SiO_4 (tephroite). In natural occurrences, the low Mg-content of fayalite-tephroite phases is more likely to be related to the limited amounts of Mg available in such crystallization environments, rather than the inability of the structure to tolerate differences between these cations sizes. Zn-bearing tephroites have been reported, and $CaMnSiO_4$ (glaucochroite), although rare in nature, has an olivine structure.

Other compositions that also possess the olivine structure, such as Ni_2SiO_4 and Mg_2GeO_4, have been prepared by laboratory synthesis. Small amounts of Ni^{2+} (ionic radius 0.69 Å in 6-coordination) are commonly present in the structure of natural Mg-rich olivines. However, the presence of Cr^{3+} and/or Fe^{3+} (which would produce unfavourable charge imbalances in the olivine structure) is often found to be associated with exsolved sub-microscopic crystallites of chromite or magnetite inside the olivine. Fe^{3+} is also likely to be present in the oxidation products commonly formed during the hydrothermal alteration of olivine.

Nomenclature

Compositions within the forsterite-fayalite isomorphous solid solution series are the most abundant of the naturally occurring members of the olivine group, and the term olivine has come to signify compositions between these two end members, with general formula $(Mg,Fe)_2SiO_4$. In the past, different names have been assigned to specific ranges of Mg:Fe ratio (e.g., chrysolite, hyalosiderite, hortonolite, ferrohortonolite), but it is preferable to indicate the composition by giving the mole proportion of either the forsterite (Fo) or the fayalite (Fa) component in the solid solution. This can be expressed in different ways; for example, an olivine with specific composition $Mg_{1.8}Fe_{0.2}$ SiO_4 can be expressed as Fo_{90} (or Fa_{10}), meaning that the olivine contains 90% of forsterite component (and 10% of fayalite component). Alternatively, the cation site occupancy in this olivine structure can be expressed as $X_{Mg} = 0.90$, $X_{Fe} = 0.10$, where $X_{Mg} = Mg/(Mg + Fe)$, $X_{Fe} = Fe/(Mg + Fe)$, and $X_{Fe} + X_{Mg} = 1$. This nomenclature can be extended to any number

of components, if small amounts of Mn, Ca, Ni, Zn, etc. are present.

Physical Properties and Stability

The densities of olivine solid solutions vary smoothly and linearly from forsterite (3.22 gm cm ^{3}) to fayalite (4.39 gm cm ^{3}). Similarly, their unit cell dimensions and optical properties vary systematically with composition. At atmospheric pressure the melting point of pure forsterite occurs at 1890°C; under anhydrous conditions the melting point increases with pressure, and under water-saturated conditions the melting point decreases with pressure. Pure fayalite melts at a much lower temperature (1205°C at 1 atm) than forsterite, because the Fe^{2+}-oxygen bonds are weaker than the shorter Mg^{2+}-oxygen bonds. For cations of the same charge, bonds to oxygen are weaker for the larger cation, so as more of the larger cations enter the structure there is a progressive reduction in the melting points of intermediate compositions. This is reflected in the crystallisation behaviour of olivine solid solutions; the first olivine crystals to separate from a liquid of given composition are richer in Mg than those of later in the crystallisation sequence, and consequently the larger Fe^{2+} ions are concentrated in the residual liquid.

Igneous olivines formed during a slow, undisturbed cooling regime will have sufficient opportunity to re-equilibrate their Mg-Fe composition with the coexisting liquid as the temperature gradually falls, so that the final crystals have a single composition. However, rapid cooling can often result in zoned olivine crystals that have a Mg-rich core and progressively more Fe towards their rims; the core represents the initial composition to form which was subsequently prevented from equilibrating with the remaining liquid by a protective overgrowth. In very rapidly cooled magmas, olivines sometimes form dendritic crystals. The morphology of olivine crystals may be equant, tabular, acicular, or dendritic; these can, in general, be related to the rate of cooling of the magma during crystallisation. In a natural silicate melt, the melting point of Mg-rich olivine is much depressed, such that crystals of composition Fo_{88} will melt in basalt magma at about 1250°C.

At high pressures in the deep earth, the olivine structure transforms to a denser spinel-type structure. For forsterite-rich compositions, the transformation to a distorted spinel phase occurs at about 140 kbar pressure at a temperature of 1000°C. This structural transition is of geophysical significance, as it is believed to be the cause of the abrupt change in seismic velocity in the Earth's mantle at about 400–500 km depth.

Alteration

Olivine is very susceptible to hydrothermal alteration, during low-grade metamorphism and weathering, and readily reacts to form serpentine and a range of iron oxides, chlorites, and smectite clays. Serpentinisation is the most common and widespread alteration process to affect olivine-rich rocks such as dunite and peridotite. The serpentine polymorphs chrysotile, lizardite, and antigorite, along with brucite, talc, and carbonates (if CO_2 is also present in the fluid) are commonly the products of this retrograde metamorphism. The following chemical re-arrangement represents the serpentinisation process:

$$\underset{\text{forsterite}}{2Mg_2SiO_4} + 3H_2O = \underset{\text{serpentine}}{Mg_3Si_2O_5(OH)_4} + \underset{\text{brucite}}{Mg(OH)_2}$$

This hydrothermal alteration of forsterite takes place at about 400°C, and for an olivine of composition Fo_{90} this reaction takes place nearer 340°C. Any iron present in the original olivine can only be accommodated in the serpentine structure to a very limited extent and is, therefore, usually converted to iron oxide or oxyhydroxide (magnetite, hematite, or goethite) inclusions that give the otherwise green serpentine a dark brownish or reddish appearance.

Occurrence

Pure forsterite is rare, but is found in certain metamorphosed siliceous dolomitic limestones (marbles). Olivine with compositions between Fo_{96} and Fo_{82} are major constituents in ultramafic rocks such as dunite and peridotite, and in prograde metamorphosed serpentintes. Mantle-derived ultramafic nodules in basalts and kimberlites usually contain olivines in the range Fo_{91} to Fo_{86}. Olivines with compositions Fo_{80} to Fo_{50} are common in gabbros and basalts (Figure 2); the actual forsterite-fayalite composition provides a useful index of fractionation for these basic igneous rocks. A wide range of olivine compositions from Fo_{98} to Fo_{40} (often as zoned crystals) and occasional almost pure fayalite grains are important constituents in some carbonaceous chondrite meteorites. Fe-rich olivines occur in alkaline and acid igneous rocks; fayalite is present in small amounts in many volcanic rocks such as

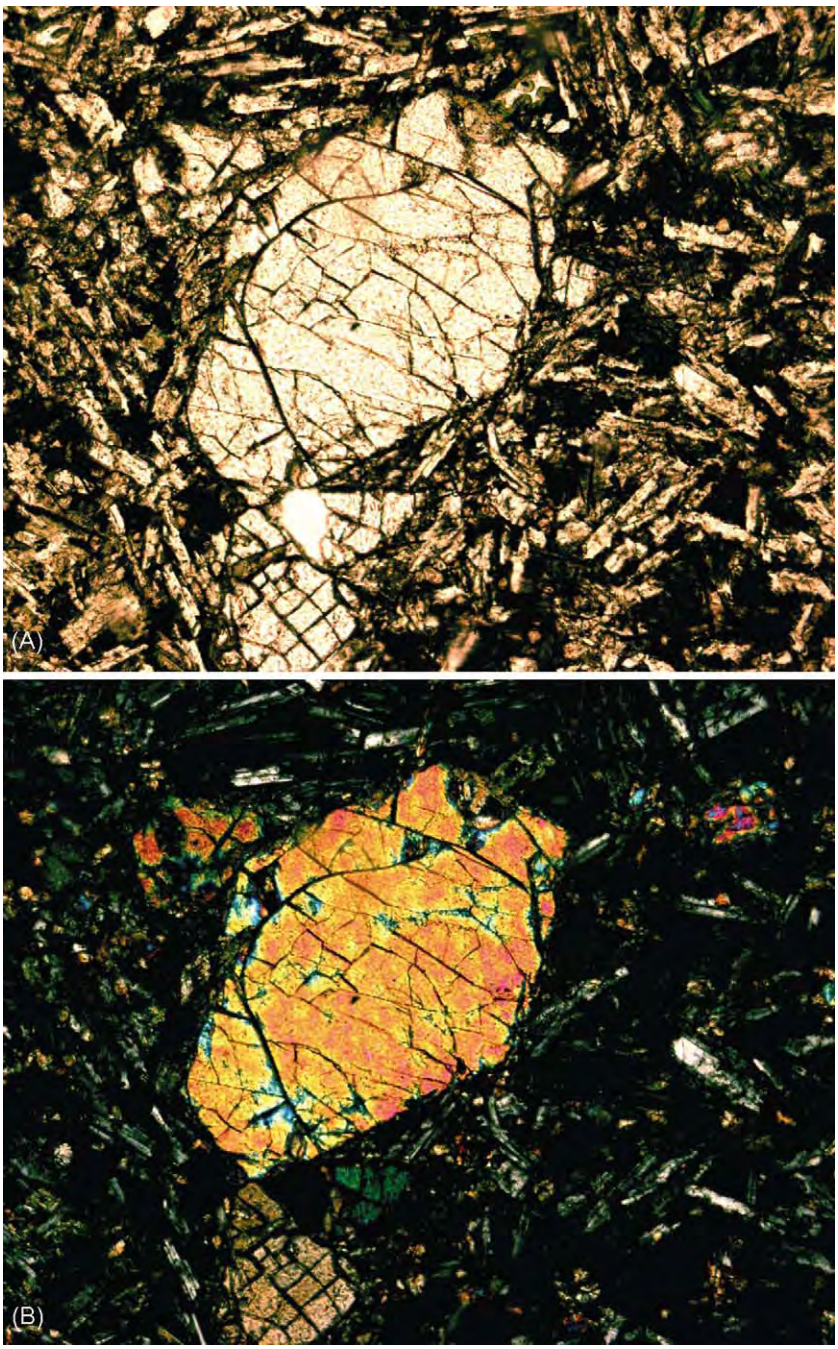

Figure 2 Basalt (from Melbourne, Victoria) seen in thin section through a polarizing microscope showing a euhedral phenocryst of olivine in plane polarized light (A), and with crossed polars (B).

obsidian, rhyolite, trachyte, and phonolite. Fayalitic and tephroitic olivines occur in rocks of metamorphic origin, such as thermally and regionally metamorphosed Fe-rich and Mn-rich sediments, respectively. Monticellite occurs in metamorphosed siliceous and magnesian limestones and in skarn zones developed by metasomatic alteration of limestones at intrusive igneous contacts. Monticellite also occurs in kimberlite and alnöite.

Meteoritic Olivine

Olivine is a major component of stony meteorites and some stony-irons (pallasites). In the former, it

occurs mainly in rounded chondrites. It is also found in some meteorites, including the almost monomineralic Chassigny stone and some basaltic shergottites. These are believed to come from Mars. Likewise, it is found in lunar-sourced meteorites and lunar surface breccias.

Other Silicates

R A Howie, Royal Holloway, University of London, London, UK

Introduction

Silicates not grouped in the major series separately dealt with, but which are of geological importance, include the garnet group, the aluminosilicates (the Al_2SiO_5 polymorphs), staurolite, the epidote group, cordierite, tourmaline, the chlorite group, and the serpentines.

The Garnet Group

The minerals (*see* **Minerals:** Definition and Classification, **Gemstones**) of the garnet group are particularly characteristic of metamorphic rocks but are also found in some igneous rocks, and as detrital grains in sediments. The group is subdivided into six principal species, which represent the end-members of an isomorphous series:

Pyrope	$Mg_3Al_2Si_3O_{12}$
Almandine	$Fe_3^{2+}Al_2Si_3O_{12}$
Spessartine	$Mn_3Al_2Si_3O_{12}$
Grossular	$Ca_3Al_2Si_3O_{12}$
Andradite	$Ca_3(Fe^{3+},Ti)_2Si_3O_{12}$
Uvarovite	$Ca_3Cr_2Si_3O_{12}$

A garnet corresponding in composition with any one end-member is rare, however, and the name is assigned according to the dominant 'molecular' type present. The garnets may be considered as two series: pyralspite (*py*rope, *al*mandine, *sp*essartine) and ugrandite (*u*varovite, *gr*ossular, *and*radite). Fairly complete and continuous variation in composition occurs within these two series, but there appears to be no continuous variation between them.

Garnets are cubic and are normally isotropic, but some calcic varieties show complex and sector twinning, which may be visible in birefringent varieties. Their colour ranges from red, orange, brown, and black for the pyralspites, to green, yellow, brown, and black for the ugrandites; they are colourless to pale pink, yellow, or brown in thin section. They are notable in having a strong power of crystallization, typically forming rhombic dodedcahedra or icositetrahedra.

The pyrope–almandine series occur in metamorphic rocks of a variety of types, of which the garnet-mica schists of regional metamorphism (*see* **Regional Metamorphism**) are typical; they are also found in certain ultrabasic rocks such as the mica peridotites and kimberlites. The pyralspites are also

known in peraluminous volcanic rocks, granites, and pegmatites. The distribution of Fe and Mg between coexisting equilibrium assemblages of garnet and biotite or garnet and clinopyroxene can be used in geothermometry. The equilibrium constant $K_{D\ Mg/Fe}^{Gt/Bi}$ for different metamorphic grades is shown in Figure 1. For the garnet–clinopyroxene pair, the pressure–temperature dependence of the Fe–Mg partition coefficient has been determined experimentally; the use of thermodynamic data for the garnet group is illustrated in Figure 2. Purplish chrome-pyrope is typical of diamondiferous kimberlites and peridotitic xenoliths.

Garnets with appreciable spessartine are usually found in granitic pegmatites and skarns.

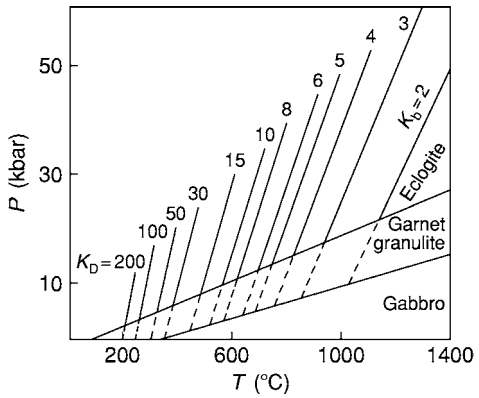

Figure 1 $K_{D\ Fe/Mg}^{Gt/Cpx}$ as a function of pressure and temperature (after Råheim and Green (1974)).

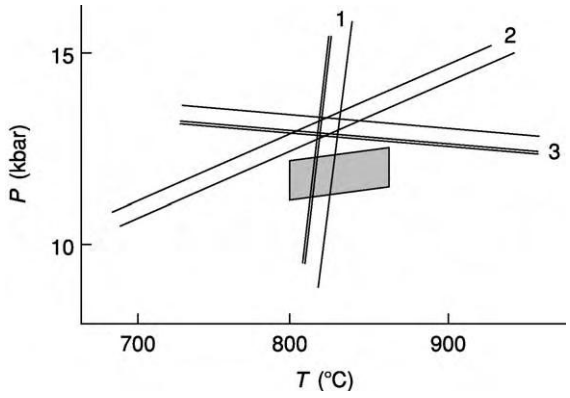

Figure 2 Thermodynamic data for natural equilibrium assem blages from pyroxene granulites of South Harris, Scotland, derived from: (1) Fe Mg distribution between garnet and clinopyroxene; (2) the activity coefficient for the $Ca_3Al_2Si_3O_{12}$ component in garnet using the equilibrium 3 $CaAl_2Si_2O_8$ (plagioclase) $Ca_3Al_2Si_3O_{12}$ + 2 Al_2SiO_5 + SiO_2; and (3) the activity coefficient for the equilibrium $CaAl_2Si_2O_8$ $CaAl_2SiO_6$ (clinopyroxene) + SiO_2. The shaded area is the apparent region of 'bracketing' of metamorphic pressure and temperature derived from other equilibria (after Wood 1975 and Wood (1997)).

Grossular is characteristically found in regionally or thermally metamorphosed impure calcareous rocks; andradite also occurs in such rocks but is more typically found in metasomatic skarn deposits.

The black garnet melanite is a Ti-bearing andradite occurring in alkaline igneous rocks and some skarns. Uvarovite is rare and any appreciable Cr content in metasomatic garnets can be detected from their green colour.

The aluminosilicates (Al_2SiO_5)

This family comprises three polymorphs, all typically found in metamorphosed pelitic rocks formed in different metamorphic conditions. Their occurrence is, thus, of particular interest in metamorphic petrology.

Sillimanite is orthorhombic, typically colourless or white, and found as optically length-slow prismatic crystals or needles.

Andalusite is also orthorhombic, typically pink in hand specimen, and found as stout, length-fast prismatic crystals. In low-grades of metamorphism the anhedral grains frequently encloses a host of inclusions of foreign matter, but rapidly acquire a prismatic outline pushing aside the impurities which then form a characteristic chiastolite pattern.

Kyanite is triclinic, typically giving inclined exctinction and having a blue colour in hand specimen.

The experimentally determined phase diagram for the Al_2SiO_5 composition is given in Figure 3, indicating the position of the triple point between sillimanite, andalusite, and kyanite.

The application of these results to metamorphic petrology, thus, clearly shows that sillimanite is the high-temperature phase, to be found in the highest

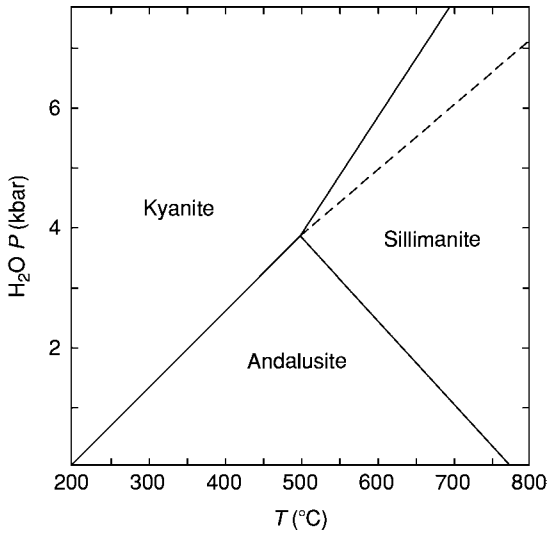

Figure 3 Phase diagram for kyanite andalusite and kyanite sillimanite equilibria.

grades of thermal metamorphism of pelitic rocks or in the highest grade of regional metamorphism of similar rocks. Andalusite is normally confined to thermally metamorphosed pelitic rocks, but may be found in some granites, probably as a result of contamination. Kyanite is typically a mineral of high-grade metamorphism of pelitic rocks, but has also been found in thermal aureoles in situations where appreciable shear-stress arose during emplacement of the igneous intrusion.

Staurolite

This yellow to brown ferromagnesian aluminous silicate characteristically occurs in medium grade metamorphosed pelitic schists and gives its name to a regional metamorphic zone. The staurolite–garnet–kyanite assemblage is typical of Barrovian-type metamorphic terrain, whereas the staurolite–cordierite–andalusite/sillimanite assemblage results from the lower pressure Buchan-type metamorphism. During the prograde metamorphism of pelitic rocks, staurolite develops earlier than kyanite, and then together with kyanite, before being replaced by kyanite and garnet:

$$\text{staurolite} + \text{muscovite} + \text{quartz} = \text{almandine} + Al_2SiO_5 + \text{biotite} + H_2O$$

Its variable Fe/Mg ratio allow it to be used in conjunction with garnet and other ferromagnesian silicates as a geoithermometer. Staurolite is affected by retrograde metamorphism, resulting in it being mantled and partially replaced by chlorite. Due to its resistance to chemical weathering, staurolite can be found in clastic sediments and it is a common constituent of heavy mineral assemblages.

The Epidote Group

All members of the epidote group contain both single [SiO_4] tetrahedral and double [Si_2O_7] tetrahedral groups, with large cavities within this framework typically occupied by large cations, typically Ca. The general formula can be given as $X_2Y_3Z_3(O,OH,F)_{13}$, in which:

X = Ca, Ce, La, Y, Th, Fe^{2+}, Mn^{2+}, Mn^{3+}

Y = Al, Fe^{3+}, Mn^{3+}, Mn^{2+}, Fe^{2+}, Ti,

Z = Si, Be

The major compositions within the group are:

Zoisite (clinozoisite)	$Ca_2(Al,Fe^{3+})Al_2O \cdot OH \cdot Si_2O_7 \cdot SiO_4$
Epidote	$Ca_2(Fe^{3+},Al)Al_2O \cdot OH \cdot Si_2O_7 \cdot SiO_4$
Piemontite	$Ca_2(Mn^{3+},Fe^{3+},Al)_3O \cdot OH \cdot Si_2O_7 \cdot SiO_4$
Allanite	$(Ca,Mn,Ce,La,Y)_2(Fe^{2+},Fe^{3+},Al)_3O \cdot OH \cdot Si_2O_7 \cdot SiO_4$

Epidote minerals occur in a wide variety of parageneses. They are typical products of greenschist and epidote–amphibolite facies of regional metamorphism, but also form under conditions of thermal metamorphism and metasomatism, during late-stage crystallisation of acid igneous rocks, and in peraluminous granites and volcanic rocks. Epidote also occurs in the hydrothermal alteration of plagioclase. Epidote itself often has a distinctive pistachio green colour and relatively high birefringence. Piemontite is reddish brown or black, but in thin section displays striking pleochroism in yellow–amethyst–crimson; it occurs as a product of low-grade regional metamorphism and as a hydrothermal product associated with manganese deposits. The rare-earth-bearing allanite is typically dark brown and occurs mainly as an accessory mineral in many granitic rocks.

Cordierite

Cordierite is a ring silicate, typically with low refractive indices and birefringence, and tends to be confused with quartz or feldspars (*see* **Minerals:** Feldspathoids; Feldspars). Twinning is known on {110} and {310}, forming simple, lamellar, or cyclic twins. It has the composition $(Mg,Fe)_2[Si_5Al_4O_{18}] \cdot nH_2O$, and is mainly found in a metamorphic environment. The Fe/Mg ratios in coexisting cordierite and garnet in divariant equilibrium are functions of pressure and temperature and may be of use in geothermometry or geobarometry. It also occurs in contaminated igneous rocks, for example, cordierite norites.

Tourmaline

Tourmaline is a boron-bearing ring silicate with a complex chemistry. Structural determinations have shown that its general formula can be taken as $XY_3Z_6B_3Si_6(O,OH)_{30}(OH,F)$. The principal recognised varieties can be distinguished in terms of their *X*, *Y* and *Z* cations;

	X	*Y*	*Z*
Elbaite	Na	Al,Li	Al
Olenite	Na	Al	Al
Dravite	Na	Mg	Al
Schorl	Na	Fe^{2+}	Al

Tsilaisite	Na	Al,Mn	Al
Buergerite	Na	Fe^{3+}	Al
Liddicoatite	Ca	Li,Mg	Al
Uvite	Ca	Mg	Al,Mg
Feruvite	Ca	Fe^{2+}	Al,Fe^{3+},Mg
Ferridravite	Na	Mg	Fe^{3+}
Chromdravite	Na	Mg	Cr
Foitite	□	Fe^{2+}	Al,Fe^{3+}

In the *X* position, Na may be partially replaced by K or Ca if valency conditions are satisfied; thus, in uvite the substitution NaAl = CaMg. For the commonest tourmaline varieties, *Y* can be predominantly Fe^{2+} as in schorl, Mg as in dravite, or (Al + Li) as in the elbaite series.

Optically, pleochroism is variable in intensity but is particularly strong for the iron-bearing tourmalines. The absorption is always $\omega > \varepsilon$, with the result that maximum absorption occurs when the *z*-axis is lying perpendicular to the vibration direction of the polariser. Thus schorl is black, but in thin section shows strong pleochroism from blue to yellow. Dravite is brown, while in the elbaites show a range of colours in hand specimen from red (rubellite), green (verdelite), blue (indicolite), to bi-coloured or colourless (achroite). Tourmaline crystals typically show striations along the length of prismatic faces.

Tourmaline is typically a mineral of granite pegmatites, pneumatolytic veins, and some granites; it is also commonly found in metamorphic rocks, as a product of boron metasomatism, or as a result of recrystallisation of dertrital grains from the original sediment. In granitic rocks, the tourmalines belong to the schorl–elbaite series and are generally iron-rich; typical tourmaline-bearing granites have black prismatic crystals visible in hand specimen and showing yellow or bluish yellow pleochroism in thin section. Both black and coloured tourmalines occur in the original pegmatitic phase, while rubellite and the zoned tourmalines are mainly restricted to the sodium replacement unit in the so-called pneumatogenic stage.

The Chlorite Group

The term chlorite is a portmanteau name for a mineral with a layered structure resembling the micas, but generally with a green colour. The chlorites principally occur in low-grade regionally metamorphosed rocks, as hydrothermal alteration products of ferromagnesian minerals in igneous rocks, and together with clay minerals in argillaceous sediments.Their general formula can be given as (Mg, $Fe^{2+}Fe^{3+}$,Mn,Al)$_{12}$[(Si,Al)$_8$O$_{20}$](OH)$_{16}$. The chlorites have a perfect basal cleavage and occur commonly as fine-grained scaly or massive aggregates.

The occurrence of very substantial, varied, and often continuous cation substitution in the chlorites has led to a proliferation of varietal names based mainly on chemical composition; commonly these cannot be specifically characterized optically.

The crystal structure (**Figure 4**) consists of regularly alternating negatively charged tetrahedral–octahedral–tetrahedral, 2:1, layers: talc-like layers with composition $Y_6Z_8O_{20}(OH)_4$ and positively charged interlayer brucite-like layers, $Y_6(OH)_{12}$, where *Y* and *Z* represent octahedral and tetrahedral sites, respectively. The chlorites are monoclinic

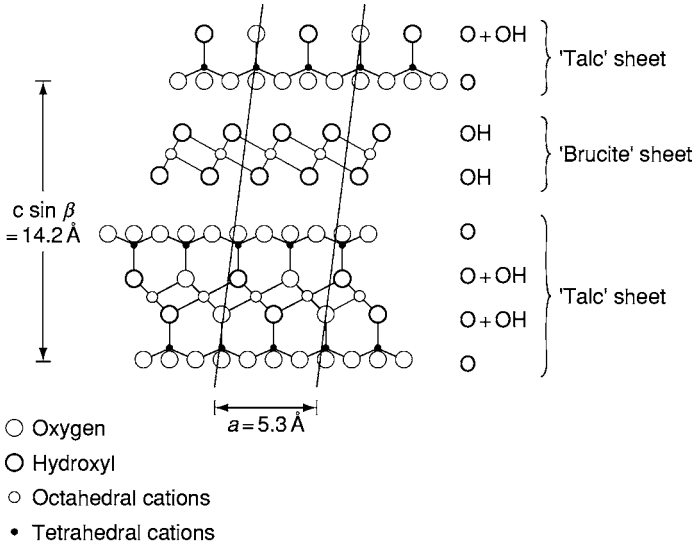

Figure 4 Idealized crystal structure of chlorite; projection on (010) (after Brown and Bailey (1962)).

(pseudohexagonal), like the micas, because of the offset of the layers.

In most common chlorites there are 12 octahedral cations per $O_{20}(OH)_{16}$ and approximately equivalent amounts of Al in tetrahedral and octahedral sites; such minerals are referred to as tri-octahedral chlorites. In a small number of chlorites, however, the number of octahedral cations is <10; these varieties are described as dioctahedal.

The principal factors influencing the optical properties of the chlorites are the iron/magnesium ratio (Figure 5). Most chlorites are optically positive, but the more iron-rich varieties are optically negative. Near the crossover point, where the birefringence passes through zero, abnormal birefringence colours (i.e., those not in the normal spectral range) may be seen.

In metamorphic rocks, chlorite is an early product of lithification and diagenesis, forming during the development of slaty cleavage in pelitic sediments. They are developed from mixed-layer clay minerals in such sediments, resulting from the expulsion of interlayer alkali ions, the fixation of (Fe,Mg) and increased tetrahedral substitution that occurs concurrently with increasing grain size. Chlorite is also a common constituent of rocks of the zeolite facies; in the lower part of the facies it is often associated with laumontite, stilbite, or heulandite, whereas in the upper part it occurs in assemblages with prehnite and pumpellyite. In the greenschist facies, chlorite–actinolite–epidote–albite assemblages are common and with increasing grade chlorite is involved in the production of amphiboles. In rocks of higher metamorphic grade, chlorite is a typical breakdown product associated with the retrogression of such ferromagnesian phases as garnet, staurolite, and biotite.

In igneous rocks, chlorite is a common product of the hydrothermal alteration of pyroxenes, amphibole, or biotite. Partial or complete chloritisation of biotite is particularly common in granites, and in most cases the transformation is pseudomorphous. The association of chlorite with albite and quartz is an essential characteristic of adinoles. Low-temperature hydrothermal Alpine-type veins in lowgrade metamorphosed sediments carry chlorite in addition to adularia and quartz.

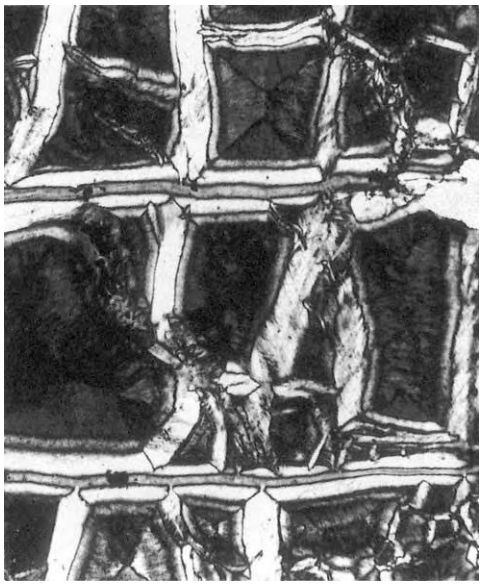

Figure 8 'Window' and 'hour glass' textures of chrysotile and lizardite in serpentinite. Crossed polars ×120.

Serpentine

There are three principal forms of serpentine – lizardite, antigorite, and chrysotile – all with approximate composition $Mg_3Si_2O_5(OH)_4$. The most abundant is lizardite and the least common is chrysotile, though the latter is perhaps best known as it often occurs in veins of silky fibres, and was an important source of commercial asbestos. All three species have a layered structure: one part consists of a pseudo-hexagonal network of linked SiO_4 terahedra all pointing one way; joined to this sheet is a brucite layer in which, on one side only, two out of every three hydroxyls are replaced by apical oxygens of the SiO_4 tetrahedra. Although much of the matrix surrounding chrysotile veins is extremely fine-grained lizardite, electron microscopy shows that it has platy morphology. The fibrous nature of chrysotile is explained by it consisting of layers curved cylindrically or spirally, usually about the *x*-axis. The fundamental fibrils typically have average outer and inner diameters of about 250 and 75 Å, respectively (Figure 6). Antigorite is structurally distinct in having a large *a* cell parameter of ~33–51 Å, which can be related to the curvature of serpentine layers about *y* and their inversion to form a corrugated sheet structure with periodicity *a* (Figure 7).

The chemistry of most serpentines is relatively simple, with minor substitution of Al for Si and of Fe for Mg. The fine-grained nature of most serpentines makes a complete optical description impossible, but the refractive indices (1.54–1.55) and birefringes are low. They show a variety of textures, many of which ('mesh' and 'hour-glass') are pseudomorphous after olivine (**Figure 8**) or 'bastite' after pyroxene or amphibole.

The serpentine minerals typically form by the retrograde hydrothermal alteration of ultrabasic igneous rocks such as dunite and peridotite. The main mineral altered is olivine which frequently contains too much iron to be accommodated in the serpentine structure, resulting in its exsolution as iron oxide; this may occur as magnetite which alters to hematite to give the reddish mottled appearance reputedly resembling the skin of a serpent. Serpentines may also form, associated with thermally metamorphosed siliceous dolomitic limestones.

Pyroxenes

R A Howie, Royal Holloway, University of London, London, UK

Pyroxenes are the most important group of rock-forming ferromagnesian silicates, and occur as stable phases in almost every type of igneous rock. They are also found in many rocks of widely different compositions formed under conditions of both regional and contact/thermal metamorphism.

The pyroxenes include both orthorhombic and monoclinic species: the orthopyroxenes and the clinopyroxenes. The orthopyroxenes consist essentially of a simple chemical series of (Mg, Fe)SiO_3 minerals (*see* **Minerals:** Definition and Classification) in contrast to the larger group of clinopyroxenes which have a very wide range of chemical compositions. There is a virtually complete series with a complete range of Fe/Mg ratios.

The clinopyroxenes can be considered, as a first approximation, as members of the four-component system $CaMgSi_2O_6$–$CaFeSi_2O_6$–$Mg_2Si_2O_6$–$Fe_2Si_2O_6$. The nomenclature used to describe these pyroxenes is illustrated in Figure 1 (*see* **Rocks and Their Classification**). The $Ca_2Si_2O_6$ end-member (wollastonite) is not a pyroxene (see below).

The crystal structure of the pyroxenes is based on infinite single chains of linked silicon—oxygen tetrahedra, the [Si_2O_6] groups, these chains being linked laterally by octahedral layers of (Ca, Mg, Fe, Na, etc.) cations (Figures 2 and 3). The formulae of the commoner pyroxenes are as follows:

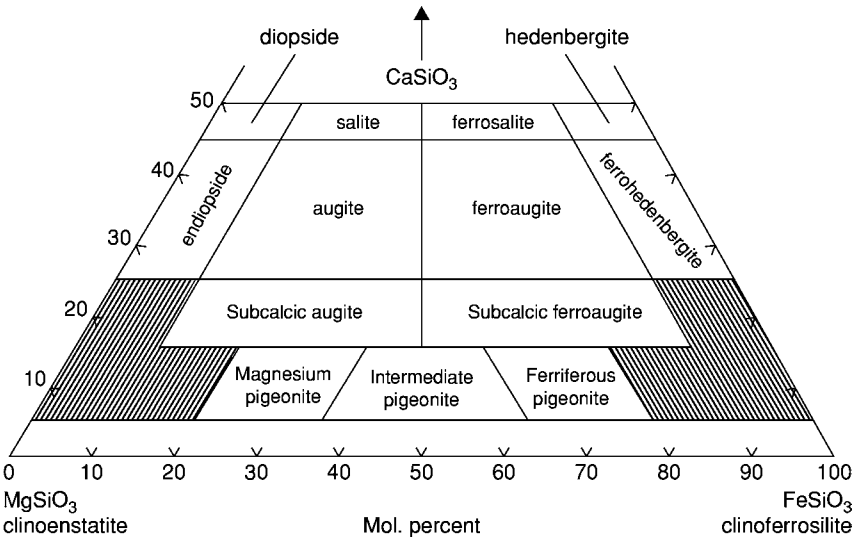

Figure 1 Nomenclature of clinopyroxenes in the system $CaMgSi_2O_6$ $CaFeSi_2O_6$ $Mg_2Si_2O_6$ $Fe_2Si_2O_6$.

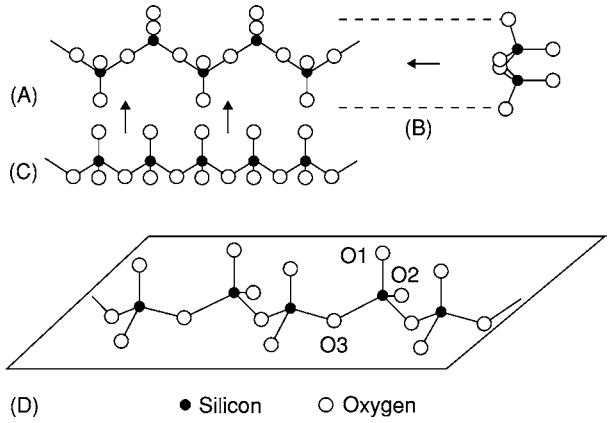

Figure 2 Idealized illustration of a single pyroxene chain as seen in projections on (A) (100), (B) along *z*, and (C) along *y*.

Orthopyr-	$Mg_2[Si_2O_6]$	enstatite
oxenes	$Fe_2^{2+}[Si_2O_6]$	ferrosilite
Clinopyr-	$CaMgSi_2O_6$	diopside
oxenes	$CaFe^{2+}[Si_2O_6]$	hedenbergite
	$(Mg, Fe^{2+}Ca)$	pigeonite
	$(Mg, Fe^{2+})[Si_2O_6]$	
	$(Ca, Mg, Fe^{2+}, Fe^{3+}, Ti, Al)_2$	augite
	$[(Si, Al)O_6]$	ferroaugite
	$(Ca, Na)(Mg, Fe^{2+}, Fe^{3+}, Al)$	
	$[Si_2O_6]$	omphacite
	$NaAl[Si_2O_6]$	jadeite
	$NaFe^{3+}[Si_2O_6]$	aegirine
	$(Na, Ca)(Fe^{3+}, Fe^{2+}, Mg)$	aegirine
	$[Si_2O_6]$	augite
	$LiAl[Si_2O_6]$	spodumene

Optically, the orthopyroxenes are colourless to greenish under the microscope and bronze to black in hand specimen. They have a good {210} cleavage and straight extinction. Their other properties vary with the Fe/Mg ratio.

The clinopyroxenes also are colourless to greenish under the microscope, have a good {210} cleavage, but with variable extinction angles from 0 to 45°. Within the $CaMgSi_2O_6$–$CaFeSi_2O_6$–$Fe_2Si_2O_6$–$Mg_2Si_2O_6$ quadrilateral, which covers 90% of the common rock-forming clinopyroxenes, their optical properties vary systematically, allowing their composition to be estimated.

The occurrence of members of the pyroxene group in general reflects the compositions of their parent rocks. Mg-rich enstatites are important constituents associated with olivine, diopside, and spinel in ultrabasic and ultramafic rocks. Other orthopyroxenes of intermediate composition are essential constituents of the granulite facies of metamorphic rocks. Diopside is formed by the metamorphism of siliceous dolomites, but is not uncommon as an early of basic igneous rocks. Pigeonite is a constituent of many andesites and dacites and can be distinguished by its small optic axial angle. In layered igneous intrusions, it may invert to lamellae of augite ± orthopyroxene. The most common clinopyroxenes are augites; these are essential constituents of basic igneous rocks, and also occur in ultramafic rocks, lherzolites and websterites, and in ultrabasic nodules and xenocrysts in basic rocks. They also occur in dolerites and in basic lavas.

The sodium-bearing clinopyroxene Jadeite is a diagnostic mineral of rocks generally considered to have formed in a high-pressure environment; it is particularly characteristic of eclogites and related

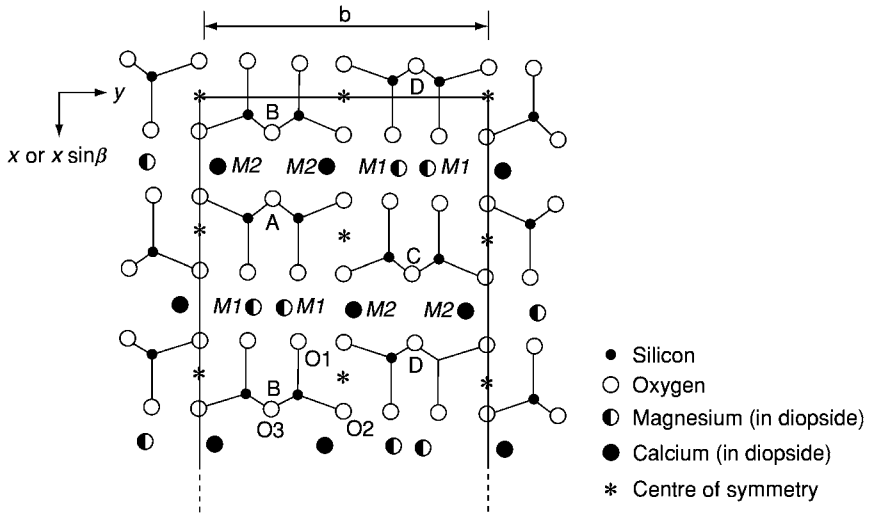

Figure 3 Projection along *z* of an idealized pyroxene structure, showing the pyroxene chains and the two distinct cation sites *M*1 and *M*2. The latter are in oxygen polyhedra which also form chains or bands parallel to *z*.

rocks. When near its end-member composition of $NaAlSi_2O_6$ Jadeite, is colourless or pale green (one variety of the gem material jade); it is typically found in metagreywackes and related rocks of regional metamorphism, particularly in the blueschist facies. Aegirine and aegirine-augite illustrate the replacement of ferric iron in the substitution $NaFe^{3+} = Ca(Mg, Fe^{2+})$; they are mainly found in alkaline or peralkaline igneous rocks. The lithium pyroxene spodumene is generally white and is restricted to Li-rich granitic pegmatites.

Wollastonite ($CaSiO_3$) and the three manganese-rich silicates rhodonite, bustamite, and pyroxmangite are all triclinic. Sometimes referred to as 'pyroxenoids', they differ from the pyroxenes in having, respectively, three, five, five, and seven silica tetrahedra in their structural chains. Wollastonite is a common mineral of metamorphosed siliceous limestones, whereas the three manganese-rich species typically occur in Mn-orebodies, usually associated with metasomatic activity.

Quartz

R A Howie, Royal Holloway, University of London, London, UK

Quartz is the second most abundant mineral in the Earth's crust being hard (7 on Mohs scale) and resistant to many forms of chemical weathering, with the result that it becomes concentrated in sedimentary rocks while the coexisting feldspars are rapidly weathered away. It has a compact framework structure and has trigonal symmetry. It is an essential mineral in many acid plutonic igneous rocks such as the granites (*see* **Igneous Rocks:** Granite) and granodiorites, and also in hypabyssal and volcanic rocks of equivalent composition. Metamorphism of such igneous or sedimentary rocks gives rise to quartzites and quartz-rich veins.

Although the chemical composition is comparatively simple, most quartz consisting of 99.9% SiO_2, it has α (low-temperature) and β (high-temperature) forms, with a transition at around 573°C, and several polymorphic forms, mostly at higher temperatures and pressures. This leads to the phase diagram for SiO_2 being extremely complex. There are the high-temperature polymorphs tridymite and cristobalite, both typical of volcanic rocks, and the more recently discovered high-pressure phases coesite and stishovite (Figure 1). Coesite occurs at a static pressure of

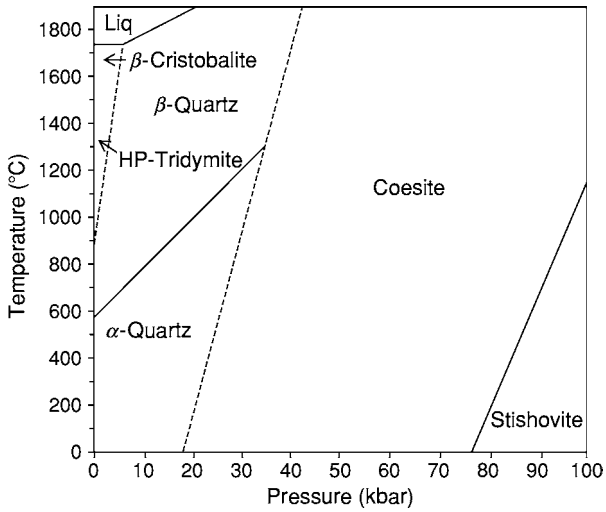

Figure 1 Phase diagram for the silica system (after Klein and Hurlbut, (1973) *Manual of Mineralogy*, 21st edn, p. 527. © *John Wiley and Sons* (Reprinted with permission).

$\geq$29 kbar; it is found as inclusions, generally partially replaced by quartz, in zircon, garnet, monazite, and other phases formed in low-temperature–high-pressure conditions and is used as an indicator of such ultrahigh-grade metamorphic conditions in rocks which have generally been exhumed relatively rapidly in orogenic belts (as in the Himalaya, the Alps and in SE China). Stishovite requires even higher pressures (of around 130 kbar) for its formation and is typical found in meteorites or meteorite impact craters, also in tektites.

Microscopic fluid inclusions often occur in quartz, and may contain a gas phase as well as a liquid and one or more microscopic crystals of such minerals as halite, sylvite, calcite, etc., believed to have been precipitated from the same source as the quartz. The development of sophisticated microanalytical techniques has allowed the composition of these liquids and solids to be determined and to the determination of the temperature at which the original precipitation and crystallization occurred. This has important applications in unravelling the petrogenetic history of both igneous and metamorphic rocks as well as in the geochemistry and conditions of deposition of ore deposits and the provenance of sedimentary rocks (*see* **Sedimentary Rocks:** Mineralogy and Classification).

Chalcedony is a group name for the compact varieties of silica composed of minute crystals of quartz with submicroscopic pores. The colour and texture vary considerably according to the impurities present, but in general such materials may be subdivided into chalcedony in which the colour is fairly uniform, and agate in which the colour may be arranged in bands or concentric zones. The terms 'chert (*see* **Sedimentary Rocks:** Chert)' and 'flint' are used for opaque dull-coloured or black chalcedony, and in common usage chert is taken as the name for this material when it occurs in stratified or massive form in rocks, while the term flint is generally restricted to dark chalcedony occurring in nodular form in a rock matrix, particularly in the chalk. Jasper is a red opaque massive form of chalcedony.

Natural hydrous silica may be divided into three well-defined structural groups (*see* **Minerals:** Other Silicates): opal-C (well-ordered γ-cristobalite), opal-CT (disordered α-cristobalite, α-tridymite), and opal-A (highly disordered, nearly amorphous). Opal may be colourless, milky white, yellow, red, green, blue, or black. In precious opal a play of delicate colours is seen, due not to chemical impurities but to optical diffraction from a randomly faulted close-packed structure of minute transparent silica spheres (around 0.25 μm). Colourless opal is a major constituent in hot-spring deposits and deep-sea precipitates.

Quartz is an extremely important in many industrial processes. At the simplest level it is raw material for the production of glasses, ceramics, and foundry moulds. Most quartz sands are a golden yellow due to the quartz particles being encased by a thin coating of iron oxides and/or hydroxides, and the iron would cause any glass to be dark green. In certain geological situations, however, the beach sands may be rolled to and fro by the tides for several million years, leading to the erosion of the iron coating and forming silver sands, which are much sought after for glass manufacture. For the more technical applications requiring an even higher degree of purity, colourless vein quartz is used, or nowadays reliance is placed on the manufacture of synthetic single crystals of quartz in an autoclave. One of the main technical aspects of quartz lies in its piezoelectric properties, whereby the crystal develops an electric polarization when mechanically stressed in an appropriate direction. In the construction of quartz oscillators, thin plates of quartz are cut in a particular direction specified to generate a desired resonant vibrational frequency.

Although most quartz is colourless or white, well-known coloured varieties include amethyst (violet), citrine (yellow to brown), and smoky quartz. Each of these contains either a substitutional or interstitial component other than SiO_2. For amethyst and citrine, iron is an important constituent (Fe 25–280 ppm). In smoky quartz the brownish or black colour is due to natural radiation acting upon Al^{3+}-bearing quartz.

Quartz is an essential constituent in many igneous, sedimentary, and metamorphic rocks, and also occurs as secondary material, often forming a cementing

medium in sediments. Quartz is also a common constituent of hydrothermal veins.

In granites, microgranites, tonalities, etc., quartz typically forms anhedral grains due to it being one of the final minerals to crystallize. Quartz phenocrysts in fine-grained rapidly cooled rhyolites, pitchstones, and quartz porphyries may show euhedral outlines, although in some of these rocks the quartz phenocrysts may suffer magmatic corrosion. In intermediate igneous rocks, the amounts of quartz are less than in those of granitic composition, and in basic rocks it usually amounts to less than 5% (though it is more abundant in some quartz dolerites).

Because of its chemical and physical resistance to erosion, quartz is an abundant mineral and becomes concentrated during sedimentary processes to give rise to sands and sandstones of various types. Secondary quartz is often deposited around pre-existing grains (of quartz or other minerals) and is a common cementing material in sediments.

Quartz is a common mineral in many metamorphic rocks, occurring in the metamorphosed equivalent of quartz-bearing sediments and igneous rocks. Although in low-grades of metamorphism quartz may survive unchanged, in the higher grades it undergoes recrystallization with concomitant increase in grain size. In addition, much is developed by the release of SiO_2 in reactions taking place during metamorphism. Intergrowths of quartz and other minerals are fairly common, particularly those of quartz and K-feldspar as in graphic or micrographic granite, and quartz and plagioclase as in myrmekite in association with K-feldspar.

The typical occurrence of tridymite is in acid volcanic rocks such as rhyolite, obsidian, trachyte, andesite, and dacite. In such rocks it is often found in cavities and may be associated with such minerals as sanidine, and less frequently augite or fayalite. Cristobalite is also a mineral of volcanic rocks, and may be found in (metastable) association with tridymite. It is often a late product of crystallization, sometimes replacing tridymite. The ability of cristobalite to occur as a metastable form, outside its equilibrium field, means that no definite conclusions can normally be drawn as to conditions at the time of its crystallization.

The SiO_2 polymorph coesite was first identified with quartz and fused silica glass in sheared porous sandstones at Meteor Crater, Arizona, and in granite and pumiceous tuff near the rim of the Ries crater, Bavaria, developed by the shock wave generated by the meteoritic impact. It is also being increasingly recognised as microscopic inclusions in such minerals as zircon, pyrope garnet, and other high-grade metamorphic minerals where it has often been partially inverted to quartz, resulting in radial cracking of the garnet around the inclusions. This coesite is considered to have crystallized in nearly static pressure conditions at $\geq$28 kbar, followed by fairly rapid exhumation.

Sulphates

G Cressey, The Natural History Museum, London, UK

Introduction

Gypsum ($CaSO_4 \cdot 2H_2O$), the most common of the sulphate minerals, is also known as alabaster (a fine-grained massive form), satin spar (a fibrous variety of gypsum), or selenite (colourless transparent gypsum crystals). Gypsum is often found in considerable thicknesses within evaporite sequences and in association with limestones and shales. Large deposits of alabaster gypsum are commonly observed at the sole of many large-scale tectonic dislocations and thrust faults. Gypsum is of great importance as a raw material in the production of cement and plaster for the building industry.

Crystal Structure of Gypsum

In the crystal structure of gypsum, calcium ions are coordinated by six oxygens from sulphate (SO_4) tetrahedral groups, and by two oxygens from water molecules (H_2O). Two layers of SO_4 tetrahedra are bound together by calcium ions forming a double-layer sheet. Water molecules are located at each side of these double-layer sheets. The water molecules are oriented such that one of the two hydrogens of each water molecule points almost perpendicular to the sheets; this facilitates weak hydrogen bonding to the next layer in the structure. These hydrogen bonds point approximately along the *y*-axis of the crystal, forming a layer of weak hydrogen bonding perpendicular to the *y*-axis, and explain the easy (010) cleavage of gypsum. The proton (H^+) positions in gypsum have been determined in deuterated gypsum by neutron diffraction, as weakly scattering proton positions cannot be determined accurately by X-ray diffraction methods (Figure 1).

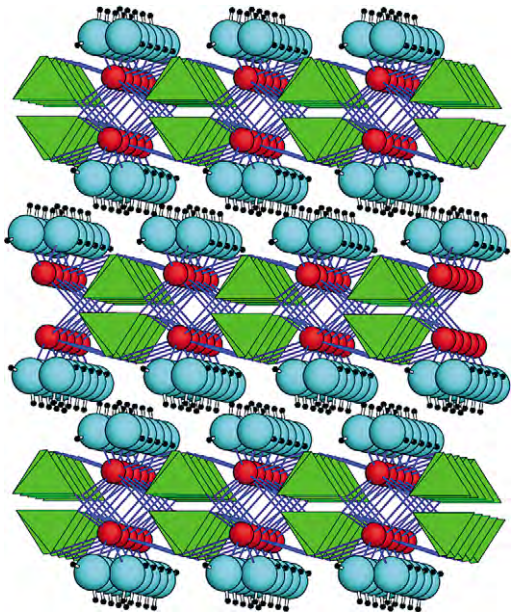

Figure 1 The structure of gypsum (view looking almost down the *z* axis): SO_4 tetrahedral units (green) and calcium ions (red) form double layer sheets perpendicular to the *y* axis. At each side of these sheets, water molecules (with oxygen in blue and hydrogen shown as small black dots) form weak hydrogen bonds to the next layer in the structure.

Physical Properties of Gypsum

The weak hydrogen bonding in the structure of gypsum, occurring in layers perpendicular to the *y*-axis, accounts for the perfect (010) cleavage and is also responsible for the anisotropic thermal expansion behaviour of gypsum. The *b* dimension of the unit cell increases the most with temperature, and this is principally because the hydrogen bonds oriented across the sheets easily lengthen with increasing temperature. The static compressibility of gypsum is also highly anisotropic and, as is the case with the thermal expansion, is related to the hydrogen-bonding orientation across the sheet structure; these hydrogen bonds more easily shorten with pressure and therefore the *b* lattice parameter has the greatest compressibility.

Upon heating to about 65°C, gypsum dehydrates to form the hemihydrate phase, bassanite ($CaSO_4 \cdot 0.5H_2O$), with its *z*-axis parallel to that of the gypsum; this is known as plaster of Paris. Further heating dehydrates the sulphate completely, forming γ-$CaSO_4$ (a polymorph of anhydrite, $CaSO_4$) at about 95°C. γ-$CaSO_4$ is also known as 'soluble anhydrite', as unlike anhydrite it can be re-hydrated. Anhydrite has a different structure and cannot be easily hydrated. Commercial plaster of Paris consists mainly of calcium sulphate hemihydrate (bassanite) and is made by heating gypsum to about 200°C. Heating gypsum at higher temperatures produces anhydrite and this change is irreversible. At the stage where bassanite and/or γ-$CaSO_4$ are produced, re-hydration to gypsum ($CaSO_4 \cdot 2H_2O$) easily occurs; this is the process of the setting of plaster of Paris to form an interlocking mass of gypsum crystals.

Occurrence of Gypsum

Gypsum occurs mainly as sedimentary deposits associated with limestones and shales and in evaporite deposits. Gypsum can form by the direct evaporation of brine, by hydration of anhydrite and by oxidation of sulphides. Gypsum is also one of the products of the reaction of acid sulphate solutions with carbonate rocks. Seawater contains about 3.5% dissolved material, of which 80% is sodium chloride and about 4% is dissolved calcium sulphate. The experimental evaporation of seawater results in the crystal deposition sequence: calcium carbonate – calcium sulphate – sodium chloride – sulphates/chlorides of magnesium – sodium bromide/potassium chloride.

Gypsum also occurs in soils either as disseminated crystals or in horizons beneath calcrete layers. Percolating waters, which in dry seasons are drawn to the surface by capillary action, can evaporate and crystallize gypsum, sometimes in the form described as 'desert roses'. The calcium sulphate formed in evaporates is sometimes gypsum, sometimes anhydrite, and often both minerals occur together. Some geological evidence suggests that the original material of certain gypsum beds was anhydrite; this is supported by the fact that some gypsum beds grade into anhydrite at depth. Along with jarosite and goethite, gypsum is one of the products formed by the oxidation of iron sulphide (pyrite). Gypsum is also found in volcanic regions along with native sulphur where it forms by the reaction of sulphur-bearing fluids and gases with calcium-bearing rocks. Natural bassanite is rare, and nearly always forms as a product of alteration of gypsum. It has been found along with gypsum in volcanic craters, and in some soils and peat deposits.

Other Sulphates

The most abundant barium mineral in the Earth's crust is barite, $BaSO_4$, and this is also the least soluble sulphate mineral. It commonly occurs in hydrothermal metalliferous veins, but also occurs in cementations and nodules in sedimentary rocks. Because of its high density (4.5 g cm ^{3}) barite is widely used as a component of drilling muds in the petroleum industry, or in other dense fluid media, and also as a filler or extender in the manufacture of paper, plaster, rubber and plastics. There is a complete solid solution series between $BaSO_4$ (barite) and $SrSO_4$ (celestine), although natural compositions are usually near to end-member compositions, reflecting either the Ba-rich or Sr-rich geochemical environments. $PbSO_4$ (anglesite) is isostructural with $BaSO_4$ (barite), so a complete solid solution between these two end members would also be expected, and some natural samples occur that are intermediate in composition. At room temperature, about 6% Ca^{2+} can be accommodated in the $BaSO_4$ structure. About 8% Ba^{2+} replacement of Ca^{2+} is the limit of solid solution tolerated by the $CaSO_4$ (anhydrite) structure.

The oxidation of pyrite (FeS_2), especially when mediated by the action of bacteria, frequently results in the formation of powdery assemblages of iron sulphates. This alteration commonly occurs during the storage of pyrite-bearing materials under humid conditions. Sulphates produced in this way include melanterite ($FeSO_4 \cdot 7H_2O$), rozenite ($FeSO_4 \cdot 4H_2O$), szomolnokite ($FeSO_4 \cdot H_2O$) and rhomboclase ($Fe^{3+}(SO_4)_2\,(H_3O^+) \cdot 3H_2O$).

Several hundred compounds that contain essential sulphate (SO_4) groups are known to occur in nature; these include sulphates, sulphate hydrates, sulphate hydroxy hydrates, sulphate/chlorides, and sulphate/arsenate/phosphate/vanadates of alkali- and transition-metals.

Sulphides

D J Vaughan, University of Manchester, Manchester, UK

Introduction

The sulphide minerals are the major source of world supplies of a very wide range of metals and are the most important group of ore minerals. In addition to their concentrated occurrence in ore deposits and areas of mineralization, a limited number of sulphide minerals are found as accessory minerals in rocks. However, only pyrite, pyrrhotite, galena, sphalerite, chalcopyrite, and possibly the binary copper sulphides of the chalcocite family could be classed as rock-forming minerals. Pyrite (FeS_2) is by far the most abundant sulphide mineral. The very fine particle iron sulphides found in reducing environments beneath the surfaces of Recent sediments and soils, although transient species, are also volumetrically important. Formerly referred to as amorphous iron sulphide, these phases are now known to be largely composed of fine-particle mackinawite (tetragonal FeS) and, in some cases, the sulphospinel mineral greigite (Fe_3S_4). Both phases are metastable in relation to pyrite and pyrrhotite. As well as being important sources of metals, sulphide minerals are potential sources of pollution. In particular, the release of sulphur through the weathering of sulphides in natural rocks or in mine wastes generates sulphuric acid, resulting in acid rock drainage or acid mine drainage, and a significant proportion of the sulphurous fumes generated by combustion of coal (or by the smelting of sulphide ores) originates from sulphide minerals; these fumes react to form acid rain. A more positive role may have been played by sulphide minerals in the emergence of life on Earth; although speculative, such theories have been developed following the discoveries of ocean-floor hydrothermal systems generating large volumes of sulphide minerals and associated with novel life forms and ecosystems.

The mineralogy, mineral chemistry, and geological occurrences of sulphide minerals have been well researched, particularly because of their economic and environmental importance. The crystal structures, chemical compositions, physical properties, thermochemistry, and phase relations of the major sulphides were well established by the latter part of the twentieth century, as were the macroscopic and microscopic characteristics of sulphide minerals in natural occurrences. Recent decades have seen major advances in the understanding of the chemical bonding in sulphide minerals and in the surface chemistry of sulphides. An understanding of the genesis of sulphide-ore deposits has developed through systematic geological, petrographic, compositional, and isotopic studies of ores and host rocks.

In this article, the compositions, crystal structures, physical properties, and certain aspects of mineral chemistry and geological occurrence of the major sulphide minerals will be reviewed, with suggestions given for further reading.

Compositions and Structures

Several of the common sulphide minerals were among the first minerals to be studied by X-ray crystallography, and since that time the structures of nearly all the mineralogically significant sulphides have been determined. It is possible to categorize the mineral sulphides into a series of groups based on major structure types, or having key structural features in common, as shown in Table 1. In many cases, these structures are the classic structures of crystalline solids, such as the rock-salt structure of the galena group (Figure 1A), the sphalerite and wurtzite forms of zinc sulphide (Figures 1B and 1C), or the nickel arsenide structure (Figure 1E). The disulphides are characterized by the presence of dianion (S–S, S–As, As–As, etc.) units in the structure: as well as the pyrite structure, in which FeS_6 octahedral units share corners along the *c*-axis direction, there is the marcasite form of FeS_2, in which octahedra share edges to form chains along the *c*-axis (Figure 1D). The structures of loellingite ($FeAs_2$) and arsenopyrite (FeAsS) are variants of the marcasite structure that have shorter and alternate long and short, respectively, metal–metal distances across the shared octahedral edge (see Figure 1D). A few sulphides such as molybdenite, covellite (Figure 1F), and mackinawite have layer structures, and a small number exhibit structures that are best characterized as containing rings or chains of linked atoms (e.g. realgar, AsS). A diverse group of sulphides, the metal-excess group, is composed of an unusual set of structures that is well illustrated by the important example of the mineral pentlandite ($(Ni,Fe)_9S_8$; Figure 1G).

As can be seen from Table 1, in many of these groups a number of minerals share the actual structure type, but there are also, commonly, other minerals that have structures based on these 'parent' structures and that can be thought of as being derived from them. The relationship between a derivative structure and the parent structure may involve

Table 1 Sulphide structural groups

1. The disulphide group					
Pyrite structure	*Marcasite structure*	*Arsenopyrite structure*	*Loellingite structure*	*Derived by As/S ordered substitution*

In each case the metals are shown as smaller or shaded spheres. Adapted from Institute of Materials, Minerals and Mining, Sulphite Deposits their origin and Processing, ed. P. Gray, 1990.

- ordered substitution (the structure of chalcopyrite ($CuFeS_2$) is derived from that of sphalerite (ZnS) by alternate replacement of zinc atoms with copper and iron, resulting in an enlarged (tetragonal) unit cell; the structure of stannite (Cu_2FeSnS_4) results from further ordered substitution of half of the iron atoms in chalcopyrite by tin (Figure 2A));
- a stuffed derivative (talnakhite ($Cu_9Fe_8S_{16}$) is derived from chalcopyrite by the occupation of additional normally empty cavities in the structure (Figure 2B));
- ordered omission (monoclinic pyrrhotite (Fe_7S_8) is derived from the nickel arsenide structured troilite by removal of iron atoms, leaving holes (vacancies) that are ordered (Figure 2C)); or
- distortion (the troilite form of FeS is simply a distortion of the parent nickel arsenide structure form (Figure 2C)).

In some cases, the relationships involved are more complex, as, for example, in certain of the sulphosalts (minerals with a general formula $A_mT_nX_p$ in which common elements are *A*: Ag, Cu, and Pb; *T*: As, Sb, and Bi; *X*: S, and which contain pyramidal TS_3 groups in the structure). Here, the resulting structure is composite and made up of slabs or units of a parent structure (or structures) arranged in an ordered fashion.

The compositional variations of the major sulphide minerals are reasonably well characterized, both as a result of numerous analyses of natural samples from a wide variety of deposits and as a result of systematic laboratory investigations of the phase equilibria. Many metal sulphides show evidence that the elements comprising them are not combined in simple whole-number ratios, i.e. they exhibit nonstoichiometry. In certain cases, the deviation from a simple ratio is considerable. For example, the pyrrhotites are sometimes given the general formula $Fe_{1-x}S$ where $0 < x < 0.125$ and the varying compositions correspond to varying concentrations of vacancies in sites that would otherwise be occupied by iron atoms. However, in systems such as these, ordering of the vacancies occurs at low temperatures, and the result may be a series of stoichiometric phases of slightly different compositions. Although Fe_7S_8 has a (monoclinic) superstructure resulting from vacancy ordering, the situation in the intermediate or hexagonal pyrrhotites is more complex. Some of these pyrrhotites may represent ordered phases with clearly defined compositions (Fe_9S_{10}, $Fe_{11}S_{12}$, etc.), but more complex and partial ordering in these systems may occur. One problem is certainly that free-energy differences between a series of phases resulting from vacancy ordering are very small, making a successful investigation of the relationships between synthetic products very difficult.

Other examples of nonstoichiometry involve relatively small deviations from the simple ratio. For example, galena (PbS) exhibits a range of nonstoichiometry of 0.1 atomic %. Galena is apparently stable over a wide range of values of aS_2 (activity of sulphur), and at high aS_2 it has lead vacancies, whereas at low aS_2 there are sulphur vacancies.

Electrical, Magnetic, and Optical Properties

The metal sulphides also show a tremendous range of electrical and magnetic behaviours. As Table 2

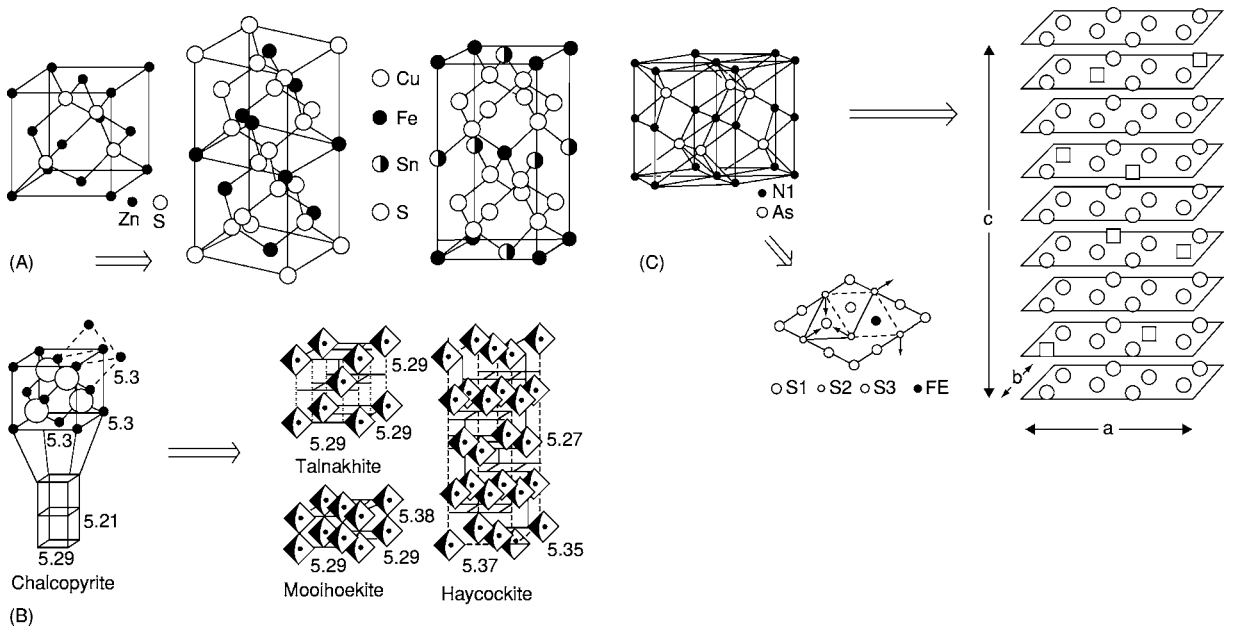

Figure 2 Parent and derivative crystal structures in the sulphide minerals. (A) The sphalerite (ZnS) structure with the chalcopyrite ($CuFeS_2$) and stannite (Cu_2FeSnS_4) structures. (B) The sphalerite and chalcopyrite unit cells with octahedra of metals outlined, within which may be an additional metal ion in the minerals talnakhite ($Cu_9Fe_8S_{16}$), mooihoekite ($Cu_9Fe_9S_{16}$), and haycockite ($Cu_4Fe_5S_8$); the arrangement of additional occupied metal sites is as shown (also shown are the dimensions of the parent sphalerite cell in (A)). (C) The niccolite unit cell of high temperature FeS, which has vacancies in place of iron atoms in monoclinic pyrrhotite (Fe_7S_8) that are ordered as shown, with vacancies represented by squares (and only iron atom layers shown); also shown in a projection onto the basal plane are the distortions that occur in the troilite modification of FeS. Adapted from Institute of Materials, Minerals and Mining, Sulphite Deposits their origin and Processing, ed. P. Gray, 1990.

Table 2 Magnetic and electrical properties of some major sulphide minerals

Mineral species	*Magnetic properties*	*Electrical properties*
Sphalerite (ZnS)	diamagnetic	insulator (E_g~3.7 eV)
'Iron sphalerite' (Zn,Fe)S	paramagnetic	semiconductor (E_g~0.5 eV for *ca.* 12 at.% Fe)
Galena (PbS)	diamagnetic	semiconductor (n and p type, E_g~0.41 eV)
Pyrite (FeS_2)	diamagnetic	semiconductor (n and p type, E_g~0.9 eV)
Cattierite (CoS_2)	ferromagnetic (T_c 110 K)	metallic
Chalcopyrite ($CuFeS_2$)	antiferromagnetic (T_N 823 K)	semiconductor (n type, E_g~0.5 eV)
Covellite (CuS)	diamagnetic(?)	metallic
(monoclinic) Pyrrhotite (Fe_7S_8)	ferrimagnetic (T_c 573 K)	metallic
Carrollite ($CuCo_2S_4$)	Pauli paramagnetic	metallic
Pentlandite $(Ni,Fe)_9S_8$	Pauli paramagnetic	metallic

E_g, band or 'energy' gap; T_c, Curie temperature; T_N, Nèel temperature.

indicates, whereas such non-transition-metal sulphides as sphalerite and galena are diamagnetic; diamagnetism is also exhibited by pyrite and marcasite (the other FeS_2 polymorph). Substitution of iron for zinc in sphalerite leads to paramagnetic behaviour, and many transition-metal sulphides show various forms of magnetic ordering at lower temperatures, including antiferromagnetism (e.g. chalcopyrite), ferromagnetism (e.g. cattierite), and ferrimagnetism (e.g. monoclinic pyrrhotite, although hexagonal pyrrhotites are antiferromagnetic). Other transition-metal sulphides that are metallic conductors exhibit the weak temperature-independent paramagnetism known as Pauli paramagnetism. Metallic conductivity occurs in many sulphides of diverse magnetic character, and, in addition, numerous sulphides are semiconductors and a smaller number (e.g. pure sphalerite) are insulators. Among semiconducting sulphides, both intrinsic and impurity (or extrinsic) conduction mechanisms occur, and conduction both via electrons (n-type) and via holes (p-type) is common. Such variations are often a consequence of the presence of very minor impurities or of

slight nonstoichiometry (e.g. galena (PbS) shows p-type conductivity in lead-deficient samples and n-type conductivity in sulphur-deficient samples).

Given that the great majority of sulphide minerals are opaque, the optical properties of interest are those observed in reflected light from polished sections. The qualitative optical properties commonly serve for routine identification, but definitive characterization can be greatly aided by measuring reflectance at set wavelengths, or a whole series of wavelengths, across the visible-light region.

Sulphide Mineral Stability

Much work has been done to establish the stability relations of sulphide minerals in terms of variables that include temperature, pressure, composition, and the activities of various components.

The Fe–S system is the most important binary sulphide system because the iron sulphides are, by far, the dominant sulphide minerals in terms of geological abundance and variety of geological occurrences. Furthermore, the Fe–S system is an integral part of other important more complex systems such as the Fe–Zn–S, Cu–Fe–S, and Fe–Ni–S systems. The phase relations in the condensed Fe–S system above 400°C (**Figure 3A**) have been the subject of numerous studies and, in contrast to the low-temperature relationships, are well understood. The central part of the system is dominated by the large high-temperature pyrrhotite field of solid solution from stoichiometric FeS towards more sulphur-rich compositions. This high-temperature form with a hexagonal NiAs-type structure accommodates solid solution by random vacancies at the iron sites within the lattice. Hence, the compositions of high-temperature pyrrhotites, except for pure FeS, are best given as $Fe_{1-x}S$, where x is 0 to ~0.14. The maximum thermal stability of the pyrrhotite solid solution at pressures below about 1 atmosphere is 1192°C, above which it melts congruently. Pyrite has, at low pressures, a maximum thermal stability of 742 ± 1°C. The upper thermal stability of pyrite rises by approximately 14°C per kilobar of confining pressure. In spite of numerous studies, the phase relations in the Fe–S system at temperatures below 350°C are incompletely understood. A temperature–composition diagram for the system between FeS and FeS_2 from 0°C to 350°C is shown in **Figure 3B**. Phase relations in the compositional regions Fe–FeS and FeS_2–S remain straightforward, essentially as shown in **Figure 3A**, but the central part of the system is exceedingly complex. This complexity is caused by the crystal chemistry of the pyrrhotites, as discussed above, where iron atoms can be omitted, leaving holes or vacancies. At low temperatures, ordering of vacancies occurs, resulting in the development of various superstructures. The best-known of these superstructures is that of monoclinic pyrrhotite (Fe_7S_8). In this case, the vacancies occur in alternate layers of iron atoms parallel to the basal plane and in alternate rows in those layers (**Figure 2C**). This is known as the 4C structure, because the superstructure has a unit cell that is four times the c dimension of the parent nickel arsenide-type cell.

Although the structure of monoclinic pyrrhotite is well established, the structures of those compositions lying between FeS and Fe_7S_8 remain uncertain. Numerous superstructure types have been reported for these intermediate pyrrhotites, including examples with nonintegral multiples of the parent-cell c and a dimensions (so-called NC and NA types). Many reported superstructures have not been observed in natural samples, where there is evidence of compositions clustering around $Fe_{11}S_{12}$, $Fe_{10}S_{11}$, and Fe_9S_{10}, as well as Fe_7S_8. These compositions also correspond to superstructures with high degrees of order, the 5C (Fe_9S_{10}) and 6C ($Fe_{11}S_{12}$) superstructures. The thermodynamic stability of the various pyrrhotites, particularly the intermediate pyrrhotites, is problematic, with kinetic controls exerting the major influence over the compositions and structure types observed. The highly ordered monoclinic pyrrhotite (Fe_7S_8) and troilite (FeS, a 2C superstructure produced by distortion of the nickel arsenide high-temperature form) may be stable phases in the system, but reported or measured free-energy minima suggest that only pyrite and troilite are truly stable phases.

Much sulphide is formed in sedimentary or hydrothermal environments, so phase equilibria in aqueous systems are of particular interest. The stability of pyrite, for example, has been considered as a function of many variables. Perhaps the best-known relationships are those at 25°C, for which the stability of pyrite in aqueous solution has been examined as a function of the changing activities of two or more components in the system when the others are held constant. Thus, for the system Fe–S–O–H, the activity of hydrogen ions (pH) has been plotted against the 'activity of electrons' (Eh), and either one or both of these variables have been plotted against the activity of sulphur (expressed as pS^{2-} or pS_2). **Figure 4** shows Eh–pH plots illustrating the stability of pyrite and other sulphides and oxides of iron in water at 25°C and 1 atmosphere total pressure. **Figure 4A** shows relationships at a total dissolved sulphur activity of 10^{-1} and illustrates the large stability field of pyrite under reducing conditions over a wide pH range. By contrast, the stability field of pyrrhotite is extremely small. Under more oxidizing conditions, haematite is the dominant iron mineral, with magnetite having

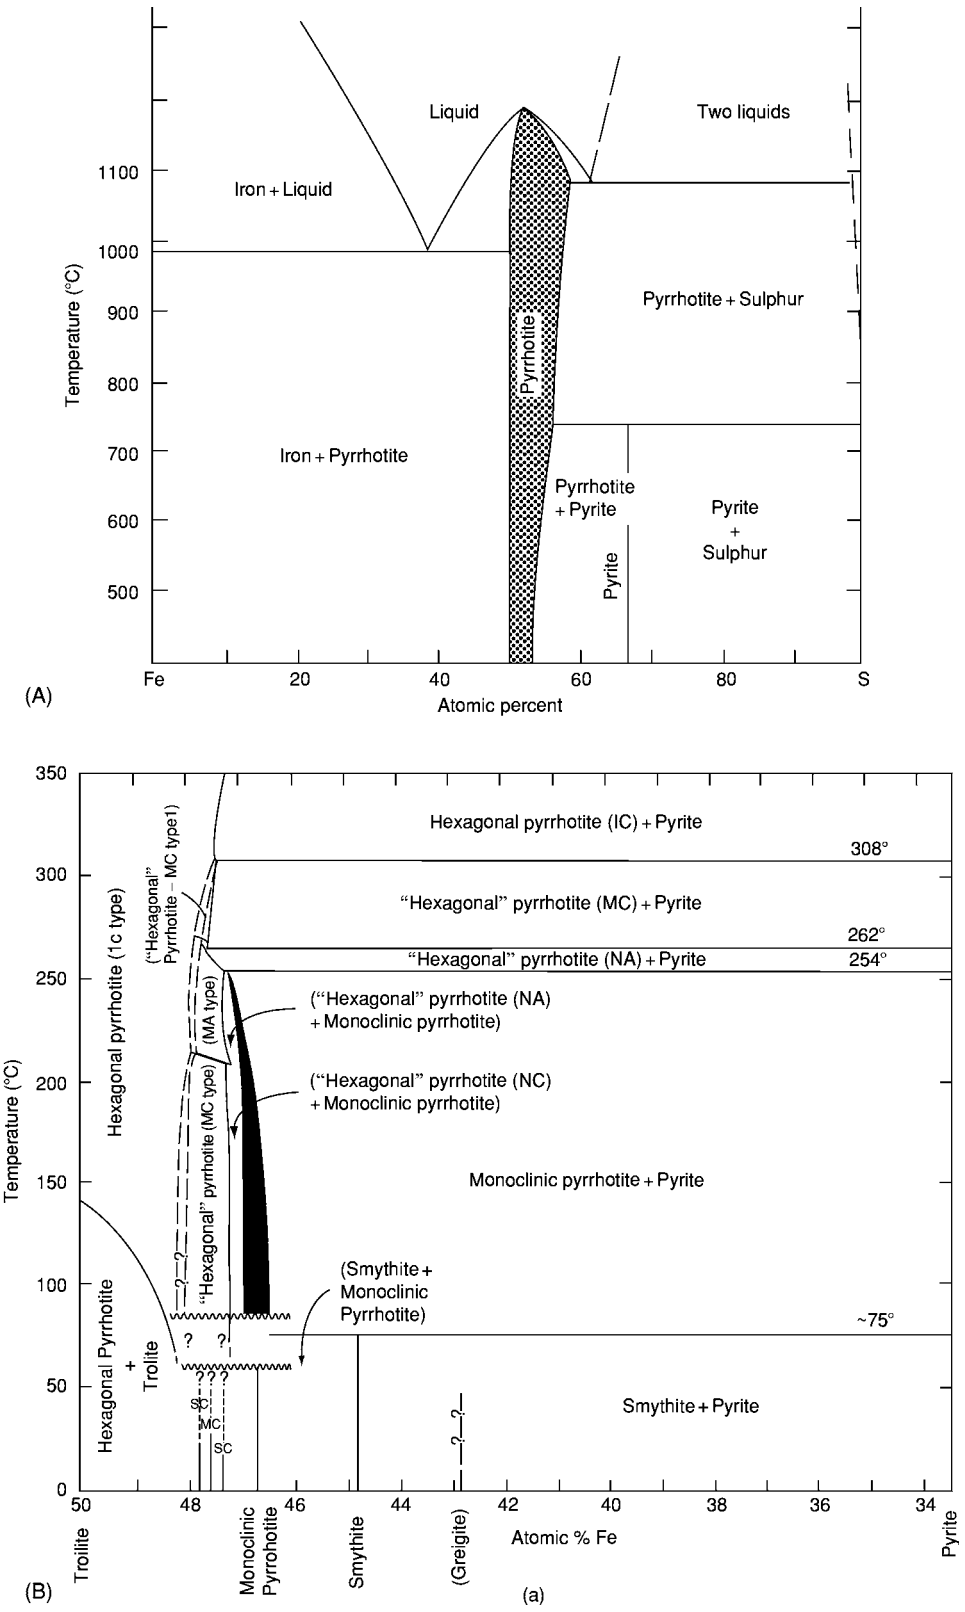

Figure 3 The iron sulphur system: (A) phase relations in the Fe S system above 400°C at low pressure; and (B) phase relations in the central portion of the Fe S system below 350°C. Figure 4 Stability relations of iron sulphides and oxides in water at 25°C and 1 atmosphere total pressure (A) at a total activity of dissolved sulphur of 10^{-1} and (B) at a total activity of dissolved sulphur of 10^{-6}.

only a very small stability field. The effect of lowering the total sulphur activity to 10^{-6} is shown in Figure 4B: the pyrite field is now much smaller and the magnetite field has increased in size. Notable from examination of Figure 4 is the very large stability field of pyrite relative to pyrrhotite in sediments. It can also be seen that quite low sulphide activities can stabilize pyrite over a considerable range of Eh conditions, and that iron oxides or carbonate will form only when the sulphide activity of the environment is very small.

The problem of metastability is implicit in the study of iron sulphides. For example, certain iron sulphides that are common in nature, such as marcasite (FeS_2) and mackinawite ($Fe_{1+x}S$), are not included in the phase diagrams of Figure 3. These sulphides cannot be synthesized by a direct reaction between iron and sulphur in dry systems but only by precipitation from solution. In the natural aqueous systems where such iron sulphides form, reduced sulphur is readily available from the bacterial reduction of sulphate. Here mackinawite is the dominant precursor phase, with the ultimate stable product being pyrite. Details of the reaction pathways involving mackinawite and other less common precursors are still being established, but Figure 5 makes an attempt to summarize known and more speculative phase transformations.

When interpreting the mineral assemblages and textures in order to understand the genesis of sulphide

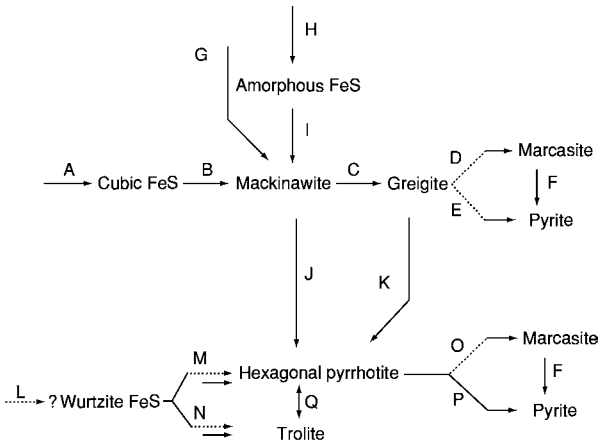

Figure 5 Summary of known and speculative phase transformations and reactions in the low temperature iron sulphur system (redrawn after Lennie and Vaughan, *Geochem. soc. spec pubh. No. 5*, p.128, 1996). The letters on the diagram are as follows: A, formation from Fe^{2+} or Fe and HS or H_2S at a pH of 4 5 ($T < 523$ K); E, inferred sulphidation of greigite at a pH of more than 5 ($T < 523$ K); F, solid state transformation; G, sulphidation of Fe by H_2S at a pH of 3 10 ($T < 523$ K); I, ageing of amorphous precipitate; J, solid state transformation, kinetics not established; L, precipitation from Fe^{2+} by HS at a pH of 4 6 (wide range of temperatures to above 573 K); M,N, reaction of Fe^{2+} and HS or H_2S at a pH of 4 5 (or speculative transformation of proposed wurtzite FeS structure) to form either (M) hexagonal pyrrhotite ($T > 413$ K) or (N) troilite ($T < 413$ K); O, marcasite after pyrrhotite; P, pyrite formed by sulphidation of pyrrhotite (this reaction is rapid above 573 K); Q, troilite hexagonal pyrrhotite reversible phase transition. Reproduced with permission from Geochemis try of Hydrothermal Ore Deposits, ed. H. L. Barnes, 1997, John Wiley and Sons.

ores, temperature–composition relations in the subsolidus region are particularly useful. This is because many sulphide minerals undergo changes in the solid state down to relatively low temperatures. These changes give rise to a wealth of intergrowth textures produced by exsolution or unmixing, as exemplified by the Ni–Fe–S system (Figure 6). Such changes occur because, at elevated temperatures in many sulphide systems, there are extensive fields of solid solution that shrink with falling temperature. In the case of the Ni–Fe–S system, it is the breakdown of the so-called monosulphide solid solution and the segregation of pentlandite according to the reaction

$$(Fe, Ni)S = Fe_{1-x}S + (Fe, Ni)_9S_8$$

monosulphide solid solution = pyrrhotite + pentlandite

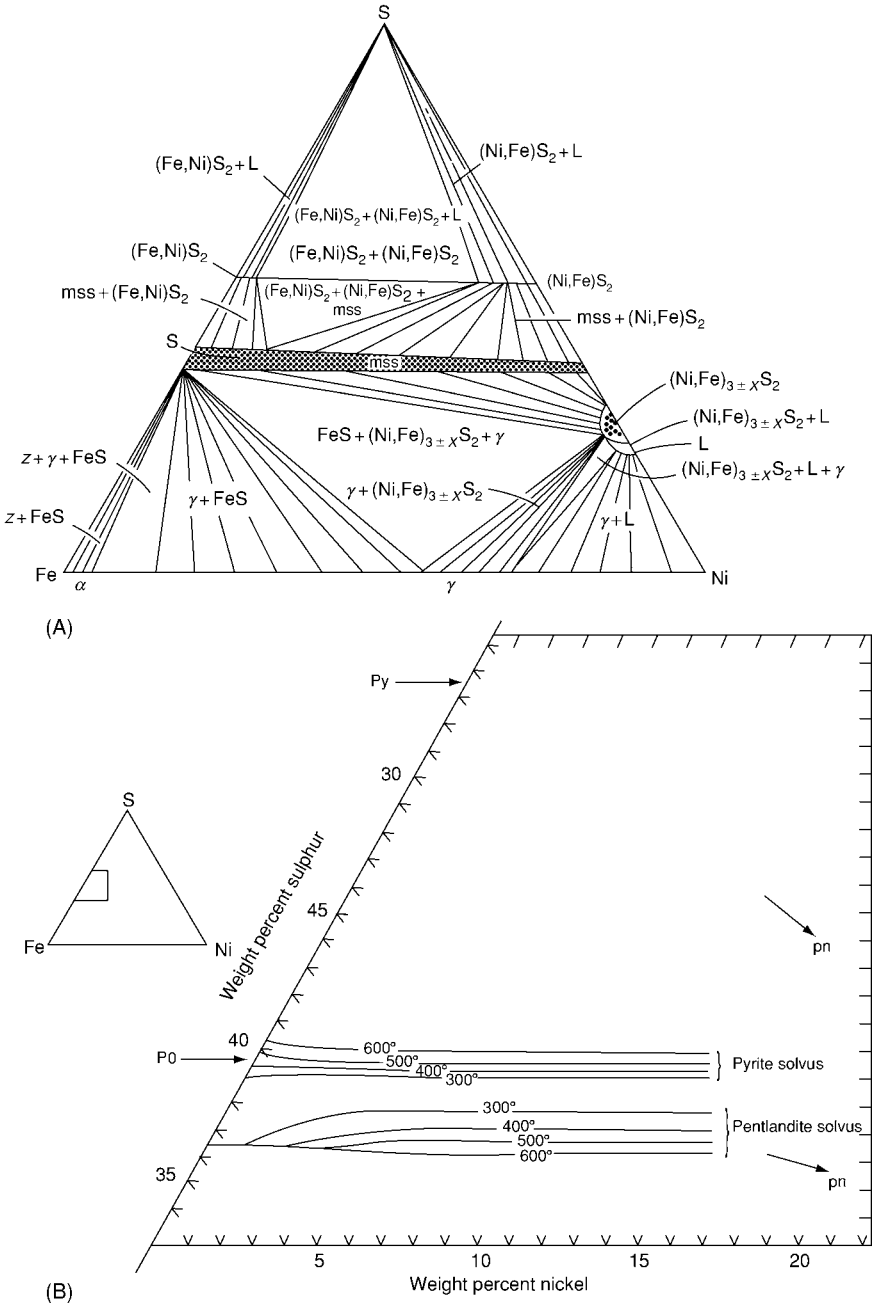

Figure 6 (A) The condensed phase relations in the Fe Ni S system at 650°C. Note the absence of pentlandite and the area of monosulphide solid solution (*mss*) that spans the system from $Fe_{1-x}S$ to $Ni_{1-x}S$. (B) A portion of the Fe Ni S system, showing the compositional limits of the monosulphide solid solution in (A) at 600°C, 500°C, 400°C, and 300°C. Pentlandite flames exsolve from the *mss* as the sulphur poor boundary retreats during cooling. Reproduced with permission from Geochemistry of Hydrothermal Ore Deposits, ed. H. L. Barnes, 1997, John Wiley and Sons.

that is central to understanding the assemblages and textures in the sulphide nickel ores. Such processes may lead to completely separate grains of the two phases being formed on exsolution, or the two phases may be intergrown as laths, blebs, etc., often with a clearly defined crystallographic relationship. The crystal structures of the two phases will partly dictate the kind of texture that forms, but other crucial factors are the monosulphide solid solution bulk starting composition and the cooling history. The majority of binary and ternary and many quaternary sulphide systems have now been studied as regards temperature–composition relations, yielding evidence of the maximum stability temperatures of phases, solid solution limits, and coexistence of phases under the equilibrium conditions pertaining in such experiments.

The stable phase relations may also be defined in terms of the activities of components and, in regard to the sulphide minerals, it is the activity of sulphur (aS_2) that is most important. Thus, a 'petrogenetic grid' commonly used to present sulphide mineral relationships plots aS_2 against temperature (actually log aS_2 versus 1/temperature because sulphidation boundaries then plot as straight lines in many cases) as shown in Figure 7. Such diagrams show the progressive development of assemblages through sulphidation from metal to monosulphide to (where appropriate) disulphide.

A limited number of sulphide systems have proved valuable in geothermometry and geobarometry. Notably useful in geothermometry is the mineral arsenopyrite (FeAsS). Phase relations in the Fe–As–S system are shown schematically over the temperature range 688°C to 363°C in Figure 8. In the higher temperature range, arsenopyrite coexists with pyrrhotite, loellingite, arsenic, or an (As,S) liquid (represented on cooling by an arsenic sulphide) in the assemblages labelled 1 to 4. From 491°C to 363°C, arsenopyrite can coexist with pyrite, pyrrhotite, loellingite, arsenic, or (As,S) liquid in the assemblages labelled 5 to 8. Because arsenopyrite composition is a function of both temperature and the equilibrium with the coexisting phases in the system, it can be used in geothermometry only in buffered assemblages, i.e. those labelled 1 to 8 in Figure 8. For these assemblages, the composition of arsenopyrite has been calibrated as a function of temperature to provide a geothermometer. A method has also been devised of using the d_{131} X-ray spacing curve to determine arsenopyrite composition

$$(\text{As, at.}\%) = 866.67d_{131} - 1381.12.$$

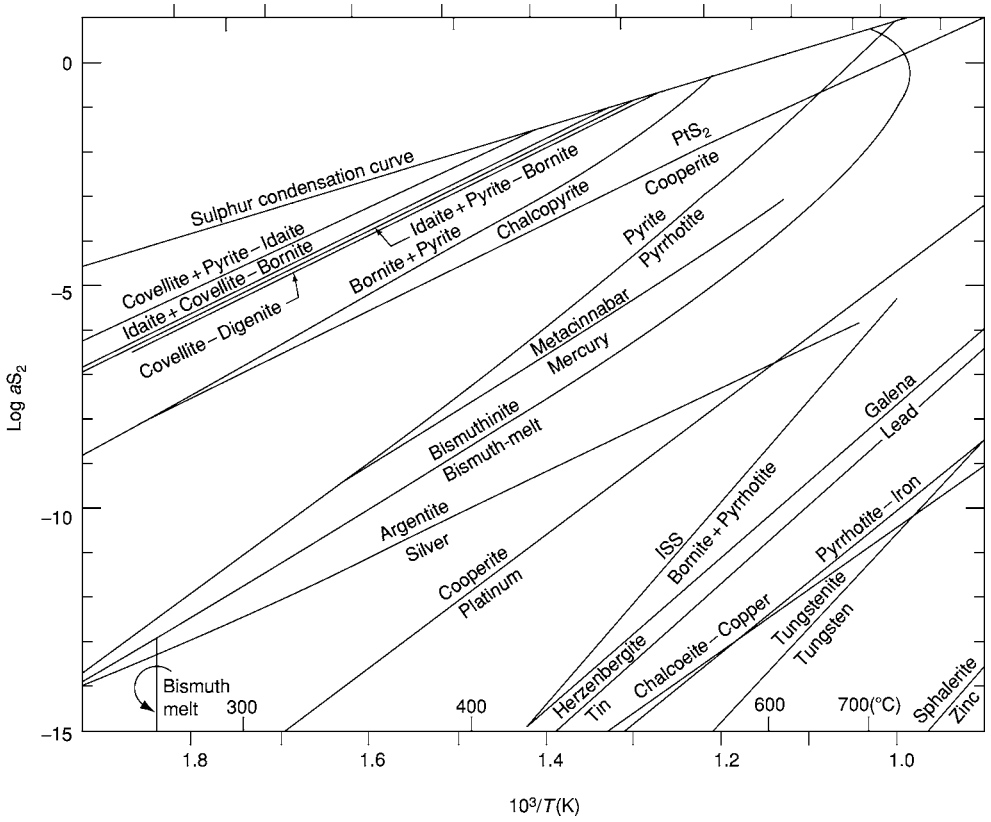

Figure 7 Sulphidation curves for various sulphides as a function of temperature. ISS intermediate solid solution.

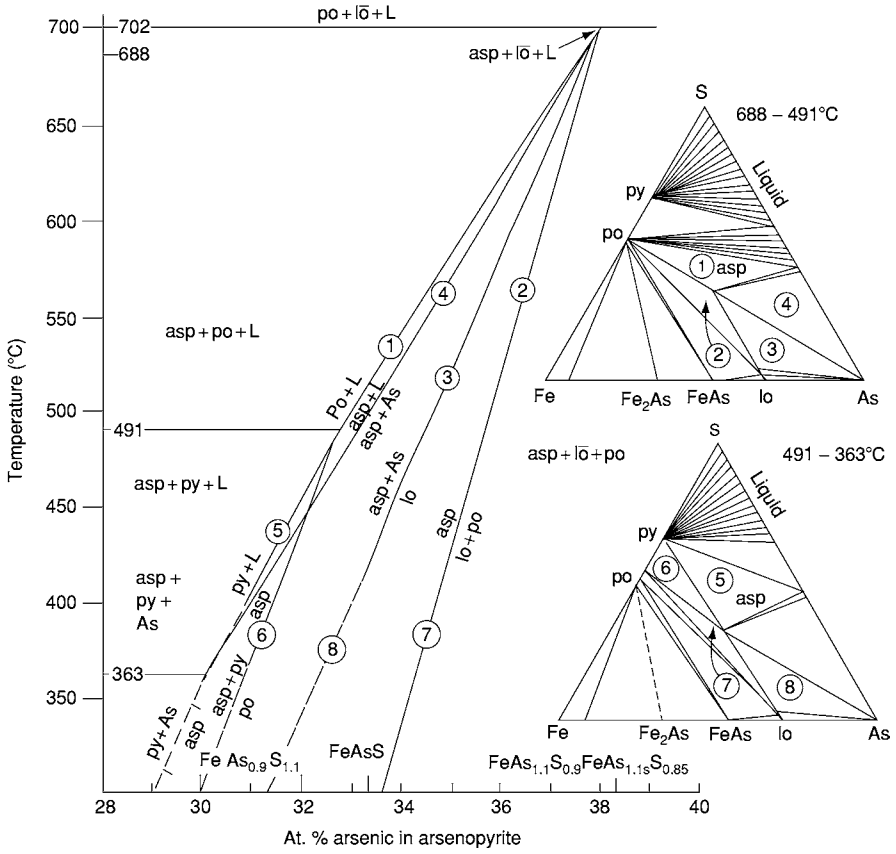

Figure 8 Pseudobinary temperature composition plot, showing arsenopyrite composition as a function of temperature and equilibrium mineral assemblage. The assemblages numbered 1 8 in the Fe As S phase diagrams on the right correspond to the labelled curves in the left hand diagram. Abbreviations: asp, arsenopyrite; py, pyrite; po, pyrrhotite; lo, lollingite; L, liquid.

Critical evaluation of the arsenopyrite geothermometer, using volume calculations, has revealed that pressure will shift the sulphidation buffer curves in Figure 8 for the system Fe–As–S to higher sulphur activities (e.g. by up to 10 times for arsenopyrite coexisting with pyrite). The effect of pressure on the composition of arsenopyrite buffered by two other phases is not large and can be ignored for low-pressure hydrothermal deposits but needs to be taken into account in metamorphosed deposits.

The sphalerite geobarometer is based on the observation that increasing pressure reduces the FeS content of a sphalerite equilibrated with pyrite and hexagonal pyrrhotite in a manner that is independent of temperature (Figure 9). Sphalerite is sufficiently refractory to preserve the original composition unless it remains in contact with pyrrhotite or chalcopyrite: low-temperature re-equilibration of sphalerite generally reduces the original FeS content and results in pressure estimations that are too high.

A very important aspect of sulphide geochemistry and mineral chemistry is concerned with the mechanisms and kinetics of sulphide oxidation, particularly in regard to pyrite, the overwhelmingly dominant sulphide in most natural systems. This is because of the applications of such studies in both mineral-processing technology and environmental chemistry (particularly in relation to the generation of acid waters). Despite a large amount of work, reflected by a substantial literature, many aspects of pyrite oxidation remain unresolved. This is because, in addition to the large number of variables (whether oxidation is in air, water, or other aqueous fluid; pH; Eh; temperature; presence of various oxidants; role of bacteria), the oxidation of pyrite to form sulphate requires the transfer of eight electrons per sulphur atom and must involve several steps, with sulphur species of intermediate oxidation states. The literature almost universally acknowledges that any oxidation reaction mechanism is surface-reaction controlled. It is suggested that, in aqueous solution, pyrite oxidizes by a combination of the half-reactions

$$FeS_2 + 8H_2O = Fe^{3+} + 2SO_4^{2} \quad + 16H^{+} + 15e$$

and

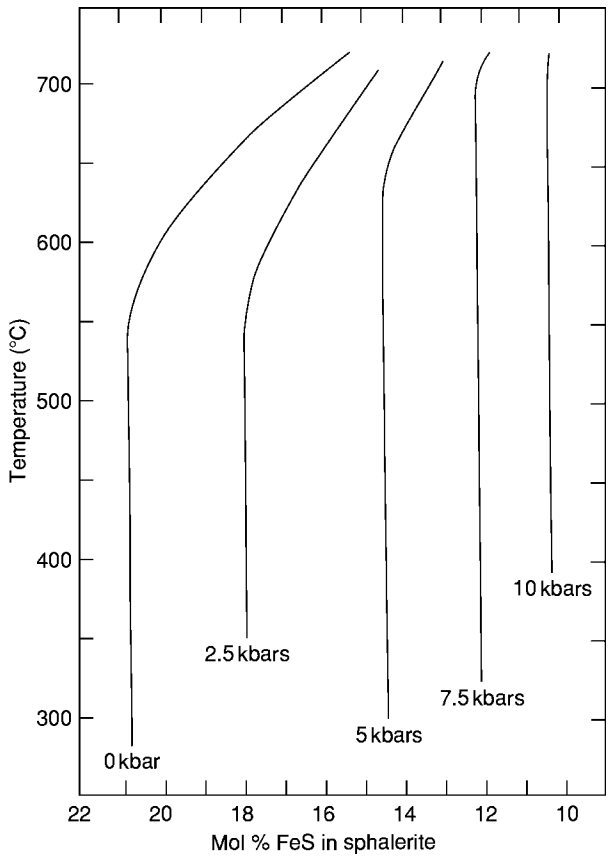

Figure 9 Plots of the FeS contents of sphalerite coexisting with pyrite and hexagonal pyrrhotite at 0, 2.5, 5, 7.5, and 10 kbar at temperatures from 300°C to 700°C. Reproduced with permission from Geochemistry of Hydrothermal Ore Deposits, ed. H. L. Barnes, 1997, John Wiley and Sons.

$$FeS_2 = Fe^{3+} + 2S + 3e \quad ,$$

for which the Eh and pH determine the dominant pathway: the sulphate route dominates under ambient conditions. At low pH, pyrite may be oxidized by O_2 and Fe^{3+}_{aq}:

$$FeS_2 + 7/2O_2 + H_2O = Fe^{2+} + 2SO_4^{2} + 2H^+$$

and

$$FeS_2 + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + 2SO_4^{2} + 16H^+$$

The rates of pyrite oxidation are dramatically affected by the presence of bacteria; for example, at low pH, *Thiobacillus ferrooxidans* can accelerate the oxidation of Fe^{2+} by a factor of more than 10^6. Recent work on the mechanism of pyrite oxidation emphasizes the importance of the fact that pyrite is a semiconductor. Electrons can be transferred from sulphur atoms at an anodic site, where oxygen atoms from water molecules attach to sulphur atoms to form sulphoxy species, through the crystal to cathodic Fe(II) sites, where they are acquired by the oxidant species (usually O_2 or Fe^{3+}). Bulk measurements of oxidation rate show that the concentration of O_2 or Fe^{3+} is critical, so it appears that the 'cathodic' reaction is the rate-determining step.

The study of the surface structures and reactivities of sulphide minerals is being revolutionized by the application of the scanning probe microscopy techniques of scanning tunnelling microscopy and atomic force microscopy. These are leading to models of surface structures and reactions that have been developed from direct observations of the systems at the atomic scale.

Sulphide Paragenesis: Rocks, Sediments, and Ore Deposits

The major ore deposit types that contain substantial amounts of sulphide minerals are shown in Table 3 along with the major minerals they contain, the metals extracted from them, and examples of specific deposits.

Pyrite is exceptionally widespread in its occurrence, being known as an accessory mineral in many of the major rock types that make up the crust of the Earth and as a major or minor phase in many types of ore deposit. However, in ultramafic and mafic intrusive rocks, especially in the so-called 'sulphide nickel' deposits, it is pyrrhotite that dominates. The sulphides in these deposits (pyrrhotite, pentlandite, chalcopyrite, and, in some cases, pyrite) are regarded as having formed by the crystallization of an immiscible sulphide melt that separated from the main silicate melt. Studies of the sulphides in the best-known of all layered basic intrusions, the Bushveld Complex, also show a dominance of pyrrhotite, pentlandite, and chalcopyrite along with minor but economically vital platinum group minerals. In the classic Skaergaard intrusion (Greenland), pyrite is present chiefly in small amounts in the latest rock fraction, the acid granophyre. In the Stillwater Complex, the principal sulphides include pyrite, chalcopyrite, and pyrrhotite, which are fairly conspicuous near the floor of the complex and at one or two higher horizons.

In felsic igneous rocks, the predominant sulphide is pyrite. In addition to its occurrence as an accessory phase in a wide range of such rocks, pyrite is the dominant sulphide mineral in porphyry copper deposits, in which chalcopyrite is the most important ore mineral, along with various binary copper sulphides. Anhedral to euhedral grains of sulphides occur in these ores, where the mineralization is as disseminated grains or veinlets in host intrusions, which range in composition from quartz diorite to

Table 3 The major types of sulphide ore deposit

Type	*Major minerals*	*Metals extracted*	*Examples*
Ores related to mafic and ultramafic intrusions			
Sudbury nickel copper	po, pn, py, cpy, v	Ni, Cu, Co, PGM	Sudbury, Ontario
Merensky reef platinum	po, pn, cpy	Ni, Cu, PGM	Merensky Reef, South Africa
Ores related to felsic intrusive rocks			
Tin and tungsten skarns	py, cass, sph, cpy, wolf	Sn, W	Pine Creek, California, USA
Zinc lead skarns	py, sph, gn	Zn, Pb	Ban Ban, Australia
Copper skarns	py, cpy	Cu, Au	Carr Fork, Utah, USA
Porphyry copper/molybdenum	py, cpy, bn, mbd	Cu, Mo, Au	Bingham Canyon, Utah, USA Climax, Colorado, USA
Polymetallic veins	py, cpy, gn, sph, ttd	Cu, Pb, Zn, Ag	Carnsell River, NWT
Ores related to marine mafic extrusive rocks			
Cyprus type massive sulphides	py, cpy	Cu	Cyprus
Besshi type massive sulphides	py, cpy, sph, gn	Cu, Pb, Zn	Japan
Ores related to subaerial felsic to mafic extrusive rocks			
Creede type epithermal veins	py, sph, gn, cpy, ttd, asp	Cu, Pb, Zn, Ag, Au	Creede, Colorado, USA
Almaden mercury type	py, cinn	Hg	Almaden, Spain
Ores related to marine felsic to mafic extrusive rocks			
Kuroko type	py, cpy, gn, sph, ttd, asp,	Cu, Pb, Zn, Ag, Au	Japan
Ores in clastic sedimentary rocks			
Quartz pebble conglomerate gold uranium	py, uran, Au	Au, U	Witwatersrand, South Africa
Sandstone hosted lead zinc	py, sph, gn	Zn, Pb, Cd	Laisvall, Sweden
Sedimentary exhalative	py, sph, gn, cpy, asp	Cu, Pb, Zn, Au, Ag	Sullivan, British Columbia, Canada
lead zinc (Sedex)	ttd, po		Tynagh, Ireland
Ores in carbonate rocks			
Mississippi Valley type	py, gn, sph	Zn, Pb, Cd, Ga, Ge	South eastern Missouri

Abbreviation: po, pyrrhotite; pn, pentlandite; py, pyrite; cpy, chalcopyrite; v, violarite; cass, cassiterite; sph, sphalerite; wolf, wolframite; gn, galena; bn, bornite; mbd, molybdenite; ttd, tetrahedrite; asp, arsenopyrite; cinn, cinnabar; uran, uraninite; PGM, platinum group metals.

quartz monzonite. Large masses of pyrite, sphalerite, galena, or chalcopyrite are also found in ore deposits formed by contact metamorphism (skarn deposits). Pyrite occurs, often as a major phase, in the majority of hydrothermal vein deposits and dominates the ore mineralogy of those deposits that might broadly be described as 'volcanogenic'. These include the ores that occur in thick volcanic sequences, such as the Kuroko deposits of Japan. In the so-called 'black ore' of Kuroko-type deposits, irregular masses of galena are intergrown on a fine scale with sphalerite, pyrite, and chalcopyrite. In the Besshi-type deposits of Japan, the sulphides occur in dominantly sedimentary sequences and are again dominated by pyrite, chalcopyrite, sphalerite, and galena.

In sulphide ores in volcanosedimentary sequences that are associated with ophiolite complexes, as in the Troodos Complex deposits (Cyprus), pyrite and chalcopyrite dominate. An understanding of the genesis of these deposits has rapidly developed in recent years through the observation of present-day volcanic and hydrothermal activity on the seafloor. The disseminated to massive stratiform sulphide ores that occur, often conformably, within sedimentary sequences grade into the volcanogenic deposits discussed above. Again, pyrite is the dominant ore mineral in these deposits, which include the Kupferschiefer-Marl Slate of northern Europe and the Copperbelt of Zambia and Zaire. The latter contains not only a range of copper and copper–iron sulphides (chalcopyrite, bornite, chalcocite, covellite) but also significant amounts of cobalt in pyrite and the sulphospinel mineral carrollite.

In the context of sedimentary rocks, sulphides (galena and sphalerite with some pyrite) are major phases in many of the lead–zinc–barite–fluorite ores, which occur chiefly in limestones, and pyrite, along with the copper sulphides, occurs in the uranium–vanadium–copper ores that are associated with sandstones in areas such as the Colorado Plateau, USA. In the gold–uranium ores that occur in conglomerates in the Witwatersrand, South Africa, and Elliot Lake, Ontario, Canada, pyrite is the major opaque phase. As well as occurring as common accessory minerals in black shales, sulphides, especially pyrite and marcasite, are the major opaque mineral in coals. The formation of sulphides in all of these environments is probably linked to the reaction of metals, particularly iron, released by the dissolution of detrital oxides and silicates, with sulphur produced by the bacterial reduction of sulphate present in interstitial waters. This is observed in Holocene sediments, with pyrite (preceded by mackinawite and possibly greigite) forming through a diagenetic process occurring in the reduced

zone beneath the sediment surface. The occurrence of marcasite is much more restricted than that of pyrite. It is never found as a primary phase in any magmatic association and is indicative of environments that have probably been low temperature and where an aqueous phase was present at the time of formation.

Many studies have been undertaken of sulphur isotope ratios ($^{32}S : {}^{34}S$) in sulphide minerals from rocks and ore deposits. Initially these studies were aimed at developing criteria to distinguish ore deposits of igneous–hydrothermal origin from those of sedimentary syngenetic origin. Since bacterial reduction of sulphate substantially enriches the involved sulphur in ^{32}S (by 50% or more in the case of H_2S), such enrichment is taken as an indication that the sulphur has passed through the sedimentary cycle. This key reaction and others that involve isotope exchange and occur during ore formation have been the basis for the application of sulphur isotope studies to genetic problems. However, studies of both synthetic systems and natural ores have shown that the isotopic composition of sulphur is also controlled by changes in pH and oxygen fugacity in the reacting system. When these can be determined, for example by using carbon isotope ratios, valuable information about the formation of a deposit may be obtained. Coexisting pairs of sulphide minerals, such as pyrite co-existing with galena, sphalerite, chalcopyrite, or pyrrhotite, have also been used for sulphur isotope geothermometry. The fractionation of sulphur isotopes between co-existing mineral pairs has been calibrated as a function of temperature for use in such geothermometric studies.

Tungstates

P A Williams, University of Western Sydney, Penrith South DC, NSW, Australia

Introduction

Tungstates are compounds containing negatively charged oxytungstate ions. In the mineral kingdom, the simple tetraoxotungstate(VI), or tungstate ion, WO_4^{2-}, is present. As with the case of molybdate(VI), tungstate ions can polymerize under acid conditions to produce polytungstate and heteropolytungstate species, but minerals containing such complex anions are exceedingly rare and remain poorly understood and characterized. Only a few minerals containing essential tungstate are known, though some of these have great commercial significance. The standard potential at 25°C is −1.26 V for

eqn [1], and this explains the fact that tungstates with W in its highest oxidation state (+6) dominate the mineralogy of the element in both the primary and the secondary environments.

$$WO_4^{2} + 2H_2O + 2e \rightarrow WO_2 + 4OH \qquad [1]$$

Tungstenite, WS_2, is an extremely rare species, isomorphous with its common congener molybdenite, MoS_2. Table 1 provides a list of known naturally occurring tungstates. The so-called tungstic acids of stoichiometry $WO_3 \cdot nH_2O$ are not listed because they are simple lattice compounds. However, due to possible confusion as to the attribution of certain species to the tungstate class, Table 1 does include certain species that are in fact related. For example, alumotungstite and ferritungstite are derivatives of WO_3 with the pyrochlore structure. Substitution of W by Al or Fe gives a positive charge discrepancy that is compensated by incorporation of other cations in a vacant lattice site. In related fashion, raspite, $PbWO_4$, the dimorph of stolzite, contains chains of edge-linked WO_6 octahedra. Pinalite, russellite, and tungstibite are complex layer structure oxides; cerotungstite-(Ce) and yttrotungstite-(Y) are complex secondary oxyhydroxide species containing chains of WO_6 octahedra. The same situation may obtain for anthoinite and mpororoite, two poorly characterized minerals that require further investigation.

Table 1 Tungstate(VI) minerals

Mineral	*Chemical composition*
Simple tungstates	
Ferberite	$MnWO_4$
Hubnerite	$FeWO_4$
Paraniite (Y)	$Ca_2Y(AsO_4)(WO_4)_2$
Raspite	$PbWO_4$
Sanmartinite	$ZnWO_4$
Scheelite	$CaWO_4$
Stolzite	$PbWO_4$
Basic double salts	
Anthoinite	$WAl(O,OH)_3(?)$
Cuprotungstite	$Cu_3(WO_4)_2(OH)_2$
Mpororoite	$WAlO_3(OH)_3\ 2H_2O(?)$
Pinalite	$Pb_3WO_5Cl_2$
Russellite	Bi_2WO_6
Tungstibite	Sb_2WO_6
Complex uranium salts	
Uranotungstite	$(Fe,Ba,Pb)(UO_2)_2(WO_4)(OH)_4\ 12H_2O$
Polytungstates	
Phyllotungstite	$(Ca,Pb)Fe_3H(WO_4)_6\ 10H_2O$
Rankachite	$CaFeV_4W_8O_{36}\ 12H_2O$
Other complex species	
Cerotungstite (Ce)	$CeW_2O_6(OH)_3$
Ferritungstite	$(W,Fe)(O,OH)_3$[a]
Alumotungstite	$(W,Al)(O,OH)_3$[a]
Yttrotungstite (Y)	$YW_2O_6(OH)_3$

[a]Other cations, including Ca, Na, and Pb, may substitute in a site vacancy to compensate for charge imbalance (see text).

Primary Tungstates

All of the primary tungstates, including ferberite, hübnerite, paraniite-(Y), sanmartinite, and scheelite, contain the simple WO_4^{2} ion. Paraniite-(Y) and sanmartinite are both extremely rare minerals, but other members of the group have great economic importance, constituting the only minerals of tungsten to have value commercially. Scheelite takes up molybdenum in the lattice and a complete solid solution extends to the isomorphous mineral powellite, $CaMoO_4$. Primary scheelite, however, does not usually contain much molybdenum. The term 'wolframite' was formerly applied to members of the ferberite–hübnerite series and the nomenclature is still commonly in use. Solid solution in the series is in fact limited to about 20 mol% in each end-member and the separate end-member terms are now applied to individual specimens, depending on the exact composition.

Economically valuable deposits of the Alpine Cleft or sedimentary types of scheelite are well documented, but the main settings of scheelite, ferberite, and hübnerite mineralization are either with acid-intrusive rocks or associated skarns. Frequent associates of the tungstates are cassiterite, SnO_2, molybdenite, MoS_2, base metals such as copper, and minor amounts of gold. Important mines were once located in all continents, but at present deposits in China, Indochina, and Brazil are the main sources of tungsten.

Secondary Tungstates

Scheelite is also well known as a secondary mineral, especially associated with the oxidation of ferberite and hübnerite. In this setting, it also may incorporate molybdate in its lattice. Other secondary tungstates are rare, with perhaps the most frequently encountered species being stolzite. Notable locations of stolzite include the Clara mine and other mines in the Black Forest in Germany, and at Broken Hill and the Cordillera mine in New South Wales, Australia. The Clara, Broken Hill, and Cordillera mines have produced raspite as a mineralogical curiosity and the latter is renowned for the association of the dimorphs with cuprotungstite.

As with molybdate (*see* **Rocks and Their Classification**), polymerization of tungstate in acid solutions yields polymeric species. These are represented in the mineral kingdom by phyllotungstite and rankachite. Both are much rarer than are their molybdenum-bearing congeners and are of academic interest

alone. None of the secondary tungstates represents an economically important source of tungsten.

Vanadates

P A Williams, University of Western Sydney, Sydney, Australia

Naturally occurring vanadate(V) minerals are described here, together with the environments in which they are found. Attention is drawn to the existence of polyvanadates as well as to normal vanadates. In the latter, extensive solid solution involving arsenate and phosphate is evident. The chemistry of polymerisation of vanadate in acidic solution is well understood and is reflected in many examples in the mineral kingdom. Depending upon the prevailing redox potential in the solutions from which such species crystallise, highly coloured, mixed V(IV, V) species are formed, the so-called vanadium bronzes. Significant amounts of vanadium are recovered from secondary vanadate minerals, but much is derived from the treatment of vanadium-rich fly ash and the mining of primary oxide minerals that carry minor amounts of the element.

Vanadates are compounds containing negatively charged oxyvanadium ions and are extremely widespread in the natural environment in small amounts. A list of them is given in Table 1. Nearly all of the vanadates are found in the oxidised zones of base metal ore bodies or in other supergene environments, such as drainage channels and oxidised sedimentary rocks. A few, including wakefieldite-(Y), clinobisvanite, and pucherite occur as accessory minerals in granite pegmatites, while others such as leningradite, averierite, and stoiberite are volcanic sublimates. Many vanadate minerals contain the simple tetraoxovanadate(V) or vanadate ion, VO_4^3 . The arrangement of such minerals under the first heading in Table 1, however, obscures the fact that in many cases complex solid solution phenomena attend naturally occurring examples. Some of the formulae indicate solid solution series where these are found to be significant for all known examples of particular phases. Nevertheless, all of the simple vanadates incorporate other ions in their lattices. With cations, this phenomenon is common and several series are known, including the descloizite-mottramite and mounanite-krettnichite pairs, for example. Solid solution involving anionic substitution is ubiquitous. Phosphate and arsenate frequently substitute for vanadate in these minerals, albeit to different extents. The vanadate ion, VO_4^3 , is somewhat larger than phosphate and arsenate ions, whose thermochemical radii are 230 and 237 picometres, respectively. Other

Table 1 Vanadate minerals

Normal vanadate, oxyvanadate and chlorovanadate(V) minerals	
Averievite	$Cu_5O_2(VO_4)_2$ n(Cu,Cs,K)Cl ($n \approx 1.2$)
Brackebuschite	$Pb_2(Mn,Fe,Zn)(VO_4)_2(OH,H_2O)$
Čechite	$Pb(Fe,Mn)VO_4(OH)$
Cheremnykhite	$Pb_3Zn_3O_2(TeO_4)(VO_4)_2$
Clinobisvanite	$BiVO_4$
Descloizite	$Pb(Zn,Cu)VO_4(OH)$
Dreyerite	$BiVO_4$
Duhamelite	$Pb_2Cu_4Bi(VO_4)_4(OH)_3$ $8H_2O$
Fingerite	$Cu_{11}O_2(VO_4)_6$
Gamagarite	$Ba_2(Fe,Mn)(VO_4)_2(OH)$
Hechtsbergite	$Bi_2(VO_4)(OH)$
Heyite	$Pb_5Fe_2O_4(VO_4)_2$
Howardevansite	$NaCu(Fe,Al,Mn)_2(VO_4)_3$
Kolovratite	$Ni_xZn_y(VO_4)_z$ nH_2O
Kombatite	$Pb_{14}O_9(VO_4)_2Cl_4$
Krettnichite	$PbMn_2(VO_4)_2(OH)_2$

Uvanite	$(UO_2)_2(V_6O_{17})$ $15H_2O(?)$
Vanalite[h]	*ca* $NaAl_9(V_{12}O_{44})(OH)_4$ $33H_2O$

[a] Vanadium bronzes that contain variable amounts of V(IV); stoichiometries are indicative.
[b] Related to minerals of the straczekite group.
[c] Contains V(IV) in a V_4O_{16} cluster linked by phosphate groups.
[d] A heteropolytungstate containing V(V) and W(VI).
[e] A hydrated, mixed Al(III) V(IV,V) oxide cluster species.
[f] Sherwoodite is the calcium salt of the 14 vanadoaluminate heteropolyanion $(AlV_{14}O_{40})^n$, in which a portion of the vanadium is in the V(IV) state.
[g] Contains a V(IV) oxyanion cluster.
[h] Contains a mixed V(IV,V) isopoly or hereropolyanion.

comparable ions, such as silicate, may also substitute with charge balance compensation. Thus, many of the formulae conceal more complex compositions for natural materials, although substitution for vanadate is more limited in many cases than is found for mutually soluble phosphate and arsenate analogues and related minerals.

Separate mention is made in Table 1 of the layered uranyl vanadates, which represent important ore minerals both of uranium and vanadium. Carnotite and tyuyamunite are perhaps the most significant in this respect. All of these species are members of the group of minerals known as the uranium micas. Their structures are based on infinite sheets of linked uranyl

(UO_2^{2+}) and vanadate ions (phosphate and arsenate in the cases of the autunite, meta-autunite, and related groups), with other cations, hydroxide ions, and water molecules lying between the sheets. Limited substitution of phosphate and arsenate is reported for the vanadate minerals, which are extremely insoluble species.

In aqueous V(V) solutions at low concentrations, only mononuclear species are present, these comprising VO_2^+, $VO(OH)_3$, $VO_2(OH)_2$, VO_3OH^2, and VO_4^3. In contrast to this, at higher total V(V) concentrations under acid conditions, extensive polymerisation of vanadate occurs according to the following equations:

$$2VO_4^3 + 2H^+ \leftrightarrow V_2O_7^4 + H_2O \quad \text{(pyrovanadate)}$$

$$3VO_4^3 + 6H^+ \leftrightarrow V_3O_9^3 + 3H_2O \quad \text{(metavanadate)}$$

$$2V_2O_7^4 + 4H^+ \leftrightarrow V_4O_{12}^4 + 2H_2O \quad \text{(metavanadate)}$$

$$5V_4O_{12}^4 + 8H^+ \leftrightarrow 2V_{10}O_{28}^6 + 4H_2O \quad \text{(decavanadate)}$$

Protonated analogues are also present in solution. The pyrovanadates, metavanadates, and decavanadates are all expressed in a number of mineral structures, as listed in Table 1. Metavanadates, in the solid state, consist of infinite chains of VO_3 composition, $(VO_3)_n$.

Divanadate and tetravanadate chains are the basic structural units of many of the vanadium bronzes, also listed in Table 1. These minerals assume a variety of colours, owing to the fact that a variable though usually small proportion of the V(V) present is reduced to V(IV). Consequent variations of stoichiometry are noted as a result of charge compensation and this is an additional feature of other members of the mineral groups containing both metavanadate and decavanadate, and their protonated derivatives. Other vanadium bronzes are based on different structural motifs, but all share the above characteristics in terms of the presence of V(IV) and attendant compositional variation. The natural expression of the vanadium bronzes, exhaustively studied as artificial compounds, is dependent upon subtle fluctuations of redox potential in the solutions from which they form. They, and other vanadium species, are important constituents of sandstone vanadium deposits and their geochemical relationships have been thoroughly explored, based on pioneering studies dating back nearly five decades. The mineral phosphvanadylite contains V(IV) in a V_4O_{16} cluster linked by phosphate groups, but its chemistry of formation remains to be elucidated.

Like the tetaoxomolybdate(VI) and tetaoxotungstate(VI) ions, vanadate forms heteropolyanions in acid solutions. Rankachite and sherwoodite are two examples, the former carrying W(VI) in the cluster and the latter being a naturally occurring salt of the well-known synthetic 14-vanadoaluminate heteropolyanion $(AlV_{14}O_{40}]^n$. No doubt, other congeners exist in nature in line with observations concerning the geochemistry of molybdenum and tungsten.

As mentioned above, vanadate minerals are an important source of the element vanadium. In addition to species already singled out in this connection, vanadinite, mottramite, and descloizite have been exploited as vanadium ores. However, the bulk of present vanadium production comes from vanadium-bearing oxides (principally magnetite) and by-product refining.

Zeolites

W S Wise, University of California–Santa Barbara, Santa Barbara, CA, USA

Introduction

Zeolites are aluminosilicate minerals that occur as low-temperature (generally less than 200°C) alteration products of volcanic and feldspathic rocks. They are well known in cavities of basalt, having crystallized as a result of diagenetic or hydrothermal alteration (Figure 1). Some zeolites completely replace rhyolitic tuff in saline alkaline lacustrine environments or through groundwater percolation. Thick sequences of sediment from arc-source terranes contain several different kinds of zeolite, which formed through diagenetic alteration and very low-grade metamorphism. These occurrences of zeolites have economic significance, because they either produce useful rock or affect the porosity of reservoir rocks.

A zeolite is a hydrated aluminosilicate mineral with a structure characterized by a framework of linked tetrahedra, each consisting of four oxygen atoms surrounding a silicon or aluminium cation. This three-dimensional network has open cavities in the forms of channels and cages, which are occupied by water molecules and non-framework cations. The channels are large enough to allow the passage of guest ionic and molecular species. This feature allows certain zeolites to exchange non-framework cations with the surrounding solution or to act as molecular sieves. For example, clinoptilolite (Table 1) can selectively remove radiogenic strontium from nuclear wastewater, and chabazite can remove carbon dioxide from methane in the gas generated in landfill sites.

Figure 1 Crystals of laumontite and calcite in a cavity in an altered basalt near Kailua, northeast Oahu, Hawaii. This area is within the former conduit system of the 2.6 Ma Koolau volcano. It is likely that the pervasive rock alteration and zeolite formation is a result of hydrothermal activity when the volcano was active. The long dimension of the cavity is 8 cm.

Each zeolite mineral or, in many cases, zeolite series has a different framework arrangement. Table 1 lists the currently recognized zeolite mineral species and series, their generalized formulae, and structure-type codes. Many more zeolites have been synthesized in the laboratory. The Structure Commission of the International Zeolite Association assigns a three-letter code to each different arrangement, including the synthetic ones. At the time of writing there are 145 structure types, of which 42 occur as minerals. For updates see the International Zeolite Association website http://www.iza-structure.org/.

Structure of Zeolites

All silicates have silicon (or other elements such as aluminium) located in the small space between four oxygen anions. This site is called a tetrahedral site because the cation is strongly bonded to the four oxygen anions. In framework silicates each oxygen anion is shared between two tetrahedral sites. Therefore, the resulting framework has two oxygen anions for each silicon cation, giving the composition $Si^{4+}O_2^2$, as in the mineral quartz (*see* **Minerals:** Quartz). Most other framework silicate minerals have aluminium in some of the tetrahedral sites, which results in a charge imbalance. For example, in some feldspars (*see* **Minerals:** Feldspars) the framework has the composition $[AlSi_3O_8]$, and the charge is balanced by the addition of alkali cations in sites near the oxygen anions bonded to the aluminium tetrahedral site.

The zeolite minerals all have framework arrangements with channels or cages (large pockets). In order to illustrate some of the variety among the zeolites, we will examine three different framework structures: natrolite (NAT), chabazite (CHA), and heulandite (HEU).

Natrolite forms long prismatic crystals, in which the basic unit of the structure is the $[Al_2Si_3O_{10}]^2$ chain (Figure 2). Continuous repetition of this unit forms long chains parallel to the prism length. Cross-linking of these chains forms channels parallel to the chains. To balance the charge in the framework, caused by the inclusion of aluminium in two of the

five tetrahedral sites, sodium cations are bonded within the channels (Figure 3). The bonding of these sodium cations to opposite sides of the channel partially collapses the channel from a possible square cross-section to an elliptical one. Each sodium cation is bonded by two water molecules, which are in turn each bonded to two sodium cations.

The crystal form of chabazite is a rhombohedron that is almost cubic. The framework consists of six-member rings of tetrahedra, which are arranged in the sequence AABBCC... (Figure 4). Each different letter represents a different position of the six-member ring around the stacking direction parallel to the *c*-axis. The distribution of aluminium in the tetrahedral sites is nearly random. Non-framework cations partially fill four different sites: (i) outside the double six-member ring and bonded with three oxygen atoms of the ring; (ii) near the eight-member ring port of the chabazite cage and bonded with three framework oxygen atoms; (iii) near the centre of the cage and not bonded with the framework; and (iv) at the centre of the eight-member ring. Positions (i) and (iii) generally contain most of the cations.

Crystals of heulandite and clinoptilolite are tabular with a perfect cleavage. The framework consists of sheets of tetrahedra with no openings large enough

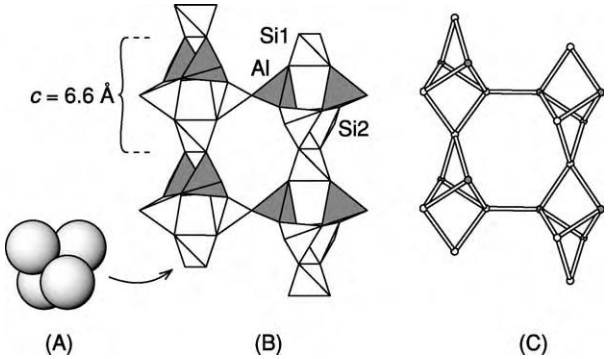

Figure 2 The framework arrangement in natrolite. (A) A representation of four oxygen anions surrounding a silicon cation (unseen). This site can be represented by a tetrahedron by reducing the oxygen spheres to points and connecting the four points with lines, as in (B). (B) Two chains of the natrolite framework. A unit of the natrolite chain consists of a Si1 tetrahedron, two Si2 tetrahedra (all three shown as white), and two Al tetrahedra (grey). The length of this unit, which is repeated continuously along the length of the chain, is 6.6 Å. Si2 tetrahedra connect with Al tetrahedra to link chains together. Because an Al O Al bond sequence is energetically less favourable than an Al O Si sequence, they tend not to occur. (C) Another way to represent the framework arrangement (topology) is to eliminate the oxygen positions and connect the tetrahedral sites with double lines. The method makes visualization of more complex arrangements easier.

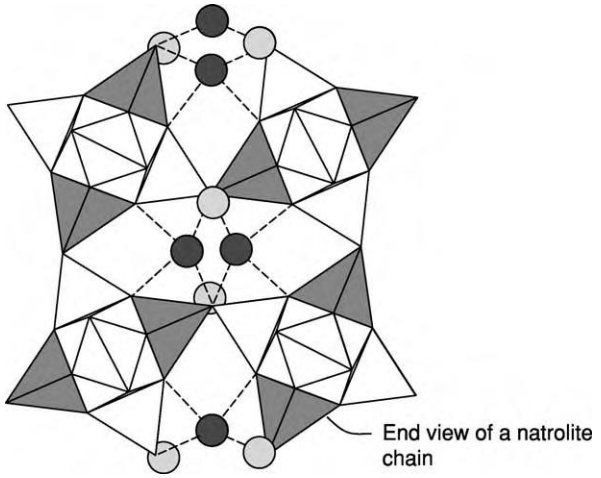

Figure 3 The bonding of sodium cations (dark grey circles) and water molecules (light grey circles) in the channels of natrolite. Sodium cations are bonded to four of the framework oxygen anions between Al and Si tetrahedra (dashed lines show bonds) and to two water molecules, which are located in spaces between linked chains (see **Figure 2**).

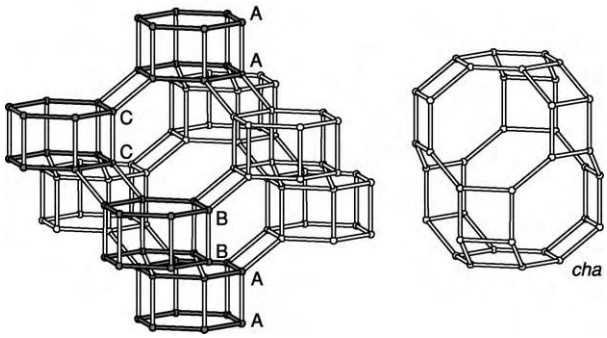

Figure 4 The arrangement of the framework of chabazite, in which only tetrahedral sites and linkages are plotted. A set of six member rings that defines the framework is darkened, to illustrate the stacking sequence AABBCC.... Within the spiral stair stepped linked double six member rings is a large space, called a *cha* cage. For clarity this *cha* cage has also been drawn outside the structure. Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

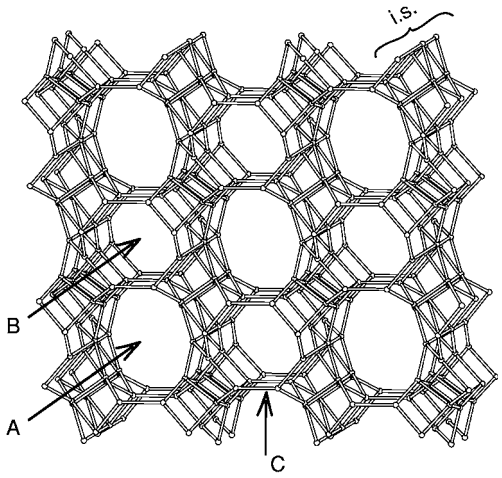

Figure 5 The arrangement of the framework of heulandite and clinoptilolite, in which only the tetrahedral sites are plotted and connected without the bridging oxygen ions. The framework consists of impermeable sheets (i.s.) that are cross linked, forming three different types of channel, A, B, and C; A and B are almost perpendicular to the page, while C is parallel to it. Non framework cations and water molecules occupy various sites within these channels. Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

to allow the passage of ions or molecules. In effect the sheets are impermeable, as shown in Figure 5. The sheets are bonded together with widely spaced oxygen bridges, between which are three different channels. There are relatively few aluminium cations in this structure, leaving the framework silicon-rich, and the distribution of the aluminium is random. Non-framework cations are located along the centres of the channels, weakly bonded to the sides and to surrounding water molecules.

Chemical Composition of Zeolites

A perusal of Table 1 shows that zeolite minerals are for the most part aluminosilicates of sodium, potassium, or calcium, with magnesium, strontium, and barium being less common. There is significant variation in composition between mineral species, but also within several of the species. Compositional variation may occur within the framework, i.e. the amount of aluminium in tetrahedral sites, and in the charge-balancing non-framework cations. One way to illustrate the range of zeolite compositions is with a plot like that shown in Figure 6. This diagram shows the wide range of silicon (or aluminium) content observed among zeolite species, as well as the variability in the non-framework cations.

Some zeolite mineral series exhibit a considerable variation in the framework composition. For example, within the chabazite structure group the silicon content ranges from high, Si/Al = 3.0, giving a framework composition of $[Al_{2.4}Si_{9.6}O_{24}]$, to low, Si/Al = 1.0, yielding $[Al_6Si_6O_{24}]$ in willhendersonite (Table 1). Other mineral series that have wide ranges of framework composition are heulandite, clinoptilolite, and phillipsite. The ratio Si/Al = 1.0 appears to be the lower limit for the amount of aluminium in any framework. More aluminium would require some Al–O–Al bond sequences, which are energetically less stable than Al–O–Si bond sequences.

Detailed structural studies of heulandite, clinoptilolite, and phillipsite indicate that the Si/Al distribution throughout the framework is random. The framework arrangements of other zeolites seem to require a fixed Si/Al ratio, with the aluminium and silicon in specific sites, i.e. an ordered arrangement. A good example is the arrangement and composition of natrolite (Figure 2). Interestingly, this is true only for well-formed crystals. Crystals that are forced to grow rapidly form small crystals with disordered structures, in which the distribution of aluminium and silicon tends to be random and the ratio of Si : Al varies from the 2 : 3 of ordered natrolite.

The ordered frameworks of some species are commonly preferential to one of these cations. For example, the sodium in analcime tightens the framework such that inclusion of calcium in the sodium sites is strongly restricted. Because only one calcium cation is required to balance two aluminium cations in the framework, they tend to distort the structure.

An important chemical property of any zeolite is its ion-exchange capacity, i.e. the extent to which external cations can be exchanged with those naturally present in the structure. High-silica zeolites (Figure 6), for example clinoptilolite, have few aluminium cations in tetrahedral sites, and therefore have few non-framework cations available for exchange. Conversely, the low-silica zeolites, such as phillipsite, have high ion-exchange capacities.

Included in the original definition of a zeolite by Cronstedt in 1756 was the release of bubbles of water vapour upon heating a crystal in a blowpipe flame. All presently recognized zeolite minerals (Table 1) contain water molecules in the channels and cages. In some, such as natrolite, the molecules are tightly bonded, whereas in others, such as clinoptilolite, the water is loosely held. Heating of the zeolite generally releases the water at temperatures of less than about 500°C. Most structures will rehydrate with exposure to a humid environment. The number of molecules listed for each zeolite is one of the least-restrictive features of their composition, because the amount held in the structure may vary with humidity.

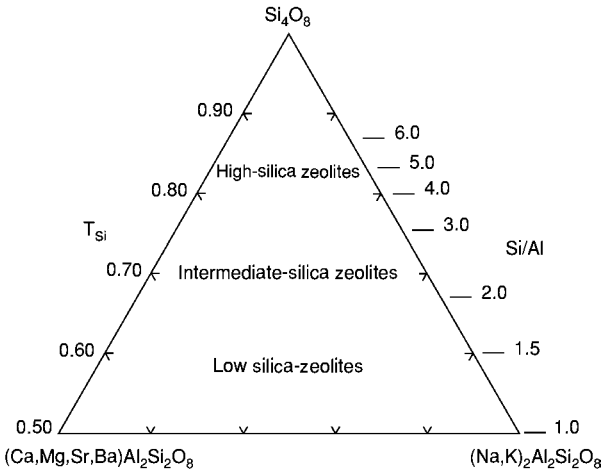

Figure 6 Compositional diagram illustrating major variations of zeolite composition. Components for the plot are: Si_4O_8 (molecular proportion [Si 2(Ca + Mg + Sr + Ba) 2(Na + K)]/4); $(Ca,Mg,Sr,Ba)Al_2Si_2O_8$ (molecular proportion Ca + Mg + Sr + Ba); and $(Na,K)_2Al_2Si_2O_8$ (molecular proportion (Na + K)/2). T_{Si} = Si/(Si + Al). London: The Geological Society.

Occurrences of Zeolites

Zeolite minerals occur in sedimentary, metamorphic, and igneous rocks, almost exclusively as alteration products. Most form at temperatures less than 250°C and at depths less than 10 km in water-saturated environments (Figure 7). The alteration process must produce an abundance of silicon and aluminium along with alkali or alkaline earth elements. This commonly occurs where volcanic materials – lava or tuff – react with surface water or groundwater, or where plagioclase-bearing rock undergoes a reaction with pore fluids.

Zeolites in Sedimentary Rocks

The most widespread and economically important of all zeolite occurrences are in sediments and sedimentary rocks composed partially or wholly of volcanic clasts. During diagenesis (*see* **Diagenesis, Overview**) the volcanic component of these rocks reacts with pore fluids to form clay and zeolite minerals. This alteration can take place in various environments, including shallow alkaline lakes, the deep seafloor, thick terrestrial pyroclastic deposits, and sandstone beds in shallow to deep marine basins. Diagenetic reactions merge with those of burial metamorphism (Figure 7), and the distinction is a matter of the terminology used by researchers in this field. In this review, diagenesis refers to all changes of the initial sediment between deposition and the completion of lithification or cementation, and metamorphism refers to changes occurring after diagenesis, generally involving the breakdown of the first diagenetic minerals in response to increases in temperature and pressure.

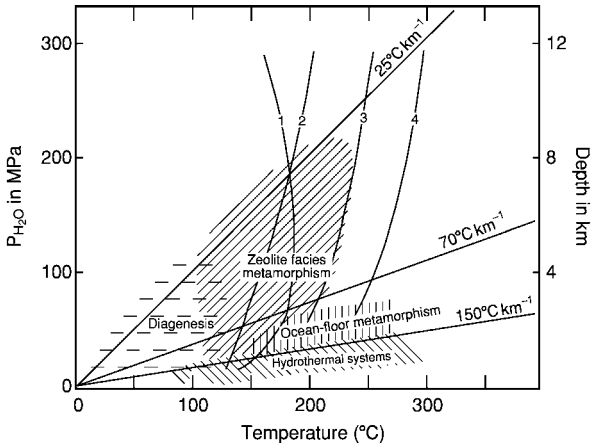

Figure 7 Pressure temperature ranges of environments of zeolite formation. The boundary between diagenesis and meta morphism overlaps considerably more than shown here. Numbered curves are experimentally determined or calculated stability limits of selected zeolites: 1, analcime + quartz albite + water; 2, heulandite laumontite + quartz + water; 3, laumontite + prehnite epidote + quartz + water at low pressure end and laumontite + pumpellyite epidote + chlorite + quartz + water at high pressure end; and 4, laumontite wairakite + water. The depth scale is based on a lithostatic gradient of 25 MPa km ^{1}. Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

Shallow alkaline lakes Beds of zeolite-rich rock a few centimetres to several metres thick occur in several areas of the world, such as the western USA, Serbia, and western Turkey. Clinoptilolite is the most abundant zeolite in these beds, but it may be associated with chabazite, phillipsite, erionite, and analcime. The zeolitic beds are interlayered with silt and were deposited in shallow playa lakes in closed basins. With no outlets, these lakes become saline and alkaline through extended periods of evaporation. Nearby explosive rhyolitic volcanism produced vitric ash that reacted with the alkaline water of the lake to produce the beds of zeolite-rich rock. Figure 8 shows the relationships between mineral zoning and hydrology in this type of environment.

Glass persists unaltered where pore solutions have a pH of less than about 8.5. The clinoptilolite zone may contain other zeolites, such as erionite, chabazite, and phillipsite, all of which pseudomorph glass shards. Analcime, which is abundant in the next zone inwards, replaces both pre-existing zeolites of the clinoptilolite zone and, less commonly, glass shards. Potassium feldspar, dominant in the innermost zone, replaces earlier-formed zeolites. This horizontal zonation of the zeolites and potassium feldspar along a single tuff bed is characteristic of this type of alteration, and puzzling to understand.

A kinetic model has been proposed to explain the formation of zeolites in tuffaceous rocks. The model

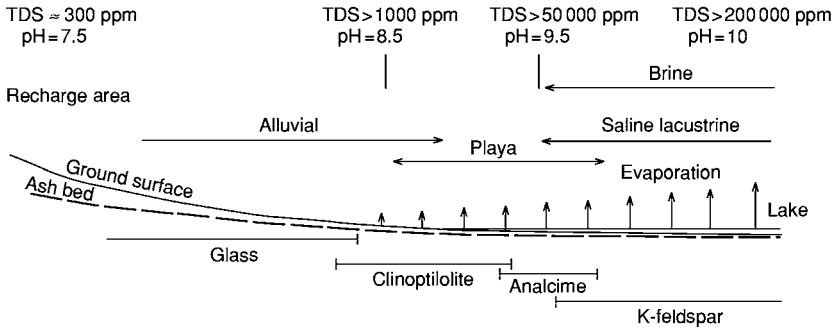

Figure 8 Relationships among hydrology, geology, and mineralogy in a playa saline lake. TDS, total dissolved solids. Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

incorporates the idea that glass dissolution proceeds at much greater rates than stable authigenic minerals, such as analcime and feldspar, can crystallize. The less-stable disordered alkali zeolites (chabazite, clinoptilolite, phillipsite, erionite) nucleate and crystallize readily, lowering the free energy of the system. With time, these metastable phases are replaced by stable ones, but changes in intensive parameters, such as temperature or pH, can greatly accelerate the reaction.

Deep sea sediment Zeolites, predominantly phillipsite and clinoptilolite, occur as a moderate component (5–15%) of many deep-marine sediments that include calcareous ooze and chalk, radiolarian ooze, hemipelagic mud, hyaloclastite, ash layers, or volcaniclastic sand. Zeolite-bearing sediment has been recovered from all parts of all oceans. Phillipsite tends to be common at shallow core depths, while clinoptilolite is more abundant in deeper (and older) sediment. Because phillipsite has been recovered from very near the sediment–water interface, it is believed that initial reactions of seawater with clay and/or volcanic debris occur at or just below the seafloor.

Thick terrestrial pyroclastic deposits Most terrestrial accumulations of volcanic material – lavas and pyroclastic deposits (*see* **Pyroclastics; Lava**) – are subject to alteration by meteoric water and groundwater. Initial alteration occurs as meteoric water percolates through permeable pyroclastic deposits and reacts with very-fine-grained glass, forming smectitic clay and alkaline vadose water (Figure 9).

Above the water table, fresh glass shards persist, even though the outer surface has been altered to smectite, and the very fine particles may be replaced by smectite and opal. Because the water-to-rock ratio is high (between 5 and 10), through-flowing vadose water carries away alkali and alkaline earth cations as they are released from the altering glass surface. The remaining alumina, iron, and silica readily form clay, but zeolite growth is minor. Below the water table, where fluid flow rates are much slower, the water-to-rock ratio is less than one, and zeolite crystallization occurs. At this depth clinoptilolite is an abundant replacement of glass shards and may be associated with chabazite, phillipsite, erionite, and mordenite, along with smectite and a silica phase. At somewhat greater depths, analcime generally replaces shards and pumice lapilli, and fills voids, but in some areas textural evidence suggests that analcime replaces clinoptilolite. At the deepest levels, authigenic albite and potassium feldspar replace pre-existing zeolites.

Compositions of the pyroclastic rock other than rhyolite lead to different zeolitic alteration products.

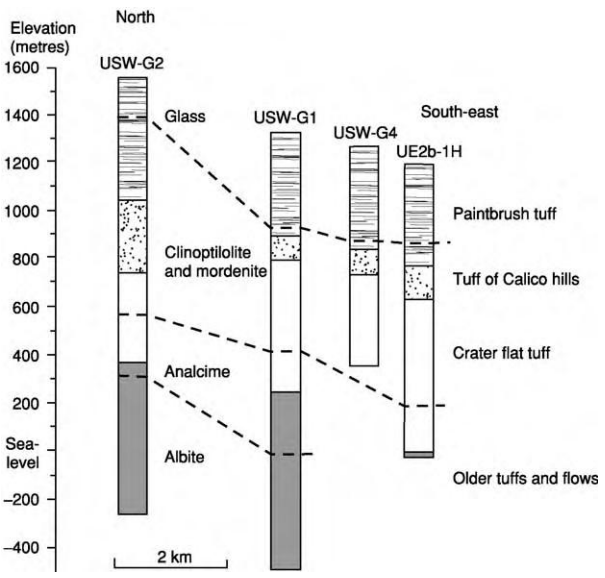

Figure 9 The relationships between diagenetic mineral facies (heavy dashed lines) and ash flow tuff stratigraphy (patterns in columns) at the Nevada Test Site, Yucca Mountain, Nevada, USA. The listed mineral is the dominant diagenetic mineral for that facies. The boundaries are higher to the north (left side of dia gram) because that is the direction of the source of eruptions and presumably the temperatures were higher. Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

For example, phonolitic and tephritic tuffs in Italy alter mainly to phillipsite.

Sandstone beds in shallow to deep basins The largest volumes of zeolite-bearing sedimentary rock are adjacent to volcanic arcs, where volcaniclastic debris is shed into fore-arc or back-arc basins. Depending somewhat on the composition and amount of the volcanic detritus, common diagenetic minerals are clinoptilolite, mordenite, heulandite, analcime, and laumontite. The amount of sediment accumulated in some basins approaches 10 km, such as that now exposed in the Southland Syncline, New Zealand.

In Japan, diagenetic minerals in Tertiary pyroclastic rocks are distributed in the following zones: zone I, unaltered glass; zone II, alkali-clinoptilolite and mordenite; zone III, analcime and heulandite; zone IV, laumontite; and zone V, albite. The boundaries between zones are approximately parallel to stratification. Drilling through these zones in oilfields shows that the zones are temperature-dependent, with the boundary between zones I and II at about 45°C, that between zones II and III at about 85°C, and that between zones III and IV at about 123°C. A similar distribution of zeolite phases is observed in the Southland Syncline, New Zealand, in a general sense,

but is complicated in detail, suggesting that fluid composition, as well as temperature, may play a role.

Because these sequences are so thick, the alteration of the original volcanic material extends beyond diagenesis into burial metamorphism, especially where early-formed heulandite and analcime are replaced by laumontite and albite. In fact, the zeolite and feldspar minerals of zones III, IV, and V in Japan show replacement textures, indicating early metamorphism.

Metamorphosed Rocks

In volcanic rock sequences, laumontite and analcime are common products following diagenesis and are developed through burial, contact, or ocean-floor metamorphism. Burial of sediment derived from arc-terrains, containing abundant volcanic detritus and plagioclase sand grains, produces such zeolite minerals as heulandite during diagenesis. Early minerals are replaced by higher temperature (or more stable) zeolites with deeper burial. The type example of this style of metamorphism, called burial metamorphism, is the Southland Syncline, New Zealand. At higher temperature and pressure, the zeolite phases ultimately give way to prehnite, pumpellyite, and feldspar.

The lowest-temperature zones of thermal metamorphic aureoles in volcanic terrains, lavas, and pyroclastic rocks may contain zeolite assemblages. Laumontite-bearing assemblages are common in the zeolite zone of the thermally metamorphosed tholeiitic pillow lavas and pyroclastic rocks of the Karmutsen Group, British Columbia. Here, too, the zeolite facies assemblages are replaced by the prehnite–pumpellyite facies. Similar sequences of mineral assemblages have been described in the Tanzawa Mountains, central Japan, although the geological history suggests a combination of thermal and burial metamorphism.

Metamorphism of pillow lavas and dykes near mid-ocean spreading ridges, now observed in cores from deep-sea drilling sites and in ophiolite sequences, commonly produces zeolite-bearing assemblages. This style of metamorphism is known as ocean-floor metamorphism; analcime and natrolite occur at the shallowest depths, and laumontite, scolecite, and heulandite occur at somewhat deeper levels.

Zeolites in Lava Flows

Many zeolites occur in cavities in basaltic rocks. Some notable localities are: the Tertiary lavas of eastern Iceland; County Antrim, Northern Ireland; the Faeroe Islands; the Deccan Plateau, India; the Jurassic basalt units of New South Wales, Australia; and the Triassic basalt belts in and near Paterson, New Jersey, and in Nova Scotia, Canada. This type of zeolite occurrence has been widely referred to as 'hydrothermal' in the literature. However, the zeolites in these occurrences may have originated in any of a number of different ways, including: burial diagenesis; burial metamorphism; hydrothermal alteration and metamorphism; reaction with groundwater in areas of high heat and fluid flow (high geothermal gradient); and reaction with surface water during the initial cooling of a lava flow or plug.

Studies of thick accumulations of basalt and andesite in extensional basins have documented regional low-grade metamorphism. In basins along the Andes of Peru and Chile the rocks are little deformed and the metamorphic grade increases with depth from zeolite to greenschist facies.

The effect of depth on zeolite crystallization in subaerial flood-basalt flows is demonstrated by the distribution of amygdale minerals in the basalt lavas of eastern Iceland. Zeolites or assemblages of zeolites define nearly flat-lying zones that cut across the lava stratigraphy (Figure 10). Similar regionally zoned occurrences of zeolite have been described in sequences in the Faeroe Islands, eastern Greenland, western Greenland, the Deccan Traps in western India, the North Shore Volcanic Group of Minnesota, the Parana lavas of Brazil, and Northern Ireland.

In Iceland and Greenland zeolite crystallization did not occur until after the accumulation and weak

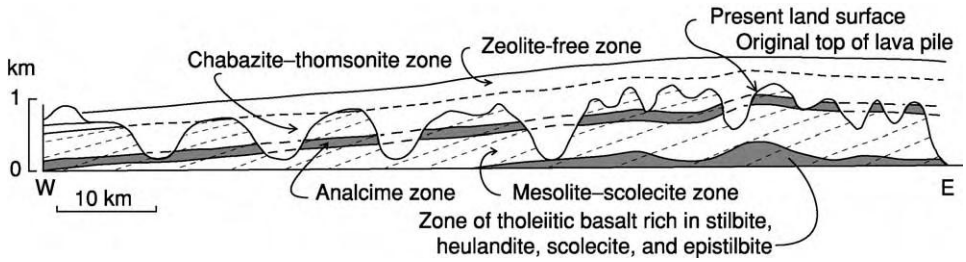

Figure 10 Diagrammatic section through the Tertiary lava pile of eastern Iceland, showing the inferred relationship between the lava stratigraphy (sloping dashed lines) and the distribution of amygdale minerals (subhorizontal bands of grey and white). Reproduced with permission from Deer WA, Howie RA, Wise WS, and Zussman J (2004) *Rock Forming Minerals, Volume 4B Framework Silicates: Silica Minerals, Feldspathoids and the Zeolites*. London: The Geological Society.

deformation of the lava pile, because the zones are parallel to the inferred original surface. The reaction of groundmass glass with interstitial groundwater results in the replacement of the glass by smectite and the crystallization of smectite, celadonite, and zeolites in open spaces. Because the water-to-rock ratio is small, the chemical composition of the glass in the host rock exerts important controls on the Si/Al ratio of the framework and on the non-framework cation content of the resulting zeolites. In the Icelandic sequences, tholeiitic basalt vesicles contain a somewhat different assemblage of zeolites from those in olivine basalt. For example, analcime occurs in olivine basalt, whereas in the same depth zone mordenite is found in tholeiitic basalt. Along with evolving zeolite assemblages, the associated phyllosilicate minerals also change with depth. In the shallowest affected rocks smectite, commonly ferroan saponite, is abundant, and this gives way to mixed-layer smectite–chlorite and ultimately to chlorite with increasing temperature. However, the range of permeability within a single flow can cause variations in the degree of crystallization and in mineral assemblages.

Hydrothermal Alteration

Hydrothermal alteration is a chemical replacement of the original minerals (or glass) in a rock by new minerals where hot water delivers reactants and removes the aqueous reaction products. Hydrothermal systems may develop alteration aureoles within sequences of volcanic rocks (*see* **Tectonics:** Hydrothermal Activity). The best-known examples are in active geothermal areas, where the alteration process is presently occurring. However, the term hydrothermal is also used to refer to the alteration caused by a fluid phase following magmatic crystallization of pegmatitic bodies.

Active geothermal systems Zeolites have been found in drill cores from several active geothermal areas, for example in Japan, Iceland, the Wairakei geothermal field (New Zealand), and Yellowstone National Park (Wyoming, USA). These systems involve warm to hot (70–150°C) water circulating through relatively large volumes of rock. Common zeolites found in this environment are mordenite, analcime, heulandite, clinoptilolite, laumontite, yugawaralite, and wairakite.

Late-stage crystallization and alteration of pegmatitic bodies Zeolites are common phases in the late stages of pegmatite crystallization. Early in the formation of a pegmatite dyke, magmatic crystallization produces the bulk of the minerals, but as the magma is depleted and the temperature decreases excess water forms a fluid phase. This fluid produces minerals at lower temperatures, many as alteration products of earlier phases. Excellent examples of hydrothermal zeolite formation in pegmatite bodies are found in the Lovozero Massif, Kola Peninsula, Russia. Here, all of the pegmatite pods, lenses, pipes, and dykes are nepheline syenite. Some analcime may be magmatic in origin but much of it, along with the very abundant natrolite, is of hydrothermal origin.

Zeolites also occur in vapour pockets late in the crystallization of granitic pegmatite dykes, mostly as a result of the alteration of feldspar either by residual magmatic fluid or by introduced water. Laumontite and stilbite are commonly precipitated along fractures or in miarolitic cavities. A well-known example is the granodiorite pegmatite dykes near San Piero in Campo on the island of Elba, Italy, where mordenite, dachiardite, stilbite, epistilbite, heulandite, and chabazite occur with pegmatite pocket minerals quartz, tourmaline, beryl, pollucite, and lepidolite.

Fractures and cavities in granitic gneiss Gash fractures formed by the semi-brittle deformation of granitic gneiss may fill with water before the rock has completely cooled, and new minerals may crystallize in the open space. These are the well-known alpine clefts, which contain chlorite, adularia, and quartz crystals that grow at the expense of wall-rock minerals. In some cases reactions continue, producing zeolites such as stilbite, heulandite, scolecite, and chabazite.

Alteration along faults An early discovery in the drill hole into the San Andreas fault zone at Cajon Pass, southern California, was the pervasive occurrence of laumontite and stilbite in shattered granodiorite and gneiss. Both minerals replace plagioclase and fill microfractures throughout the fault zone. This mineralization is attributed to groundwater circulation in fractured and frictionally heated rocks within the fault zone.

Uses of Zeolites

In those areas of the world where beds of vitric tuff or other volcanic-rich sedimentary rock have been altered to nearly pure zeolite, the deposits are suitable for economic exploitation. Over the past 40 years considerable effort has been directed towards finding uses for those zeolites that occur in relative abundance. Applications have been developed in agriculture, in wastewater treatment, in gas separation or enrichment, in building construction, as catalysts, and in energy storage from solar collectors. The most common zeolite

occurring in large quantities is clinoptilolite, so most applications involve this mineral.

The cation-exchange capacity, cation selectivity, and molecular-sieve property of bulk zeolites are being applied to various aspects of agriculture. Some of the beneficial effects of using clinoptilolite are improved growth and feed utilization, improved eggshell quality in chickens, reduced free ammonia in the rumens of sheep and cattle, and reduced exposures to ammonia and odours in feed lots. Zeolites are used in soil conditioning to improve plant productivity, increase fertilizer efficiency, and aid remediation of soils. For example, clinoptilolite-bearing tuff is used to increase the yield of wheat in Azerbaijan. Zeoponics is a new method of plant growth, using artificial soil with zeolite as a major component. As in other agricultural applications, the zeolite helps to control soil solutions.

The selectivity of clinoptilolite for certain heavy metals is the basis for many applications in water and wastewater treatment. Examples are the removal of ^{137}Cs from contaminated waters resulting from the Chernobyl accident and the removal of copper from electroplating effluents.

The molecular-sieve property of many zeolites is used to separate gases. Phillipsite has been shown to have adsorption selectivity of ammonia over methane in gases from coal gasification. In Japan activated mordenite is used to increase the oxygen in air for steel making, and in the USA chabazite is used to separate carbon dioxide from methane in gas from a landfill site in southern California.

Where zeolitic tuff is abundant it has been used as a dimension stone at least since Roman times to construct castles and cathedrals in Italy and other countries of Europe. These tuffs are also used as a constituent of lightweight aggregate, as in the production of pozzolanic cement.

Although most zeolites used as catalysts are synthetic and made for specific applications, a few natural zeolites have also been tried. Natural ferrierite has been shown to be an effective material as a Claus tail-gas catalyst, to remove elemental sulphur from gas streams, and natural mordenite is effective in the hydroisomerization of n-hexane, with results similar to those of synthetic mordenite.

Glossary

Hydrothermal alteration Alteration of a host rock by hot water percolating through fractures, generally where the water-to-rock ratio is very large.

Metastable zeolites Those zeolites that crystallize quickly but are later replaced by more stable phases (zeolites or feldspars).

Oxygen bridge The oxygen anion between two tetrahedral sites.

Tetrahedral sites The space between four tightly held oxygen anions.

Zircons

G J H McCall, Cirencester, Gloucester, UK

Introduction

The word 'zircon' is very old; the word in Arabic, *zarqun*, is said to derive from the original form of the word in Persian *zar* ('gold') and *gun* ('colour'). Zircon is an orthosilicate mineral with the formula $ZrSiO_4$. Its hardness on Moh's scale is 7.5 and it is slowly attacked by hot concentrated sulphuric acid. Its density is 4.6–4.7. Its fracture is uneven and may be conchoidal in metamict varieties. Its streak is white. Some of the properties of zircon are given in Table 1.

Structure

Zircon is tetragonal (Figure 1), with a unit-cell structure where $a = 6.61$ Å and $c = 5.99$ Å. X-Ray diffraction analysis shows that each zircon atom is surrounded by a tetrahedral group, with four oxygen atoms surrounding a central silicon atom (Figure 2).

Chemistry

Zircon always contains an amount of hafnium, with the HfO_2/ZrO_2 ratio varying. The amount is usually minute, but certain zircons from Norway contain up to 24% of HfO_2. Hafnian zircon occurs mainly in pegmatites. Zoned crystals of members of the zircon–hafnon series from Mozambique were described by Correia Neves and colleagues in 1974; these crystals ranged from hafnian zircon to zirconian hafnon to hafnon ($HfSiO_4$). Zircon is thus a source of hafnium and well as zirconium. Phosphorous may also replace silicon. Zircons often contain rare earth elements and may be metamict (amorphous). Yttria, which is commonly present, is related to the isostructural nature of xenotime (YPO_4) to zircon. Some metamict zircons are mixtures of silica, cubic ZrO_2, and baddeleyite (monoclinic ZrO_2). Uranium and thorium are present in zircons from granites, a property that makes zircons valuable for radiometric age determinations. Chemical analyses of zircons from two geographical locations are given in Table 2.

Table 1 Properties of zircon

Property	*Description*
Refractive index	Optically positive ω 1.923 1.960 ε 1.961 2.015
Birefringence	δ 0.042 0.065
Dispersion	Very strong D
Cleavage	{110} imperfect, {111} poor
Twinning	Rare, on {111}; some zoning may occur

Occurrence

Zircon, a commonly occurring accessory mineral in igneous rocks, is fairly common as a detrital mineral in sediments and is also found in metamorphic rocks. It is always present in ancient shoreline concentrations of heavy minerals ('black sands'); on the coasts of Queensland–New South Wales and Western Australia (Capel, Yoganup, and Eneabba), it is typically subordinate to ilmenite and rutile.

Gemstone Zircon

Mined for a very long time for gemstone purposes in Ceylon (Sri Lanka), zircon did not really become popular until the 1920s. It is perhaps the most variable of the gemstone minerals, and its legendary mystical qualities are now known to be due to the contained radioactive elements. Grains in alluvia and heavy mineral sand deposits are commonly rounded by erosion and do not possess the full crystalline shape, short to long columnar prisms with bipyramidal terminations. Zircon has the second highest index of refraction after diamonds; the dispersion gives it an intensive lustre and cut stones have a vivid fire. Though zircon is quite hard, it is brittle and it is susceptible to damage by scratch marks. The radioactive elements in zircon do with time destroy the internal structure, producing the metamict forms, and such crystals are of lower than gemstone quality. Zircons of this type are classified as 'low quality'. Those not metamict are classified as 'high quality', and there may be varieties classified as 'intermediate'. Table 3 shows how the optical properties vary systematically with the amount of radioactivity. Heating up to 800–1000°C transforms minerals of intermediate and low quality to high quality, with colour changes, and the colour varies according to whether an oxidizing or reducing atmosphere is present during the heating. Pale blue 'starlite' and straw-yellow 'jargoons' are popular. Colourless, lucid zircon gemstones have been incorrectly termed 'Matura diamonds'. Artificially produced zircons may change colour over time, either growing pale or returning to their original hue. Gem-quality zircons never occur as very large crystals and are mined from placer deposits in Sri Lanka, Cambodia, and Thailand. Some natural gem-quality zircons are shown in Figure 3. Zirconia is an artificial imitation of diamond, a double oxide of zirconium and yttrium.

Zircon as an Economic Heavy Mineral

Zircon occurs typically in placer deposits (Table 4). The placers in which zircon occurs are commonly known as 'black sands'.

Beach Placers

The most important minerals in beach placers are cassiterite, diamond, gold, ilmenite, magnetite, monazite, rutile, xenotime, and zircon. Black sand deposits commonly contain ilmenite, monazite, rutile, xenotime, and zircon, all valuable minerals. Ilmenite may be dominant, as in Travencore, India, and Capel/Yoganup, Western Australia, but elsewhere rutile is dominant, as in the deposits of Queensland and Eneabba, Western Australia. Recent marine placers occur at different levels, owing to Pleistocene sea-level changes, and they may be many kilometres inland, as at Eneabba. The tidal zone and wave-cut terraces are optimum situations for such deposition.

Table 3 Variation in optical properties with amount of radioactivity

Classification	*D*	*ω*	*ε*	*δ*	*Radioactivity*
Normal zircon	4 6 4 71	1 924 1 934	1 970 1 977	0 036 0 053	Low
Intermediate	4 2 4 6	1 903 1 927	1 921 1 970	0 017 0 043	Medium
Metamict zircon	3 9 4 2	1 782 1 864	1 827 1 872	0 0 008	High

Table 4 Classification of placers

Mode of origin	*Class*	*Alternative classification*
Accumulation *in situ* during weathering	Residual placers	Eluvial
Concentration in a moving solid medium	Eluvial placers	Colluvial
Concentration in a moving liquid medium (water)	Stream or alluvial placers, beach placers, offshore placers	Fluvial, strandline, marine placers
Concentration in a moving gaseous medium (air)	Aeolian placers	Desert aeolian, coastal aeolian

In Eastern Australia, these deposits of rutile and zircon occur over a stretch of 900 km in a strip 13 km wide, the thickness of the deposits averaging 30-40 m. Typical sites of beach placer deposition are shown in Figure 4. Deposition is by wave and shore current action. Preservation of beach deposits of heavy minerals would seem to require either progradation or sea-level fall, to shield the deposits from further erosion. The two shorelines in south-west Western Australia are shown in Figure 5, and cross-sections of the deposits there are shown in Figure 6 (Eneabba and Yoganup).

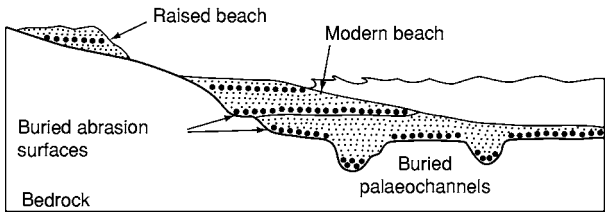

Figure 4 Typical sites of deposition of beach placer deposits. Reproduced with permission from Evans AM (1993) *Ore Geology and Industrial Minerals*, 3rd edn. Oxford: Blackwells Science Publications.

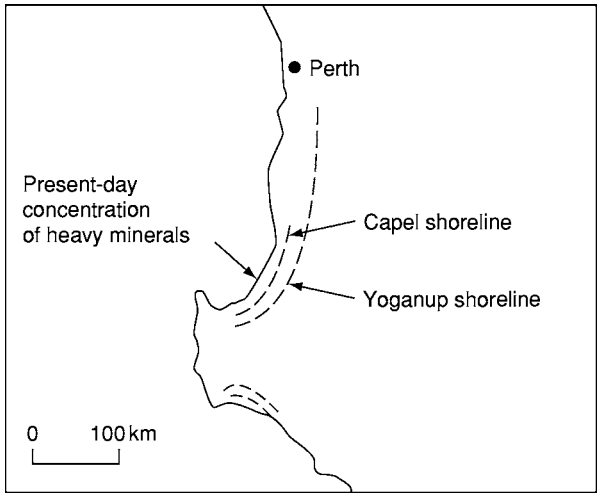

Figure 5 Sketch of the coastline in south west Western Australia, showing the two shorelines of the younger (outer) Capel deposit and older (outer) Yoganup deposit of heavy minerals. The Eneabba deposits are about 300 km north of Perth and include an older beach deposit, about 25 km inland from the present coast, as in the case of the Yoganup deposit, and aeolian dune concentrations in the Jennings part of the Eneabba deposits just to the east of the beach placers. The Eneabba deposits are dominated by rutile whereas ilmenite is dominant in the south. Reproduced with permission from Evans AM (1993) *Ore Geology and Industrial Minerals*, 3rd edn. Oxford: Blackwells Science Publications.

Aeolian Placers

Aeolian placers are formed by reworking of the beach placers by wind. The coastal dunes that are created in this way may have a great volume and may be an important economic source for extraction of heavy minerals, even if of low grade. Three types of dunes may contain mineral deposits: foredunes, transgressive dunes that have moved inland from the beach area, and cliff-top dunes. Aeolian placers may be minor and subsidiary to large beach placer deposits, but they may be large and contain deposits in their own right. The Jennings deposit at Eneabba appears to have formed as a cliff-top dune, whereas the deposits just to the west of it are beach placer deposits. High-grade deposits of rutile and zircon occur in dunes at Richards Bay, Natal.

World Production

Australia is by far the biggest producer of zircon, with 70% of the world's supply; zircon deposits are found in other regions of the world (Figure 7), primarily in South Africa. World production of zirconium mineral concentrates is shown in Table 5.

Mining and Processing

Heavy mineral sands are extracted by dredge (Figure 8), bucket-wheel excavators or draglines, and bulldozers. The raw material is then processed, first by gravity concentrators, to remove light minerals; the concentrate is scrubbed and dried, ilmenite, leucoxene, and rutile being removed by magnetic and high-tension techniques (Figure 9). The remaining minerals are then separated by a system of spirals, gravity tables, high-tension separators, magnets, and air tables to produce zircon. The complex process requires large plants on site: the different minerals of economic interest are separated at the plant location because transport of the raw mined material would be prohibitively costly. Mining these deposits is usually done under a requirement to restore the land, and at Capel in Western Australia, the land is restored to agricultural use.

Uses

The production of zirconia (ZrO_2) for ceramic refractory purposes is the main usage of zircon, but about 10% has a variety of other uses, in ferro alloys, paints, pharmaceuticals, and abrasives. Zircon is also used in leather tanning, chemical manufacture, and in nuclear industries, the latter requiring high-purity zirconium metal and extraction of the ~2% of hafnium contained in the zircon. There are foundry uses and alloy uses, including use in welding rods and sandblasting. The hafnium contained in the zircon is used in unalloyed form in nuclear reactors. Hafnium carbide is also one of the most refractory materials known.

Zircon Analyses

Zircon has a unique status as a key mineral for placing the evolution of Earth within a clear framework of precisely measured time.

Radiometric Geochronology

Before 1896, when Henri Becquerel discovered radioactivity, estimates of the ages of minerals, rocks, and Earth were dependent on theological dogma, outright

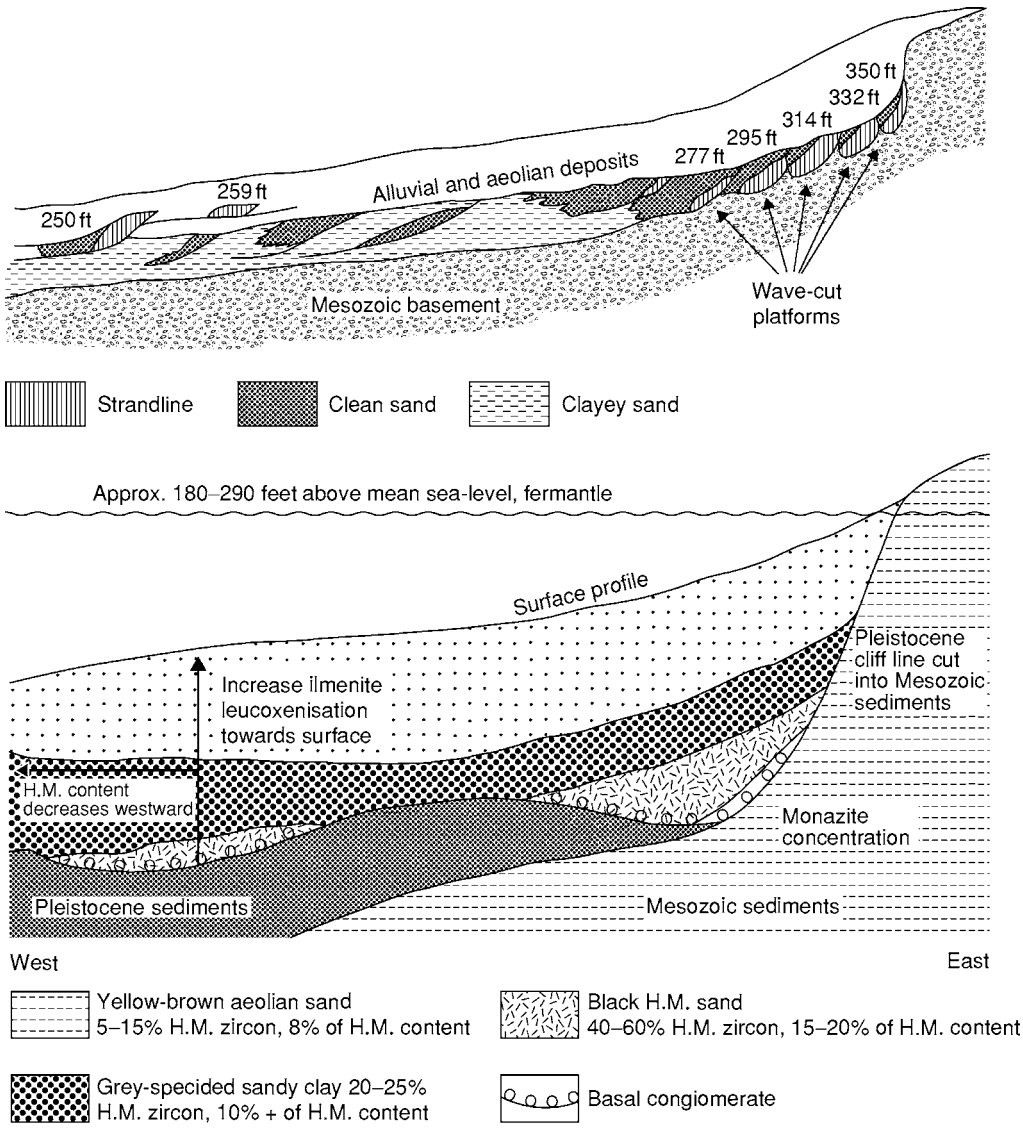

Figure 6 Cross section of the Eneabba (top) and Yoganup (bottom) beach placer deposits. H.M., Heavy mineral. Horizontal scale, 1:120; vertical scale, 1:24. Reproduced with permission from Evans AM (1993) *Ore Geology and Industrial Minerals*, 3rd edn. Oxford: Blackwells Science Publications.

speculation, or crude physical measures (e.g., estimates based on ocean salinity). By 1903, Marie and Pierre Curie had been awarded the Nobel Prize in physics for showing that a radioactive parent element decays to various daughter elements at a constant rate, and this laid the foundations for precise physical measurement of mineral and rock ages. Despite Wilhelm Rutherford realizing in 1905 that the decay of U to He and Pb provided a powerful technique for this purpose, precise dating methods were slow to develop, awaiting the discovery of isotopes by JJ Thomson and the development of mass spectrometric techniques in the 1920s by Francis Aston and Alfred Nier. It was not until the 1940s that that a wide variety of decay schemes were tested in succession (U–Pb, K–Ar, K–Ca, Rb–Sr, Lu–Hf, Re–Os, and Sm–Nd). The basic requirements are (1) that the radioactive parent element is reasonably abundant geologically, (2) that, in the sample, the daughter element remains bound with the mineral in which it formed over time, and (3) that the latter can be distinguished reliably from any concentration of the same element that may have been originally present in the mineral or rock.

Zircon Samples

Zircon forms an ideal sample material with respect to the U–Pb decay scheme, because it is an abundant

accessory in a wide range of igneous, metamorphic, and epiclastic/pyroclastic sedimentary rocks. Its structure is such that it normally does, at the time of crystallization, accommodate trace quantities of U at levels sufficient for precise analysis, and the daughter Pb tends to be retained tightly. The double isotopic decay of ^{238}U to ^{236}Pb and ^{237}Pb provides a check on any loss of radiogenic Pb. Early on, in the 1950s, the method required milligram quantities (thousands of grains) of zircon, which were separated into fractions of varying magnetic susceptibility, dissolved in acid, and isotopically analysed by conventional thermal ionization mass spectrometry (TIMS) in ion-exchange columns. Improved techniques later allowed individual zircon crystals or parts of them to be analysed.

Sensitive High-Resolution Ion Microprobe Technique

In the 1980s, the sensitive high-resolution ion microprobe (SHRIMP) technique was successfully developed at the Australian National University, Canberra, based on secondary ion mass spectrometry (SIMS). In SHRIMP analysis, a focused beam of oxygen ions sputters the surface material of a mounted and polished zircon crystal into a high-voltage field, which accelerates a complex mix of ions through an electrostatic separator and then through a conventional magnet, as in the TIMS instrument. Experimentally difficult and time-consuming stages of dissolution and ion-exchange are eliminated. SHRIMP analysis has the advantages of being faster than TIMS analysis, is essentially non-destructive, and allows analysis of very small spots ($\sim$20 μm in diameter). A disadvantage is that SHRIMP analysis requires analysis by TIMS of a standard natural zircon crystal with perfect internal homogeneity and large enough for the crushed fragments to be supplied to and used by different laboratories. In practice, finding such a standard has proved difficult. In addition, the physics of the sputtering process is poorly understood and there may be an in-built bias in isotope ratios derived.

The internal complexities of zircons have been studied in great detail using SHRIMP, particularly using electron backscatter images. Age can vary significantly within a single zircon crystal. Euhedral prismatic zircons from granites commonly contain rounded cores inherited from source rocks, and high-grade orthogneisses contain patchy areas that yield

reset metamorphic ages, rather than the original igneous age. Such ages may have no geological meaning, but development of a combination of TIMS and SIMS methods, supported by field studies, goes beyond the

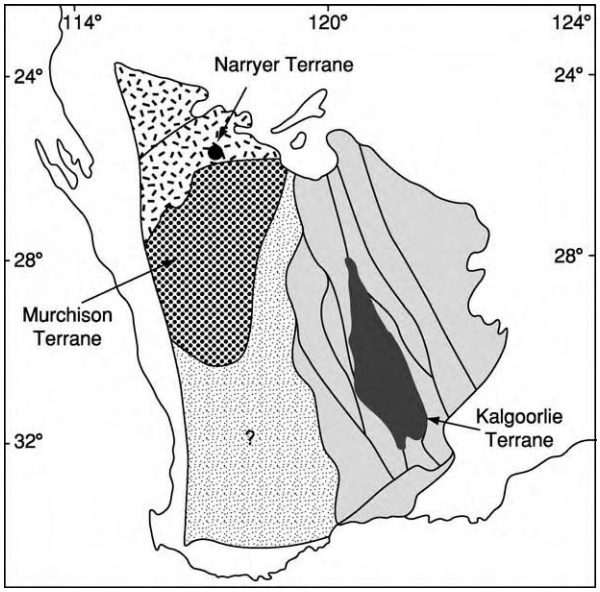

Figure 10 Location of the Narryer Gneiss Complex and Jack Hills, Western Australia.

limits of zircon geochronology based on igneous rocks, allowing complex metamorphic histories and the source rocks of sedimentary basins to be deciphered. This is a field of research that is really only just opening up.

Amelin and co-workers reported in 2001 on detrital zircons aged between 3.90 and 4.25 million years; these zircons came from the Jack Hills within the Narryer Gneiss Complex, Western Australia (Figure 10). The host rock is a metaconglomerate. Separation for SHRIMP analysis was possible for a large number of ancient grains. The experiments were carried out on SHRIMP-II at the Geological Survey of Canada, Ottawa, on 605 detrital grains from sample W74 of the metaconglomerate. Ages between 4000 and 4100 million years were found for 86 grains and 17 gave ages between 4100 and 4250 million years. Wilde and colleagues have found two zircon grains with an age of 4404 ± 8 million years using the same sample. Some grains are uniform but others show oscillatory zoning. Analysis on some spots within crystals gave no significantly different values. Some grains have visible uniform rims overgrown on zoned zircon, but, again, there is no discordance in age. A few had younger rims (3580–3650 My) and several 4100- to 4150-My-old grains have 4100- to 4150-My-old rims. These ancient zircons are not only the world's oldest dated minerals, they preserve a record of the terrestrial crust formed 100–400 My earlier than the oldest known rocks. The earliest known evidence for liquid water and a terrestrial hydrosphere comes from the 3.85-Gy-old sediments (including

banded ironstones) of south-west Greenland. The evidence derived from the Mount Narryer zircons (including oxygen isotope ratios) strongly implies that water existed on Earth at 4.4 Ga. Life may even have developed by this time, within the Hadean.

Overgrowths on Zircons

Dating of sedimentary rocks by radiometric methods has long been a difficult matter and has been achieved only to broad limits by dating igneous intrusions into them or concordant lava flows or tuffs close to the sedimentary stratum concerned. Authigenic overgrowths on zircon, a mineral that is formed at high temperature and is insoluble in groundwater, have long attracted attention. They are composed of xenotime, essentially yttrium phosphate (Figure 11). Such overgrowths occur in the Millstone Grit (Carboniferous, Namurian) of northern England. Though diagenetic glauconite has been radiometrically dated, it suffers from the defect that it is prone to postdepositional alteration. The SHRIMP technique has recently been applied to such xenotime outgrowths (xenotime contains traces of radioactive elements). The outgrowths have been shown to precede all other authigenic minerals such as quartz, and are thus thought to be very early diagenetic deposits. The xenotime is precipitated from seawater with other biogenic phosphates shortly after burial, in a zone of high bacterial activity and sulphate reduction. Xenotime outgrowths thus provide a method of obtaining what is virtually the age of deposition of a sedimentary rock, by radiometric methods. The method can be applied to rocks of any geological age, to date strata directly. This new method is especially important in the case of sedimentary rocks devoid of fossils.

Exploration Boreholes

M Vaněček, Charles University Prague, Prague, Czech Republic

Introduction

Exploration boreholes are the primary tools used in the preliminary investigation of coal and industrial mineral deposits. Complex ore deposits are studied by means of boreholes in the initial stages of prospecting and exploration. The most frequently used technique used is core drilling. The reliability of the results of exploration drilling depends on core recovery, which is influenced by choice of method and equipment (e.g., type of flushing, use of special core barrels, bit design). Correct interpretation depends also on correct assessment of the borehole inclination.

Borehole Drilling

The drilling of boreholes for mineral exploration is practised with the aim to locate mineral deposits, to define their extent and reserves, to determine hydrogeological and engineering geological conditions, and to take samples for laboratory investigations (chemical assays, dressing characteristics, etc.). Drilling intercepts yield satisfactory data in the case of mineral deposits that are not very complex, such as sedimentary deposits and other deposits forming more or less homogeneous mineral bodies. Exploration of homogeneous mineral bodies by means of drilling is usually made in square or other regularly shaped grids. If any feature of the mineral body has an anisotropic distribution, the exploration grid should be rectangular, with shorter distances between boreholes orientated in the direction of the changing feature. Where ore deposits dip, the exploratory boreholes are arranged in profiles perpendicular to the strike of the mineral body. The entire ore deposit, however, cannot be explored in detail without complete mining operations.

Rotary core drilling is the most commonly used drilling technique for creating exploration boreholes. Drilling machines rotate an annular bit to cut a narrow kerf around a central core and thus obtain unaltered samples of the drilled rocks. The core is cut by a tungsten carbide or diamond-studded drill bit and is collected in the core barrel (**Figures 1** and **2**). When the depth of the ore body is relatively shallow, the core barrel containing the cut core is retrieved by pulling the entire length of the drill stem. If the target interval is deep and a considerable number of drill

stem rods are involved, then a wire–line system is more feasible. In this case, double-tube core barrels are used; the inner barrel is removed from the bottom of the borehole by means of wire and is thus retrieved without having to bring the drill stem rods to the surface. Use of the wire–line system is limited, depending on the hardness of the rocks being drilled. If the rock is very hard, drill bits may be destroyed in a short time and the entire drill stem will have to be retrieved frequently.

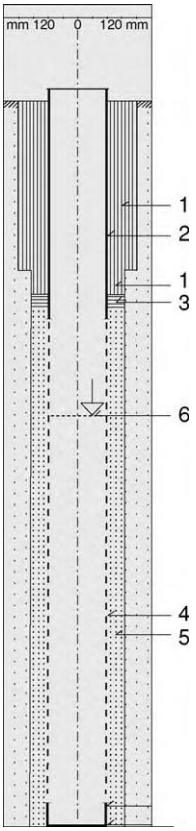

Figure 4 Detail of the hydrogeological borehole casing. 1, Cementation; 2, full casing; 3, sand; 4, perforated casing; 5, quartz pebbles (graining, 4 8 mm); 6, underground water level detected.

Special drilling machines have been designed for drilling exploration boreholes from locations below the surface (Figure 3). In comparison with surface-drilled boreholes, which may extend for some hundreds of metres, the length of subsurface-drilled boreholes usually does not exceed 50–100 m. These boreholes are drilled, often from one location, with different inclinations, from vertical to horizontal. Geological cross-sections are then based on results of fans of boreholes.

Assessment of mining conditions for mineral deposit development or extraction sometimes requires special hydrogeological approaches to exploration drilling. In these situations, the borehole casing is perforated at the underground water horizons (see Figure 4). The boreholes can be drilled using any of non-coring techniques (rotary drilling, percussion drilling, rotary–percussion drilling, etc.).

Core Recovery

One of the main problems encountered in exploration drilling is core recovery. There is a general expansion

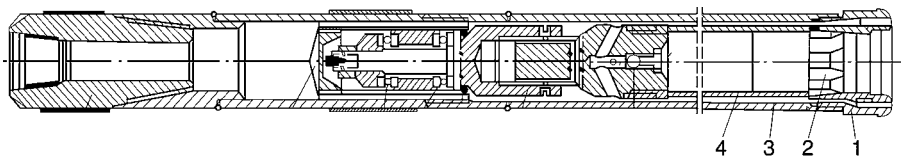

Figure 5 Double tube core barrel for exploration of coal deposits. 1, Diamond bit; 2, core breaker; 3, outer tube of the core barrel; 4, inner tube of the core barrel.

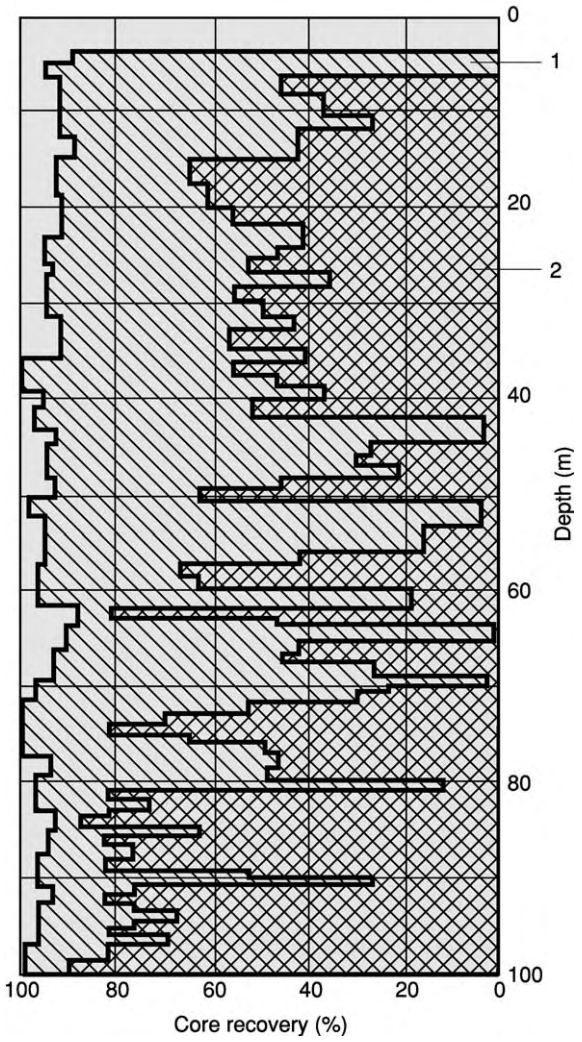

Figure 6 Comparison of the core recovery from two boreholes drilled in identical geological conditions. 1, Drilled using benton ite mud flushing; 2, drilled using water flushing. Modified with permission from Tkaný Z, Juránek O, and Brych J (1966) *Deep Diamond Drilling* (in Czech). Prague: Technical Literature Publ. House (SNTL).

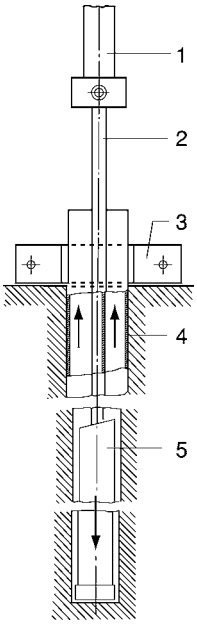

Figure 7 Detail of direct flushing tubular drill rod. 1, Drill head; 2, drill stem; 3, casing clamp; 4, casing; 5, core drilling string.

of core sample length on removal of the sample from the core barrel, related to fracturing of rocks during the drilling process. If soft rock intercalations exist in the borehole location, the core sample is likely to be lost. Because it may not be possible to determine the presence or position of soft rock prior to drilling, use of double-tube (Figure 5) or even triple-tube core barrels may increase the chances of obtaining 100% core sample recovery.

Core recovery may also depend on the type of flushing medium used. The effect of using water versus bentonite mud as the circulation fluid is shown in Figure 6. Circulation media (water, clay mud, or air) may be pumped into drill holes through the inner part of a tubular drill rod (Figure 7); in counterflush drilling, media are injected into drill holes through the annulus between the wall casing and the drilling pipe or, more often, between the inner and outer wall pipes (see Figure 8). Counterflush drilling, also called reverse-circulation drilling, has the distinct advantage over normal rotary drilling of providing relatively complete and uncontaminated samples. Though the method is considerably slower and more expensive than normal rotary drilling is, it is used increasingly in contemporary explorations of mineral deposits. Costs incurred in reverse-circulation drilling depend on geological formation hardness.

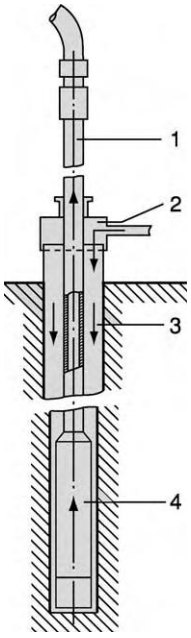

Figure 8 Detail of reverse circulation flushing drill. 1, Drill stem; 2, flush head; 3, casing; 4, core drilling string.

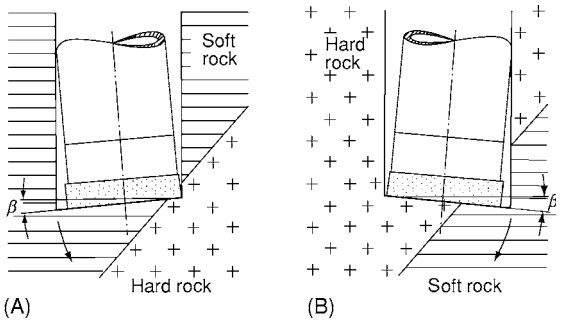

Figure 9 Change in the borehole inclination at the boundary between two layers. (A) Transition from soft to hard rocks. (B) Transition from hard to soft rocks.

Correct interpretation of exploration drilling results requires knowledge of the course of the drilled boreholes, which also relates to rock hardness. For example, if a drill bit reaches a boundary between two layers with different levels of hardness, the inclination of the borehole may change (see Figure 9) and the hole may become crooked and off-course.

Drill Bits

Drill bits of different geometry and design are used for core drilling. Surface-set bits contain a single layer of big diamonds, layered bits are made of diamonds of medium size and small size, and impregnated bits have diamond fragments distributed irregularly throughout the copper matrix of the crown. Core bits with tungsten carbide are made either with tungsten carbide inserts or with cutting edges hardened by welded-on grains of tungsten carbide. Non-coring diamond bits may be used when a core is not desired. The lack of core may be compensated by geophysical logging (recording changes in lithology, resistivity, temperature, porosity, hole diameter, etc., using special probes).

Exploration

N C White, Brisbane, QLD, Australia

Introduction

Mineral exploration aims to discover deposits of minerals and rocks that can be used to meet the resource needs of society. It encompasses the search for industrial raw materials (e.g., clay, limestone, sulphur, salts, and fertilizer minerals and rocks), ores from which metals are extracted (e.g., iron, copper, and zinc ores), and gemstones (diamonds, sapphires, and opals), and includes the search for solid fuels (coal, oil shale, and uranium) but not liquid or gaseous fuels (petroleum and natural gas). Mineral exploration can be as basic as prospecting, using elementary techniques such as panning for gold, or it can be very sophisticated, involving the use of complex technology for data gathering and interpretation. This article considers our need for mineral resources, why different groups explore for minerals and the strategies they adopt and the tools they employ, what success and failure mean in the industry, the role of governments, and the future of exploration.

Our Need for Minerals

Human beings have always been dependent on natural materials to satisfy the needs of everday life. All these materials must come from Earth, either grown as plants or animals or extracted as rocks, minerals, or fossil fuels. Some of the rocks and minerals that are important in everyday life are readily available, but many are not, and we must search for them: that search is what exploration is about.

The importance of rocks and minerals to humankind is conveyed by terms such as 'stone age', 'bronze age', 'iron age'; the emphasis on stages in the evolution of technology and civilization is related to our mastery of different rocks and our understanding of the metals that can be extracted from them. In modern civilization, there is amazing diversity in the rocks and minerals we use and in the variety of ways in which we use them. Some mineral resources are used directly, with little processing apart from shaping, polishing, crushing, or sizing (e.g., rocks used for building, aggregate used for road-making, talc used in talcum powder, or gemstones used in jewellery). Many mineral resources are consumed in industrial processes that transform them into new products (e.g., clays used to make bricks or ceramics, silica sand used for glass-making, limestone used to make lime or cement, or phosphate rock used for superphosphate fertilizer). The large group of rocks we call ores (e.g., iron, copper, and gold ores) are important because of the metals they contain. Other rocks and minerals are used in industrial processes because they aid the processing of other materials, not because anything will be extracted from them (e.g., many rocks and minerals are used as flux in smelting).

Who Explores for Minerals, and Why?

The motivation for mineral exploration is the same as for many other human activities: either we need the materials we seek or, by satisfying other people's needs, we can earn money. Though exploration is necessary to maintain the supply of essential raw materials, individuals or corporations undertake exploration for a variety of reasons, but underlying them all is the belief that there will be a good commercial return from what is discovered. The commercial return may come from selling the deposits that are discovered, from setting up a company based on the discovery and trading the company's shares, from starting a mine and selling the products, or from using the products as feed in some downstream business based on the commodity, and profiting from sales of those new products. Companies of different sizes have different objectives and reasons for exploring, and target different commodities and styles of mineralization.

Prospectors, Small Syndicates, and Small Companies with No Mines

If the small-scale exploration group plan to mine what they discover, commodities such as gold, gemstones, and tin are favoured, because processing of the ore is simple, capital costs are low, and the unit value of the commodity produced is high, so small-scale operations may be viable. Work occurs in prospective areas that are known, typically close to where the group is based. If the small-scale group plans to sell the prospects they discover, whatever the market prefers at the time is favoured, because those targets are readily marketable. Work is undertaken in prospective areas that are familiar to them, or where their financial resources allow operations.

Small Exploration Companies with Mines or Mineral-Based Businesses

If small groups that own mines or businesses plan to use the product in their business, they will explore

for the raw materials they need for their current or planned operations. This will typically take place near current or planned operations to minimize transport costs. If the plan is to produce minerals for sale, small-scale owners will explore for commodities for which they believe they have the technical skills (mining, processing, marketing) to handle, and that can be sold profitably. Typically, work is undertaken in known regions, but may expand to other regions.

Large Mining and Exploration Companies

Some large companies focus on specific commodities or metals for which they perceive they have a technical and operational advantage, or for which wish to appeal to investors wanting commodity focus (e.g., Barrick and Newmont for gold, De Beers for diamonds, Cominco for zinc, Alcoa for aluminium, and INCO for nickel). They explore where they believe they have the greatest chance of success, based on geology and legal, commercial, and security criteria. Other large companies focus on any commodities meeting their commercial criteria: typically these will be commodities with very large global markets, no barriers to entry, low production costs, and major cash flows. These companies explore where they believe they have the greatest chance of economic success, based on geology and legal, commercial, and security criteria.

Mega-Mining Houses

This small group of very large mining houses has emerged only recently as a result of mergers and acquisitions (e.g., Anglo American, BHP Billiton, and Rio Tinto). For these corporations, exploration alone can no longer deliver their growth objectives because very few individual discoveries can meet their commercial criteria, and because explorers cannot reliably predict when they will make their next economically viable discovery. Depending on the level of competition, these companies may reduce their exploration expenditure and aim instead to acquire major discoveries made by successful smaller companies. If they acquire a small company that has grown by exploration success, in many instances they discard the successful exploration group.

Strategies for Exploration

The strategies and tools applied to exploration vary with the size of the group's exploration budget and its technical capabilities. Prospectors generally work as individuals or small syndicates. Corporations employ specialist explorers, mostly geologists, but include in-house specialist geochemists and geophysicists where there is sufficient demand for their services. Large exploration groups may comprise several hundred people, with technical specialists including geologists, geochemists, and geophysicists, and a wide array of technical support staff.

The sequence typically followed by explorers is summarized in Figure 1. The first major strategic issue they face is what to explore for and where to explore for it. There are many possible targets and commodities for which to search, and the choice can be as broad as 'anything we can make money from' or as narrow as one specialist commodity. For companies planning to use minerals in their own operations, the choice of commodities is already decided by what they need. For other explorers, the choice of targets for exploration can be driven by opportunity or by strategy. In either case, the main criteria are the perceived likelihood of success and the reward for success.

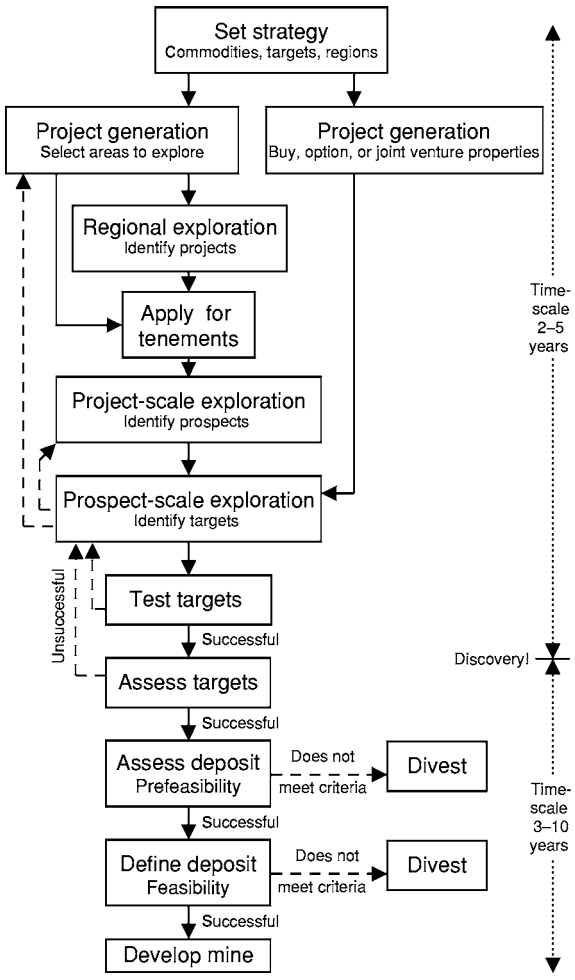

Figure 1 The sequence of stages from mineral exploration to mining.

Selecting commodities and targets is probably most crucial for large companies allocating substantial resources to exploration. They have the opportunity to explore for whatever they choose, and few restrictions on where they explore. However, because they spend a lot of money on exploration, their shareholders expect to see substantial returns for the investment. For a very large company, a small discovery that might seem to be a major success for a small company has no discernible impact on overall profitability or net capital worth. To justify large expenditures, large corporations need to focus on finding deposits that are very large and that can have a significant impact on profitability.

Once the exploration targets have been selected, the next decision is where to explore: locally, regionally, nationally, or globally. For small players, that decision is largely dictated by where they can afford to operate. It is easy to spend a lot of money on travel before any work is done, so small exploration groups typically choose a limited area of operations. To increase their chances of success, every exploration group, regardless of size, must balance between trying to be in all the best places and having as many good prospects as possible against the risk of spreading their effort too thinly and spending too much of their budget on access and support costs. The response of different explorers to these issues varies widely. At the peak of the exploration boom of the late 1990s, many exploration groups spread their activities thinly around the world, while others focused all their resources into a few priority regions. There is no right way, and either strategy can lead to success.

Even when decisions such as what to explore for and where to explore have been decided, there remain many important issues. Prospective regions may be very large, so the exploration group needs to select a region of manageable size on which to focus attention. The most important factor in making a discovery is favourable geology, but because the aim of exploration is economic success, not merely technical success, many other factors come into play. These factors include having secure title over the land to be explored, having access to the land, and having safe operating conditions, favourable legal and taxation laws, certainty of permission to progress from exploration to mining, availability of infrastructure and skilled workers, and many other issues. Previous exploration history must also be considered, because there is no point in exploring an area where previous work has been thorough, and new explorers can only repeat what has been done before. Availability of infrastructure has greatest impact for bulk commodities or industrial minerals, for which transport costs may be a substantial proportion of the sale price obtained, and the least impact for small-bulk, high-value commodities such as gemstones or precious metals, for which the product can easily be flown to market in a small plane.

Once a region has been selected for exploration, there may be opportunities to gain access to advanced projects by entering agreements with explorers already active in the area. Possible arrangements include outright purchase of an established project, option agreements (these involve progressive payments during exploration, with a major payment or share in profits or production if exploration is successful), and joint ventures involving working together to share costs and benefits. If arrangements of this kind are not possible, or the best opportunities are no better than can be obtained alone, then the best option is to explore alone.

This then raises further questions. Should the company focus its attention on known deposits and prospects, or get as close as possible to them (known as brownfields exploration)? Or should it search in other areas with apparently similar geology, but lacking known deposits (known as greenfields exploration)? The relative merits of the two approaches are a contentious issue. In brownfields exploration, it is easier to justify work and expenditures on the basis of being close to a known deposit, but how likely is it that a new deposit will be found close to an old one? With greenfields exploration, the apparent risk is higher because it involves stepping out beyond what is known, in the hope that there are new, unknown deposits to be found. Success is possible using either approach. One thing that is certain, however, is that brownfields opportunities ultimately are limited: new deposits cannot continue to be found by endlessly revisiting the same areas.

A major goal of exploration is to get to the point of testing a potential orebody as quickly and as cheaply as possible. Identifying a volume of rock that potentially hosts an orebody (the target) is an important step along that path. Identification of the target may result from the evaluation of previous work or application of a new exploration technique on a brownfields site, or from a systematic exploration program on a greenfields site. Most exploration starts with identification of a broad target area that has the potential to contain an orebody: the challenge is then to narrow the focus to a specific target that can be tested, hopefully leading to discovery. In systematic exploration, the starting region might be as large as hundreds of thousands of square kilometres, whereas the target usually has an area of much less than $1\,km^2$ (commonly $0.003\,km^2$ or less). Explorers can apply a wide array of tools and exploration methods to narrow down the area of search and define

targets for drilling. The skill in exploration lies in how those tools are used to discover an orebody.

Exploration Tools

The wide variety of exploration techniques available for exploration can be broadly grouped into three types: geological, geochemical, and geophysical. The selection of the technique or combination of techniques used varies with the target sought, the area to be explored, the geological conditions, the stage of exploration, the weathering regime, and factors such as location, topography, vegetation cover, climate, and social and cultural issues. Some techniques can be applied over large regions, whereas others can be applied only over small areas. Some require detailed ground access, whereas others can be flown by aircraft and require minimal ground access. The following discussion focuses mostly on exploration for metallic ore deposits, because for them, discovery of an economic tonnage and grade is typically the crucial step. For many bulk commodities (especially most industrial minerals), discovery is important, but the ultimate value of the find relates less to grade and more to marketability, which involves many different characteristics, such as physical properties, amenability for the ultimate application, and presence or absence of deleterious impurities. Thus, the relative importance of the early search and discovery stages, and the later testing and evaluation stages, changes with the commodity sought.

Geological Techniques

If the geological situation in which mineralization is likely to occur can be recognized by observation, then geological mapping of rock types, stratigraphy, or structure can be used (Table 1; Figure 2). Work on very prospective areas may involve more detailed studies, including petrography, fluid inclusion studies, or alteration mineralogy. Geological techniques are applicable only where geological observations can be made (i.e., where there is sufficient outcrop or where appropriate samples can be collected) or where geological inferences can be made indirectly (from aerial geophysical or spectral surveys, aerial photographs, satellite images, etc.).

Geochemical Techniques

Geochemical techniques involve the chemical analysis of geological materials such as stream sediment, soil,

Table 1 Main geological tools in mineral exploration

Tool	*Basis*	*Coverage*	*Applicability*	*Target*
Geological mapping	Systematic mapping of surface rock types, structures, hydrothermal alteration, etc.	Regional scale available globally; detailed coverage very limited	Requires reasonable distribution of exposure of bedrock, though other tools can be used to fill in missing information	An important tool in exploration for all deposit types; provides the basis for interpretation of all other datasets
Aerial photograph interpretation	A stereoscopic view of Earth's surface is provided by overlapping photographs; lineaments, colour, structures, weathering patterns, and vegetation can be used to generate a geological interpretation	Global coverage available with variable resolution and quality	Applicable if the surface is visible (no cloud cover); best in areas lacking thick vegetation cover	An important aid to geological mapping; can be used to locate orebodies that are exposed at the surface and show distinctive features
Satellite image interpretation	Satellite based scanners generate detailed images of Earth's surface	Global	Available everywhere, but application varies with density of buildings and agriculture, vegetation, rainfall, weathering, etc. Most useful in arid, well exposed regions	An important aid to geological mapping; can seldom be used to locate orebodies directly, but in favourable conditions in remote areas, can highlight alteration zones
Spectral data interpretation	A wide variety of spectral information is now available from satellites, aircraft, and ground surveys	Global for satellite systems, large areas from aircraft, small areas with ground instruments	Applicability varies with density of buildings and agriculture, vegetation, rainfall, weathering, etc. Most useful in arid, well exposed regions	A useful aid to geological mapping; in favourable conditions, can locate hydrothermal alteration related to mineralization, or, rarely, large mineralized areas

Figure 2 Geological mapping in the Farallon Negro district, Argentina. All rocks show intense hydrothermal alteration related to a major porphyry copper molybdenum gold deposit called Agua Rica.

rock, and, in some cases, water, vegetation, or air (Table 2; Figure 3). Analytical results ('anomalies') may suggest prospective areas. Geochemical techniques are applicable only where the rock that hosts the ore, or material derived directly from it, is accessible. Sampling of overlying transported material (e.g., glacial debris) is not effective unless the source of the transported material is known, or unless chemical elements related to mineralization have migrated up through the transported cover. In areas of shallow cover, drilling may be used to collect samples from beneath the cover. Proper orientation surveys are essential for effective geochemical surveys. These involve testing the response of known mineralization in a similar nearby area to verify the effectiveness of the method under the prevailing conditions, before using it routinely to look for unknown mineralization.

Geophysical Techniques

Geophysical techniques rely on variations in the physical properties of the mineralized rocks or the rocks that surround them to indicate the location of mineralization directly or indirectly (Table 3; Figure 4). The physical response may be a direct property of the rock (e.g., its density, natural radioactivity, magnetic properties, or resistivity), or an induced response produced by exposing the rock to a physical stimulus such as an electrical or magnetic field. Geophysical techniques may indicate mineralization directly, or may allow the search area to be reduced to a favourable host rock or a favourable structural environment. With the increasing availability of large-scale surveys, often involving more than one technique, the data from geophysical surveys can be interpreted to produce geological maps and to identify favourable settings for mineralization, exactly as they would be from conventional geological maps. A major advantage of geophysical techniques is that they can detect responses from mineralization buried several hundred metres below the ground surface, at depths too great to be reflected in the surface geology or detected by geochemical surveys.

Recognizing Targets

Sometimes orebodies are exposed and their surface expression can be recognized by explorers, but as exploration continues, new surface targets become fewer and fewer, and increasingly there is a need to look for more subtle targets. That typically involves the use of multiple exploration tools. The data from all the techniques used are compiled onto maps, and the strength and location of anomalies in each technique are compared. Areas that stand out with coincident anomalies from more than one technique are usually priority targets for drill testing.

One additional geological tool universally used by modern explorationists is the ore deposit model. There are models available for a wide range of ore deposit types, and new ones are regularly developed. These models summarize all the important geological characteristics (including spatial relationships) of a particular deposit type. Models include large-scale aspects such as the tectonic and structural settings,

Table 2 Main geochemical tools in mineral exploration

Tool	*Basis*	*Coverage*	*Applicability*	*Target*
Soil geochemistry	Systematic sampling of soil, usually of a selected size fraction	Large to small areas, depending on sampling density	Areas with residual soils; a very commonly used method	Most metallic deposit styles
Rock chip geochemistry	Systematic sampling of exposed bedrock as composites of small chips	Small areas only	Requires extensive exposure of bedrock	Most metallic deposit styles
Bedrock geochemistry	Systematic sampling of the upper parts of bedrock, usually by drilling through shallow cover	Large to small areas, depending on sampling density and depth of cover	Areas of strong near surface leaching, or covered by transported overburden	Most deposit styles
Stream sediment geochemistry	Systematic sampling of stream sediments, usually of a selected size fraction	Mostly large areas; application to small areas may be limited by the stream pattern density	Widely applicable in regional exploration; requires bedrock outcrop or shallow subcrop	Most metallic deposit styles
Water geochemistry	Sampling of water in streams or wells and bore holes	May be applied over large areas; sample density typically low	Depends on access to water samples in streams or bores	Limited application for base metal and uranium deposits
Soil gas geochemistry	Systematic sampling and analysis of gases trapped in soil	Mostly small areas; sampling density is high	Suitable for areas with deep soil and transported cover	Locates structures and may help find some sulphide rich deposit styles
Plant geochemistry	Sampling of one plant species or part of one plant species, followed by chemical analyses (mostly after ashing)	Mostly over restricted areas	Best in areas with high plant density but low plant diversity (usually temperate to cold areas)	Most base metal deposit styles

Figure 3 Geochemical sampling in eastern Taiwan. Sediments are dug from the creek bed, sieved to remove the largest pieces, and the finer fraction is bagged and sent to a laboratory for chemical analysis.

Table 3 Main geophysical tools in mineral exploration

Tool	*Basis*	*Coverage*	*Applicability*	*Target*
Magnetics	Measures spatial variations in the intensity of Earth's natural magnetic field	Very large areas covered by aerial surveys; smaller areas by ground surveys	Widely used as an aid to geological mapping; also a direct detection method for some deposits: applicable wherever rock magnetic properties vary	All deposits with a well defined geological setting in magnetically variable rocks; direct detection of deposits containing magnetic minerals (e.g., iron ore, chromite, diamonds, some volcanic massive sulphide deposits, some porphyry copper deposits)
Radiometrics	Measures spatial variations in the intensity of natural radiation from potassium, thorium, and uranium	Very large areas covered by aerial surveys; smaller areas by ground surveys	Widely used as an aid to geological mapping; also aids direct detection of some deposits: applicable wherever there are variations in abundance of natural radioactive elements	All deposits with a well defined geological setting; direct detection of deposits containing uranium or thorium minerals, or deposits with strong potassium enrichment in alteration zones (e.g., some volcanic massive sulphide deposits, some porphyry copper deposits, some epithermal gold deposits)
Gravity	Measures spatial variations in the intensity of Earth's natural gravitational attraction	Very large areas covered by aerial gravity gradiometer surveys; smaller areas by ground surveys	Huge areas covered by very low density ground surveys; limited coverage with high resolution aerial surveys; detailed ground surveys only in areas of low topographic relief: applicable wherever rock densities vary	Direct detection of deposits with strong density contrast to surrounding rocks (e.g., iron ore, volcanic massive sulphide deposits, kimberlites)
Electromagnetics	Measures the induced response in the Earth from an applied electromagnetic field	Very large areas covered by aerial electromagnetic surveys; smaller areas by ground surveys	Can be used as an aid to geological mapping; also aids direct detection of some deposits: applicable wherever there are variations in natural rock conductivities	Direct detection of deposits with high concentrations of conductive minerals (e.g., volcanic massive sulphide deposits, manganese deposits) or where there are associated anomalous conductivity zones (e.g., some porphyry copper deposits, kimberlites)
Induced polarization	Measures the induced electrical polarization response in minerals from an applied electrical field	Ground technique mostly applied over small areas, but large surveys also possible	Detects the presence of polarizable minerals (mainly pyrite, pyrrhotite, galena, chalcopyrite, etc.)	Direct detection of deposits with high concentrations of polarizable minerals (e.g., volcanic massive sulphide deposits, porphyry copper deposits)
Resistivity	Measures spatial variations in the resistivity of the rock mass being surveyed	Mostly applied over small areas	Detects variations in resistivity	Sulphide rich mineralization has low resistivity compared to the surrounding rock; applied to direct detection of sulphide rich masses (e.g., massive sulphide deposits)
Seismic	Records underground surface reflections produced by explosions or mechanical thumpers at the surface	Applied over huge areas for petroleum exploration; seldom used in mineral exploration	Indicates surfaces in the bedrock (e.g., faults, beds, igneous layers)	In mineral exploration, mainly used for layered complexes (e.g., Bushveld) or for engineering purposes

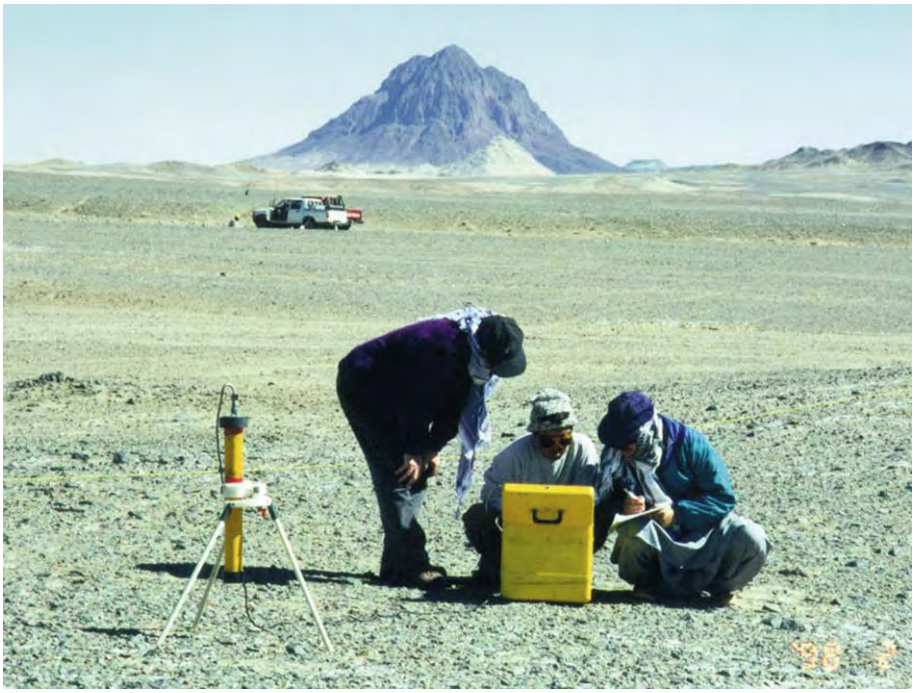

Figure 4 A geophysical survey being conducted in western Pakistan. This is an electromagnetic survey, in which electrical pulses are used to induce a response from conductive rocks in the ground. Photograph by R Irvine, reproduced with permission.

down to small-scale features such as the mineralogy of the ore, and details such as the chemistry of fluid inclusions. In most but not all cases they include genetic models summarizing how geologists believe the deposits form. They also reflect the kind of geological, geochemical, and geophysical expressions an orebody of this type should have, and so they help in the interpretation of exploration data.

Testing Targets

Once possible mineralization has been located or a target identified, it is then necessary to test it to confirm that it is what is sought, and how commercially significant it is (Figure 5). The cheapest approach in near-surface situations is to dig trenches across the mineralization to create complete exposure and to allow detailed sampling. If the target is more than a few metres below the surface, drilling is needed (Figure 6). Drilling is the most reliable means to investigate a target and is used to define the grade and extent of the mineralization. If testing confirms that potentially economic mineralization has been found, then a discovery has been made (Figure 7). Further work is then required to quantify the full significance of the discovery.

The assessment stage that follows a discovery involves gathering huge the amounts of data needed to assess whether the mineralization can be mined economically. Typically, widely spaced drilling is used first to assess the overall size of the mineralized body, and then more detailed infill is used to determine the shape, distribution, tonnage, grade, and metallurgical properties. If it is found that the indicated tonnage and grade could potentially justify starting a mine, a new stage of data-gathering follows; typically projects pass through several stages, at each of which it is reassessed to see if another more detailed stage of expensive assessment work is warranted. These stages typically include prefeasibility, full feasibility, and, if the outcomes are positive, finally a decision to go ahead and develop a mine. Depending on the commodity, the planned scale of operation, and the location of the deposit, developing a mine might cost anything from a few million dollars up to several billions of dollars. (*see* **Mining Geology: Exploration Boreholes**).

Success and Failure in Exploration

Exploration is a technical activity with a commercial objective. It is common to see these two aspects, the technical and commercial, confused in claims of success. In the case of junior companies, it is important that any success (not necessarily a commercial success) is publicly highlighted, because it is important for these groups to be seen as successful, to increase their ability to raise further funds for ongoing

Figure 5 Exploration success! The geologists are standing around the drill hole that discovered the high grade Cannington silver lead zinc orebody in western Queensland, Australia. A drill rig can be seen on the skyline, where drilling is being done further along the same orebody. The deposit was brought into production and quickly became the world's largest producer of silver.

Figure 6 A helicopter being used to move a diamond drilling rig in the Kimberley region of Western Australia. The helicopter allows the drill to be positioned with minimal disturbance and environmental damage.

exploration. By contrast, it is sometimes in the interests of major mining companies to play down expectations from their exploration, and their successes often go unmentioned, or are announced only in a low-key way. Too much publicity can increase the level of competition for ground near the discovery, and overly enthusiastic expectations may mean shareholders are ultimately disappointed if a technical discovery does not turn into a commercial success.

The most important justification for exploration is that it supplies society with the mineral products it needs. This benefit, however, is realized only if the value of the products is greater than the cost of discovery and production. Real success in exploration and mining must therefore be judged in commercial, not technical, terms. In this respect, the role of the large exploration and mining companies has particular importance. They have financial and technical

Figure 7 Examining trays of drill core from the Eloise copper gold deposit in western Queensland, Australia. Diamond drilling techniques are used, which allows deep holes to be drilled, and the core recovered allows detailed geological examination.

resources that small companies lack, and they are not so dependent on the day-to-day demands of the share market. This means they can pursue longer term goals and are more likely to discover and develop long-life mines that contribute stability to the long-term supply of major mineral commodities. Some junior companies are fast and economically efficient explorers and play an important role by supplying new exploration opportunities to larger companies and by bringing into production deposits that would be too small for major companies.

The Role of Governments in Exploration

In most parts of the world, governments regulate exploration and mining. Governments control the granting of titles, the conditions that are applied, and regulations governing safety and environmental protection. Governments also determine the availability of regional data and the cost of accessing it, and they set the levels of taxation and other imposts and concessions that are applied to the industry. Direct government involvement in exploration and mining is not regarded favourably these days, because having a government acting as both regulator and competitor involves them in a conflict of interest that may undermine trust in the regulatory process.

Although favourable geology is by far the most important determinant of how prospective a region is for exploration in a purely technical sense, the potential for commercial success from exploration is strongly influenced by the regulatory and financial environment in which it operates, as laid down by governments. Countries with relatively poor geology may still be attractive for exploration if the legal, economic, and regulatory environment is attractive; conversely, even the best geology does not compensate for a bad environment, because confidence in the stability of an operating environment is very important for explorers and miners.

The Future of Exploration

Mineral exploration is an essential part of the process of supplying the resource needs of societies: while that demand continues, so will mining and the exploration that is needed to sustain it. But exploration faces many challenges, and is currently undergoing major changes.

With the rise in environmental awareness in the second half of the twentieth century, mining was widely criticized for its environmental impact. Much of that criticism was justified, and there have been major changes, such that the modern mining industry can now operate with minimal environmental impact in the areas surrounding mines. However, it is inescapable that any process that takes material from one place to another must have an environmental impact. Mineral exploration has also come under attack by environmentalists, but most parts of the exploration process have very little to no environmental impact. Most opposition to exploration is either misinformed about what is actually done, or more commonly is based on fear of what might happen in the unlikely event that a discovery is

made, leading to mining. In fact, most exploration efforts leave no long-term trace and make no discoveries. Even when targets are identified, on further testing less than 1% prove to be of economic interest.

The mining industry as a whole, including exploration, has been criticized for not returning a satisfactory profit on money invested, but such analyses can only be sensibly done on a case-by-case basis. Over the past decade, major changes have occurred in financial markets and in how businesses operate, with emphasis on short-term financial performance. Because exploration cannot guarantee very quick returns, it lost favour with investors, with the result that in the late 1990s, exploration expenditure dropped drastically, and investment in mining developments were also sharply reduced in response to low commodity prices. If this situation were to continue, there would eventually be a shortage of some commodities, which should cause prices to rise, making exploration and mining of those commodities attractive again.

The last few years of the twentieth century represented a period of dramatic change for the mining and exploration industry. These changes are still being played out, but a new industry structure and way of operating have to be found. Throughout the world, all people seek a better life, and to fulfil that desire requires more and better houses, vehicles, roads, and everyday things. All those things have to be made from some material commodity, and most commodities can be obtained only by mining. Mining will ultimately die without exploration, so, as long as populations continue to increase and people strive for a better standard of living, requiring the use of mineral commodities, the future of mineral exploration is assured.

Mineral Reserves

M Vaněček, Charles University, Prague, Czech Republic

Introduction

Mineral reserves and mineral resources are terms that cannot be separated from each other. Their definitions are derived from the grade of geological certainty of the basic information about the mineral accumulation and from expected profitability of extracting and marketing the mineral commodity. In all main classifications (i.e., the United Nations, the USA, and the Russian classifications) the definitions of mineral resources and mineral reserves are slightly different, but in all cases the reserves form only a better known part of the resources. Procedures for mineral reserves calculation can be divided into the scalar-geometrical methods and into geostatistical methods. For the most part, in mineral statistics,

world reserves and reserve base of different minerals are introduced.

The terms mineral reserves and mineral resources are inseparably bound to each other. One of the possible definitions for resource is: "something in reserve or ready if needed". This can be made precise for mineral resources as follows: "valuable mineral deposits of an area that are presently recoverable and may be so in the future, including known ore bodies and potential ore". Mineral reserves usually represent a part of mineral resources that could be defined with respect to the quantity and quality of mineral bodies.

The evaluation of reserves/resources of a mineral deposit is based on reserve calculation procedures that would include description and analysis of main geological characteristics of the deposit, such as tonnage, grade, shape and thickness of ore bodies, and depth of mineralization etc., and on a feasibility study that analyzes expected profitability of extracting and marketing the mineral commodity in a given economy and at a given time.

Methods of reserves calculation and of economic analyzes of mining activities have developed over a long period of time. The various connoisseurs in prospecting, mining and metallurgy were the very first to be able to evaluate the worth of a mineral accumulation. In 1910, during the XI, International Geological Congress in Stockholm, the iron ore resources of the world were classified into different groups of exactitude and the symbols A, B, and C were used for the first time. At present time a special branch of economic geology, called mineral economics, deals with the reserves/resources evaluation and classification.

Due to the needs of industrialization, different systems of reserves classification and calculation have arisen. So far as the classification, i.e., group segregation, of mineral reserve tonnage is concerned, we find two schools of thought in existence. Governmental agencies, for example different geological surveys, are mostly concerned with the determination of the future potential of mineral resources. On the other hand, a reserve analysis made for or by a private enterprise usually is designed to show the various mineral tracts classified on the basis of their currently mineable nature. The classification terminology used by the governmental agencies is as follows: measured, indicated, and inferred resources. On the other hand, in mining geology there are used more readily the terms developed ore, proved ore, probable ore, and possible and/or extension ore. Single members of both classifications are not direct equivalents. For example, the developed ore may be only a part of measured or proved reserves that are prepared for immediate withdrawal by mining. Some probable ore may be the essential counterpart of some measured reserve or/and of some indicated resource. Possible ore, which is sometimes called future ore, and extension ore, are to all intents and purposes the equivalent of inferred reserve.

At present, three different reserves/resources classifications are mainly used: the United Nations International Framework Classification, the Classification System of the U.S. Bureau of Mines and U.S. Geological Survey, and the Classification of the State Commission for Reserves of the Russian Federation.

The UN Framework Classification provides information about the stage of Geological Assessment, the stage of Feasibility Assessment, and the degree of Economic Viability. Geological Study is subdivided into four consecutive stages of geological assessment, which are: Reconnaissance, Prospecting, General Exploration, and Detailed Exploration. Feasibility Assessment is subdivided into three consecutive stages which are: Geological Study, Prefeasibility Study, and Feasibility Study/Mining Report. There are two categories of Economic Viability: economic, and potentially economic, which are only quoted in the stages of Mining Report/Feasibility Study and Prefeasibility Study (**Table 1**).

With respect to a variety of meanings in the use of the terms 'reserve' and 'resource' they are redefined as follows: the Total Mineral Resource is defined as the naturally occurring concentration of mineral raw material of economic interest and with specified geological certainty. A Mineral Reserve is the economically mineable part of the Total Mineral Resource as demonstrated by Feasibility Assessment. The Remaining Mineral Resource is the balance of the Total Mineral Resource that has not been identified as a Mineral Reserve. Only the groups 'proved' and 'probable' are reserves, whereas the group 'inferred' belongs to resources. The UN Framework Classification is mostly applied in Western Europe and in some European countries with 'economies in transition' (**Figure 1**).

The U.S. Resource/Reserve Classification for Minerals defines Resource as a concentration of naturally occurring solid, liquid, or gaseous material in or on the Earth's crust in such form and amount that economic extraction of a commodity from the concentration is currently or potentially feasible. Identified Resources are resources whose location, grade, quality, and quantity are known or estimated from specific geological evidence. Identified resources include economic, marginally economic, and subeconomic components. To reflect varying degrees of geologic certainty, these economic divisions can be subdivided into 'measured', 'indicated', and 'inferred'. For the sum of measured plus indicated, the term 'demonstrated' is used. The part of an identified resource

that meets specified minimum physical and chemical criteria related to current mining and production practices, including those of grade, quality, thickness, and depth, is called Reserve Base. Reserves are that part of the reserve base which could be economically extracted or produced at the time of determination. The whole U.S. system of resource/reserve classification is illustrated by Tables 2 and 3. The U.S. Resource/Reserve Classification for Minerals seems to be the most widespread, not only in the USA, but in most of world.

In the classification of the State Commission for Reserves (GKZ) of the Russian Federation reserves and resources are distinguished. According to the grade of geological certainty the reserves are divided into the explored ones (categories A, B, C 1), and the estimated ones (category C 2). From the point of view of the economic importance, the reserves are

subdivided into economic and sub economic. In the Russian mining industry a classification of the explored reserves according to their mineable nature is used as follows: developed, prepared for extraction, and ready to extraction. Resources are divided into three groups of prognostic resources (P 1, P 2, P 3) depending on the grade of geological certainty. Main patterns of the Russian reserves/resources classification are shown on Table 4. The Russian reserves classification is used mostly in the states of the former USSR and also in some Eastern European countries.

The general procedure of a mineral reserve calculation is the same regardless of the concept that is used in making the ultimate classification, since it follows that no classification of any mineral reserve can be visualized completely until all necessary working data have been evaluated. Two main groups of traditional resource estimations can be distinguished:

1. The scalar-geometric methods or methods of geometrization
2. The spatial ('geostatistical') methods.

In the first case a complex natural shape of mineral bodies are geometrized into defined geometric bodies, the volume of which can be calculated. The following methods are distinguished:

1. Methods of blocks
2. Methods of geological sections
3. Methods of isolines.

Methods of blocks can be divided depending on a geometrical arrangement of the exploration points

(i.e., boreholes, shafts, etc.) into triangular, regular squares, rectangular, polygonal, and irregular or geological blocks. These methods differ slightly in ways of determination of volume and grade of mineral bodies. The average thickness is calculated as an arithmetical mean in all cases with an exception of the polygonal method where thickness and grade are taken from the borehole lying at the geometrical centre of each polygon. In all other kinds of blocks an average grade of the mineral body is calculated as an arithmetical mean weighted by thicknesses. Polygonal blocks and geological blocks are applied if the arrangement of the exploration points is irregular. Contours of geological blocks are derived from the geological situation (tectonic elements, facial changes, changes of thickness, etc.).

Methods of sections can be divided as follows:

1. Longitudinal sections (along the axis of the body)
2. Cross-sections.

Sections may be vertical, horizontal, and inclined, each other being parallel and non-parallel. Owing to the application of geological sections the natural shape of the body is nearly preserved. Volumes of blocks can be calculated either between two sections or using area of only one section. The first way is applied in the case of similar in shape and near in dimension geological sections, the second one is used if the shape of the mineral body is very irregular and/or if due to geological reasons a connection between two sections is not assumed. The average grade of blocks is calculated as an arithmetical mean weighted by the areas of geological sections of the body. Areas of the sections are measured by means of instruments (planimeter, scanning, etc.) or average thickness may be used.

For calculation by means of isolines there are used isopachs (i.e., isolines of thicknesses), isohypses (isolines of altitude), grade, density and their combination can be used. Volume of mineral bodies is given by contours of isolines and can be calculated using the Simpson formula. If a combination of isopachs, of isolines of grades, and of isolines of density is used the computed volume is equal to the reserve.

Geostatistics, in their most generally accepted use, are concerned with the study of the distribution in space of useful values for mining engineers and geologists, such as grade, thickness of accumulation, including a most important practical application to the problems arising in mineral deposit evaluation. Spatial or geostatistical methods are working with statistical processing of primary data and with description of a statistical character of the distribution of main properties of the deposit in space by means of variograms. The discovered statistical characteristics that allow the prediction of the distribution of studied properties in the mineral body are used for the computing of reserves. One of the most known and used geostatistical methods is so called 'kriging', a method developed for gold reserves computing in South Africa.

In the international statistical overviews of the world reserves and of the regional resources of a mineral commodity, the terms 'resources' and 'reserves' base are usually given. For the metallic ores the reserve are given mostly in terms of metal content. Reserves of naturally occurring non-metals and fossil fuels are expressed in the tonnage of raw mineral material. Quantities, qualities, and grades may be expressed in different terms and units to suit different purposes, but usage must be clearly stated and defined.

Mineral reserves can be defined also as: "a quantity of mineral raw materials in the Earth's crust which is estimated as a result of geological exploration works or during their extraction". They could be calculated for a single deposit, for an ore field or district, for a basin, for a region, for states, for continents, and for the whole world.

World mineral reserves of each raw mineral commodity are immense and their quantity is subject of changes due to the development of geological knowledge, in conjunction with considerable mining activity. For example, world resources of iron ores are estimated to exceed 800 billion metric tonnes of crude ore containing more than 230 billion tonnes of iron. World reserves in iron content are estimated to be 71 000 million metric tonnes, the reserve base being 160 000 million metric tonnes. Annual world output of iron ore mines varies by about 1 billion metric tonnes per year. World reserves of phosphate rocks are recorded as high as 12 billion metric tonnes, reserve base being 37 billion metric tonnes. World resources of coal are estimated to be about 15×10^{12} metric tonnes, of which about 1067 billion metric tonnes are recoverable reserves. In 2001 the annual world mining output of coal was 3630 metric tonnes. These few examples may give an idea as to the order of huge quantities of world mineral resources and reserves.

Hydrothermal Ores

M A McKibben, University of California, CA, USA

Introduction

Hydrothermal ores are natural, economically valuable concentrations of metallic minerals whose origins can be directly tied to the physical and chemical actions of hot aqueous fluids within the Earth's crust. Hydrothermal ores are ideally distinguished from those that form by other geological processes, including magmatic ores (formed by segregation from a melt), sedimentary ores (formed by sedimentation or precipitation from ambient surface waters), and residual ores (formed by surficial weathering). Such strict genetic distinctions are not always possible, however; for example, magmatic-hydrothermal ores (such as skarns and pegmatites) may arise from a combined process whereby an aqueous phase exsolves from a crystallizing magma. The origins of some diagenetic ores likewise may fall within a realm between purely sedimentary and hydrothermal processes. So while the defining criteria for classifying minerals and ores as hydrothermal is evidence of transport and precipitation from a largely aqueous fluid phase at elevated temperatures, there is always the caveat that transitional processes can take place.

For millennia, humans have observed connections between areas of active subaerial volcanism and the mineralizing actions of hydrothermal fluids, manifested in surficial features such as fumaroles, hot springs, geysers, mud pots, and sinter and travertine terraces. More recently, marine scientists have discovered similar active hydrothermal features on the ocean floors near mid-ocean ridge volcanic centres, particularly 'black smokers' and their associated mounds of accumulated hydrothermal minerals. In all of these instances, it is obvious that minerals containing elements of economic significance are periodically concentrated by such volcanic-related hydrothermal phenomena.

Chemical and physical clues gathered from older ore deposits, as well as deep commercial and scientific drilling into active hydrothermal systems over the last few decades, have provided additional details of hydrothermal processes that are only hinted at in surficial manifestations. These field-based data on modern and ancient systems, coupled with essential theoretical and experimental laboratory studies of hydrothermal processes, have added to our knowledge of the full spectrum of hydrothermal processes that have taken place within the Earth's crust through geological time. Thus, although hydrothermal ores are often associated with volcanism, geologists now recognize that some of these ores can be generated from processes that are peripheral to or entirely unrelated to magmatic processes.

Hydrothermal Fluids

Because of their high temperatures and pressures, hydrothermal fluids in the Earth's crust can contain relatively elevated concentrations of dissolved salts (such as NaCl) and gases (such as H_2S) (Table 1). Dissolved salts and gases can arise from a variety of sources, including evaporative concentration of

Modified from McKibben MA and Hardie LA (1997) Ore forming brines in active continental rifts. In: Barnes HL (ed.) *Geochemistry of Hydrothermal Ore Deposits*, 3rd edn., pp. 875 933. New York: Wiley Interscience.

surface waters, dissolution of evaporites, water–rock interaction, and exsolution from magmas.

The solvent (dissolving) properties of hydrothermal fluids impart their ability to create ore deposits. The high dielectric constant of water and the ability of metal cations to bond with aqueous anions (such as chloride and sulphide) give natural aqueous fluids in the Earth's crust the potential to dissolve, transport and re-deposit the elements that make up hydrothermal ore minerals.

Water vapour is far less effective than liquid water in transporting most valuable elements. The temperature and pressure conditions under which aqueous liquids can effectively transport metals depend not only on the physical properties of water but also on the amounts of dissolved minerals and gases in the water. Salts such as NaCl dramatically increase the critical temperature and pressure of hydrothermal fluids, allowing brines to exist up to magmatic conditions as very effective liquid transporters of metals.

Metals are often solubilized and carried in solution as metal–anion complexes, such as $ZnCl^{+}$ and $Au(HS)_2$. Precipitation of these metals as ore minerals occurs when physico-chemical conditions destabilize the complexes in favour of the minerals.

Cooling, boiling, depressurization, oxidation, fluid mixing and fluid–rock reaction are examples of common processes which can trigger ore mineral precipitation from fluids. For example, native gold can be deposited during shallow effervescence and oxidation of hot spring waters:

$$2Au(HS)_2 + 7.5O_{2(g)} + 2HCO_3 = 2Au_{(s)} + CO_{2(g)} + 4HSO_4$$

Likewise, Zn sulphide can precipitate when chloride brines react with carbonate wall rocks such as limestone:

$$ZnCl^{+} + H_2S_{(aq)} + CaCO_{3(s)} = ZnS_{(s)} + Ca^{2+} + H_2CO_{3(aq)} + Cl$$

In addition to reacting chemically, hydrothermal fluids will flow in response to thermal gradients, density gradients, and gradients in hydrological head or pressure. Flow rates will be highest in zones of maximum permeability, such as fracture and fault zones in brittle rocks, as well as in more porous lithologies such as sandstones and carbonates. Concentrations of ore minerals are thus formed in loci where a number of chemical and physical environmental factors have acted in concert to promote both sustained fluid flow rates and effective precipitation rates of ore minerals.

Hydrothermal Minerals

Economic geologists divide hydrothermal minerals into ore minerals (economically valuable) and gangue minerals (economically worthless). While some hydrothermal ore minerals occur as native metals or alloys, most consist of a metal combined with another non-metallic element or anion group – examples are shown in Table 2. Gangue minerals usually consist of common silicate, oxide, carbonate and sulphate minerals that do not contain sufficient concentrations of valuable metals. Nonetheless, gangue minerals can be just as important as ore minerals in providing scientific clues to the origins of hydrothermal ore deposits, particularly in regard to their age and the origins of the water in the ore-forming fluid.

Table 2 Examples of common hydrothermal ore minerals

Elements	Copper	Cu
	Gold	Au
	Mercury	Hg
	Silver	Ag
Alloys	Electrum	(Au,Ag)
Oxides	Cassiterite	SnO_2
	Cuprite	CuO_2
	Magnetite	Fe_3O_4
	Pyrolusite	MnO_2
	Uraninite	UO_2
Sulphides	Argentite	Ag_2S
	Arsenopyrite	FeAsS
	Bornite	Cu_5FeS_4
	Chalcocite	Cu_2S
	Chalcopyrite	$CuFeS_2$
	Cinnabar	HgS
	Cobaltite	(Co,Fe)AsS
	Covellite	CuS
	Galena	PbS
	Molybdenite	MoS_2
	Realgar	AsS
	Sphalerite	ZnS
	Stannite	Cu_2FeSnS_4
	Stibnite	Sb_2S_3
Sulphosalts	Enargite	Cu_3AsS_4
	Pyrargyrite	Ag_3SbS_3
	Tennantite	$(Cu,Zn)_{12}(As,Sb)_4S_{13}$
Tellurides	Calaverite	$AuTe_2$
	Sylvanite	$(Au,Ag)Te_2$
Tungstates	Scheelite	$CaWO_4$
	Wolframite	$(Fe,Mn)WO_4$
Carbonates	Cerussite	$PbCO_3$
	Smithsonite	$ZnCO_3$
Sulphates	Anglesite	$PbSO_4$

The crystal habits and textures of hydrothermal ore and gangue minerals are controlled by many factors, including fluid saturation states, nucleation/precipitation kinetics and rock surface textures. Fluids can move through brittle rocks most easily by virtue of interconnected fracture and pore permeability, and precipitation of ore minerals in such open spaces coupled with sustained flow rates (nutrient supply) often promote the development of abundant crystal faces. A straightforward textural sequence of precipitation may be recorded by bands or crusts of crystals deposited one after the other along a fracture or pore surface (Figure 1). Vugs or cavities lined with pristine euhedral crystals may remain as a consequence of the eventual cessation of precipitation or fluid flow; such mineral textures can look quite spectacular and are often a reason that people initially become interested in collecting and studying hydrothermal minerals.

Less efficient chemical flow through rocks can occur by the process of diffusion, where fluid components migrate in response to concentration gradients rather than fluid flow (advection). For example, many hydrothermal veins exhibit the development of alteration envelopes, areas of immediately adjacent wall rock in which new minerals have formed via diffusion and infiltration of chemical components from the hydrothermal fluid as it flows through the fracture (Figure 2). New hydrothermal phases such as silicates, carbonates and sulphides often form in these envelopes at the expense of primary phases in the wall rock. Some phases in alteration envelopes, such as potassium feldspars, can prove quite useful in making

Figure 1 Banded, crustiform sphalerite (ZnS, yellow to brown) and marcasite (FeS_2, green) with later pore filling, cross cutting galena (PbS, grey) in polished slab of hydrothermal ore from Olkusz mine, Silesian Cracovian lead zinc district, Poland. US 10 cent coin for scale.

radiogenic age determinations of the age of formation of the veins.

At elevated temperatures rocks become ductile rather than brittle and open fractures and pores cannot be sustained. Under these conditions, hydrothermal mineral deposition occurs more commonly by replacement rather than by open-space filling. Extreme instances of wholesale hydrothermal replacement of wall rock by ore and gangue minerals can accompany metasomatism, a metamorphic process which substantially changes the original wall-rock composition. Both fluid flow and diffusion occur during metasomatism. Skarns are probably the best example of metasomatic hydrothermal ore deposits, where wall-rock carbonate is replaced by coarse calc–silicate minerals. Such deposits typically form near the contact zones of hydrous silicate magmas, with heat and silica provided by the cooling melt.

The textures of hydrothermal ores, especially their cross-cutting relationships, are an important aspect of the study of hydrothermal ore deposits (Figure 1, Figure 3). The term paragenesis is used for the inferred sequence of mineral precipitation based on textural studies of ores. Because most hydrothermal ores consist of a mixture of opaque and non-opaque minerals, the use of reflected-light microscopy in addition to transmitted-light microscopy is essential in their study.

After raw ore is mined, it is ground up and processed in such a manner as to separate the ore and gangue minerals, often by taking advantage of the chemical, density, magnetic, or surface adsorption differences among the particular minerals. For example, cyanide solutions can be used to preferentially dissolve gold from ore, and many base metal sulphide minerals can be efficiently separated from silicate minerals by their different wetability characteristics in oil and water. Once separated, the ore minerals are then smelted and refined to produce the pure metal.

Often there are practical economic constraints in processing ores that may only be revealed by very careful microscopic study of the paragenesis. For example, some hydrothermal gold ores contain native gold or electrum encapsulated in later silica, making grinding and processing to release the gold much more difficult and expensive. In the case of one famous California gold mine, the mine plant and smelter were designed before this practical paragenetic constraint was realized, forcing expensive last-minute changes to the processing circuit!

Hydrothermal Alteration

Because the total volume of rock subject to fluid flow and diffusion is typically much greater than that subject to more localized ore precipitation, hydrothermal alteration accompanying ore mineralization is often a larger and more obvious target for exploration than the ore deposit itself. Economic geologists therefore

look for characteristic alteration mineral assemblages that tend to develop in wall rocks around hydrothermal ore mineralization. Common alteration types in aluminosilicate wall rocks are listed below. For each type, the set of alteration minerals that appears in a rock is a function of its bulk composition.

Advanced argillic:
- alunite, sericite, kaolinite, dickite, pyrophyllite, pyrite

Phyllic:
- sericite, pyrite

Argillic:
- sericite, kaolinite, halloysite, montmorillonite, calcite, biotite, chlorite, pyrite

Propylitic:
- sericite, montmorillonite, zeolite, epidote, calcite, biotite, albite, K-feldspar, ankerite, chlorite, Fe sulphides, Fe oxides, siderite

Potassic:
- sericite, calcite, anhydrite, ankerite, chlorite, biotite, K-feldspar, pyrite, Fe oxides, siderite

Other more monomineralic alteration types include silica and carbonate alteration.

Because the formation of both ores and alteration envelopes are a function of permeability and fluid flow patterns, the geometry of the alteration assemblages can sometimes give clues to the likely location of additional ore during exploration and drilling, as well as aid in reconstructing the palaeohydrology of the ore-forming system. Potassic, phyllic and advanced argillic alteration often mark the highest-temperature, most intense part of a hydrothermal system close to the ore, whereas propylitic alteration often marks the peripheral regions. Silica alteration forms mainly during cooling and tends to occur in the hydrological discharge regions of the system, whereas carbonate alteration typically occurs during heating in the recharge regions.

On the basis of empirical data and proposed genetic models for the origins of different ore types, many national geological surveys have published exploration models that aim to assist in the discovery of new deposits. These idealized models emphasize characteristic alteration assemblages, geochemical fingerprints, geological structures, rock associations and geological ages of major ore deposit types. The models should be viewed as works in progress, subject to revision as new data and theories materialize.

Origins of Ore-Forming Hydrothermal Fluids

The origins of all of the constituents in an ore-forming hydrothermal fluid can be complex and may not be the same, but usually such a fluid can be classified in terms of the origin of its main component, water. The water can be (1) derived directly from magma, (2) derived from ground or connate water heated by magmatic processes, or (3) derived from water heated by non-magmatic processes such as subsidence, tectonism and metamorphism. The following is a list of examples of hydrothermal ore types grouped on this basis.

Magma-hydrothermal fluids:
- pegmatite
- skarn
- porphyry base metal (early stage)

Magma-heated surficial and subsurface waters (including seawater):
- volcanogenic massive sulphide (black smoker)
- porphyry base metal (late stage)
- epithermal vein

Waters heated mainly by tectonism, metamorphism and subsidence:
- Mississippi Valley type (Pb–Zn carbonate)
- stratiform/stratabound base metal
- greenstone belt (orogenic) gold

The origins of water in a hydrothermal ore deposit can sometimes be inferred from the geological setting, but often it also must be based on stable and radiogenic isotope ratios, elemental geochemical signatures, and fluid inclusion compositions in the ore and gangue minerals.

Magma-Hydrothermal Fluids

Magma-hydrothermal fluids arise from the crystallization of magmas that contain water. Magmas can contain significant amounts of dissolved water, sometimes exceeding 10% by weight. They can acquire water initially from the partial melting of 'wet' source rocks containing hydrous mineral phases (amphiboles, micas), and they can also acquire water subsequently via assimilation of hydrous wall rocks during their ascent. In either case, such waters will often exhibit H and O isotopic values that reflect equilibrium exchange with magma at high temperature. Silicic magmas tend to hold more dissolved water than mafic magmas, because of the ability of water molecules to interact with highly polymerized silicate melts.

As a hydrous magma cools and crystallizes, the early precipitation of largely anhydrous silicate liquidus phases (orthosilicates, feldspars) forces the dissolved water to be contained in a progressively shrinking mass of melt. Eventually, the diminishing melt may become saturated in water, forcing exsolution of a separate aqueous fluid (often violently) upon further crystallization. Aqueous fluid exsolution also can be

triggered by a sudden drop in confining pressure on the magma in response to rapid ascent, stoping, seismic events, or collapse of an overlying volcanic edifice.

This aqueous exsolution process, traditionally termed 'resurgent boiling', can result in injection of the magma-hydrothermal fluid into the crystallized outer carapace of the magma as well as the surrounding wall rock. The aqueous fluid often carries incompatible large ion lithophile elements as well as volatile components such as CO_2, HCl, HF, $B(OH)_3$, SO_2 and H_2S. Metal ions may be carried along with the halides and sulphur, typically as metal chloride or sulphide complexes.

As this exsolved fluid reacts with the extraneous rocks and pore fluids it encounters, it cools and evolves chemically; it may also undergo further phase separations (boiling and gas exsolution). Because the stabilities of aqueous metal complexes can be strongly affected by changes in temperature, pressure, pH and other chemical parameters, the cooling, reacting fluid can precipitate hydrothermal ore minerals in open fractures and pores, as well as deposit ore minerals by replacement in suitably reactive wall rock.

Economic geologists look for a number of lines of evidence to link a specific ore deposit to a magma-hydrothermal origin. Field evidence may show spatial and temporal proximity of the ores to a source pluton; for example, veins, breccias or pegmatites which begin in a pluton and then branch out into and cross-cut surrounding wall rock. Hydrothermal alteration developed in the surrounding wall rock may show concentric mineralogical and geochemical zonation around a likely source pluton (**Figure 4**). Evidence can also include remnants of the magma-hydrothermal fluid itself, preserved as aqueous fluid inclusions trapped in the ore and gangue minerals. Such inclusion fluids will typically have very high salinities, high homogenization temperatures and daughter minerals indicative of their origin. Stable isotope ratios of H and O in the minerals may also yield values and calculated equilibration temperatures consistent with a magmatic-hydrothermal origin.

Many magma-hydrothermal ore deposits (such as the numerous skarn and porphyry base metal deposits found in the south-western United States, Chile, Papua New Guinea, and Indonesia) exhibit evidence of early exsolution of a magma-hydrothermal fluid followed by late-stage heating and entrainment of surrounding groundwaters as the pluton

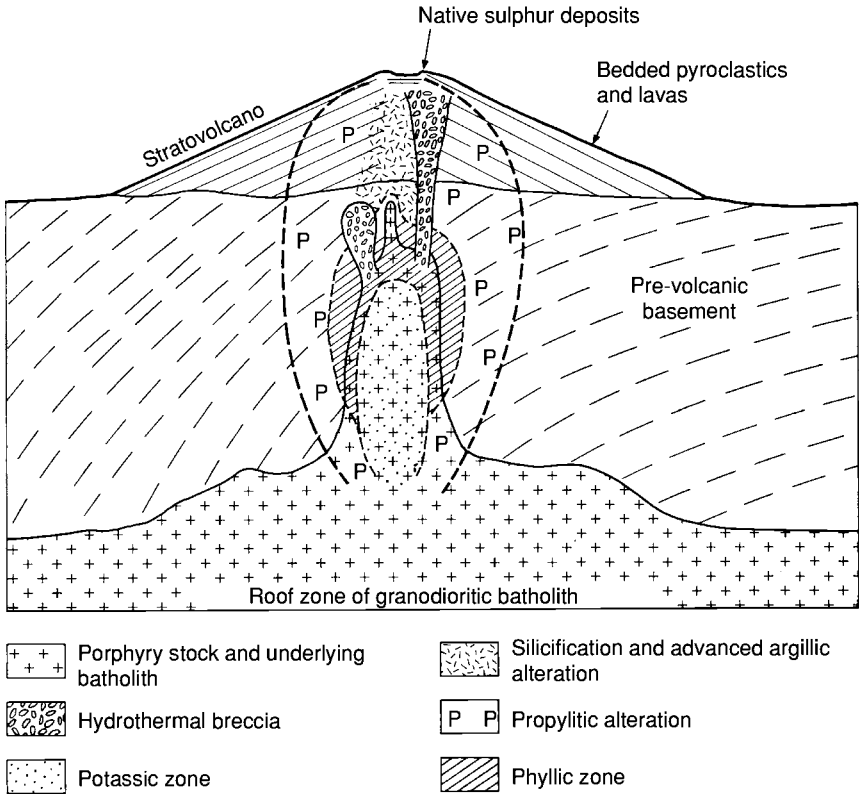

Figure 4 Diagramatic representation of a simple porphyry copper system. (Reproduced with permission from Evans AJ (1993) *Ore Geology and Industrial Minerals: An Introduction*, 3rd edn. Oxford: Blackwell.)

cools. This may result in redistribution of the early-formed ore metals and development of a larger-scale hydrothermal convective meteoric system more akin to the magma-heated systems discussed in the next section.

Examples of some major magma-hydrothermal ore deposits include Grasberg (porphyry and skarn Cu in Indonesia), Bingham (porphyry and skarn Cu in Utah), King Island (skarn W in Tasmania), and Chiquicamata (porphyry Cu in Chile).

Magma-Heated Surface, Ground and Ocean Waters

Some hydrothermal ores owe their origins to waters that were mainly heated by, but not directly exsolved from, magmas. In many cases any aqueous geochemical signature from magma degassing or exsolution is simply swamped out by the availability of shallow water from other sources. Such non-magmatic water sources include meteoric waters, groundwaters, lake waters and ocean waters. There are specific types of plate tectonic settings where such waters often become heated by proximity to magmatic processes.

In continental settings, shallow (epizonal) magmas often ascend into close proximity to surface and subsurface waters in volcanic arcs. Being topographically elevated, active continental volcanic arcs can receive abundant meteoric precipitation and are sufficiently porous and permeable (due to recurring tectonism and volcanism) that rapid recharge of their subsurface waters occurs. Crater lakes, caldera lakes, and tectonic lakes (formed from landslide blockage of drainages) provide additional reservoirs of surface water for recharge in arcs. At higher elevations and latitudes, snow and glaciers on the flanks of volcanoes can provide recent meteoric water upon melting.

This combination of shallow heat sources plus readily available meteoric water in permeable rocks creates ideal conditions for shallow convective hydrothermal systems, in which cold meteoric recharge waters descend, become heated by magmas, and rise buoyantly to discharge at or near the surface. Fumaroles, hot springs, geysers and mud pots at the surface attest to such fluid circulation cells at depth. As the heated meteoric waters circulate through the wall rocks and even the outer crystallized portions of a magma, they can acquire dissolved salts and metals and become ore-forming fluids, re-precipitating the metals as ores when they cool, boil or react with shallower groundwaters and rocks. Such shallow vein and disseminated hydrothermal ores are often termed epithermal on account of their shallow depth of formation. Examples include Creede, Colorado and Hishikari, Japan.

Arc magmas do not passively contribute only heat to overlying epithermal systems. Exsolving magmatic gases such as SO_2 and H_2S can become entrained in epithermal circulation systems, oxidizing to sulphuric acid near the surface. This results in a common association between some epithermal ores and acidic alteration (micas, clays, sulphates) of shallow wall rocks. Metals from magmas may also be exsolved into shallow epithermal systems, so they really should be viewed as hybrid systems with variable degrees of chemical input from magmatic and non-magmatic sources. Epithermal ores with evidence for a high contribution of components (especially acidic sulphur gases) from shallow degassing magmas are called high sulphidation state ores; they typically form in settings where a crater lake sits right above a shallow volcanic magma. Examples include Summitville, Colorado and El Indio, Chile.

Figure 5 schematically shows examples of many types of settings for hydrothermal systems in which epithermal and mesothermal gold deposits are formed.

It should not be surprising that magma-hydrothermal and epithermal hydrothermal processes can overlap in time and space, or that transitions between these processes should be common. Economic geologists use tools such as fluid inclusions and stable isotopes (O, H, S) to evaluate the relative roles of magmatic and meteoric components in the genesis of specific ore deposits. It is not uncommon to find deep, largely magma-hydrothermal ore deposits (such as porphyry base metal or skarn deposits) beneath temporally equivalent epithermal deposits (such as gold and silver vein and disseminated deposits) in shallower wall rock and volcanics.

Continental rifts are another plate tectonic setting where magmas and non-magmatic waters can interact to form hydrothermal ores. In such rifts, extension, subsidence and rapid sedimentation take place in conjunction with bimodal volcanism, providing opportunities for shallow basaltic and rhyolitic magmas to interact with lakes and groundwaters. Moreover, evaporation of closed-basin surface waters in rifts can lead to the development of very saline brines, which when heated by magmatism have tremendous capacity to dissolve, carry and re-precipitate ore metals derived from sedimentary and volcanic sources. Subsurface vein and disseminated ores can form in rift sediments and volcanics, along with overlying stratiform lenses and layers of ores formed when upwelling brines are injected or expelled parallel to shallow sediment layers. The Salton Trough of western North America (Table 1) and the Red Sea are modern examples of such settings.

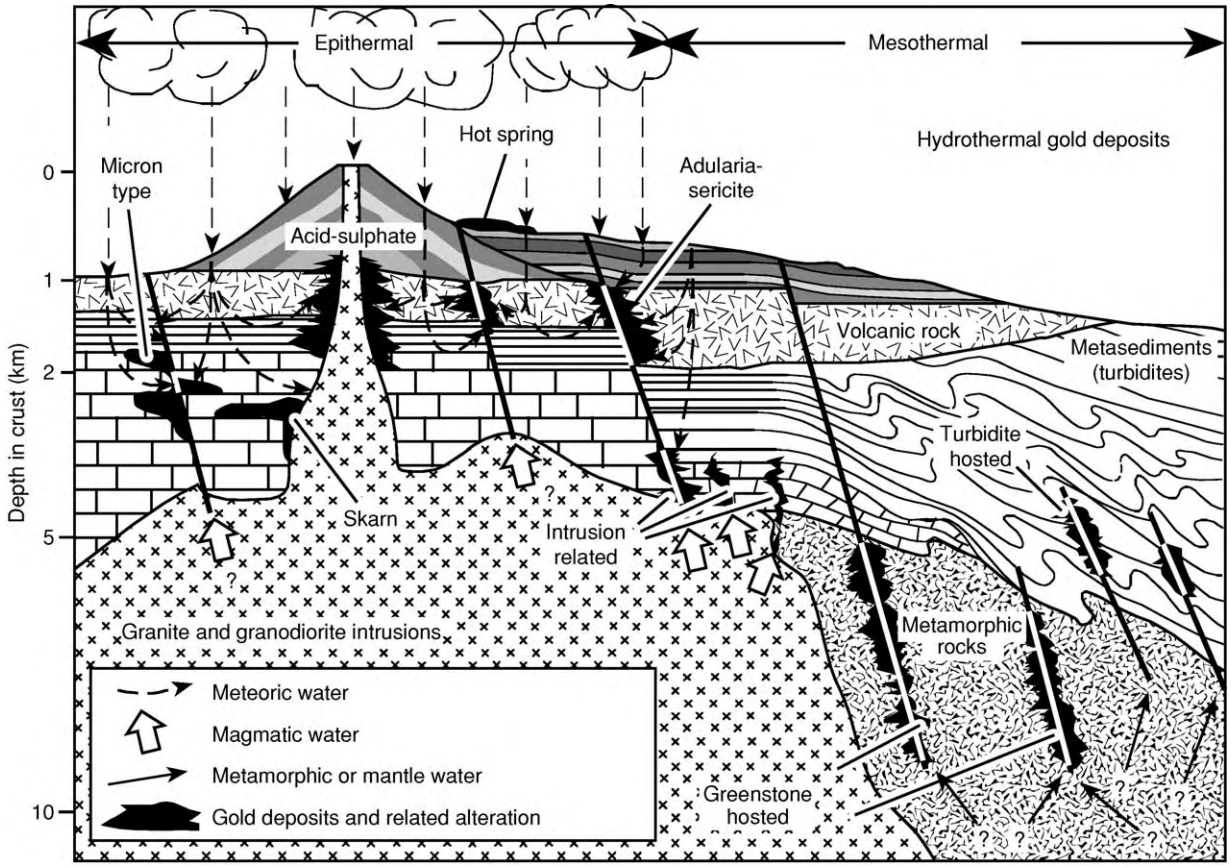

Figure 5 Schematic illustration of the wide variety of occurrences of hydrothermal gold deposits in continental crust. The terms epithermal and mesothermal refer to shallow crustal and mid crustal level deposits, respectively. (Reproduced with permission from Kesler SE (1994) *Mineral Resources, Economics and the Environment*. New York: MacMillan.)

In oceanic settings, volcanic arcs and rifts can lead to the formation of hydrothermal ores similar in principle to those found on continents. The main differences are the pervasiveness of seawater as a source of water and the dominance of oceanic crust and basaltic magmatism. Mid-ocean ridges, where roughly two-thirds of the Earth's heat flow occurs, develop large-scale hydrothermal convection systems that flux tremendous amounts of seawater through hot oceanic crust. The cold, oxidized metal-deficient and sulphate-rich seawater reacts with the hot basaltic crust and becomes a hot, reduced metal- and H_2S-rich ore-forming fluid. The metals that have been mobilized from the oceanic crust are re-deposited as vein and disseminated sulphide ores in the subsurface of the ridge structure, as well as expelled from submarine hot springs (black smokers) to form mounds and precipitates of metal sulphide on the seafloor. Only within the last few decades have earth scientists become aware of the spectrum of oceanic hydrothermal deposits that form at oceanic ridges, seamounts and back-arc basins. Many volcanogenic massive sulphide (VMS) deposits, long known to have spatial associations with altered mafic rocks, are now recognized as remnants of ancient oceanic ridge and back-arc hydrothermal systems that have since been accreted to or obducted onto the continents. The Cu–Pb–Zn districts of Kuroko, Japan and Jerome, Arizona are ancient examples; modern settings include massive sulphide deposits forming along the Juan de Fuca ridge in the north-eastern Pacific.

Hydrothermal Fluids Not Directly Affiliated with Magmatic Processes

Hydrothermal fluids and ores can be formed via heating mechanisms that have no direct association with magmatic processes. Basin subsidence through the normal geothermal gradient can heat sediment pore fluids and induce free convection, enhancing their ability to carry and redistribute metals. Such processes may be responsible for unconformity-related basinal uranium deposits such as those found in Saskatchewan (Canada) and Northern Territory (Australia). Rapid subsidence may also induce

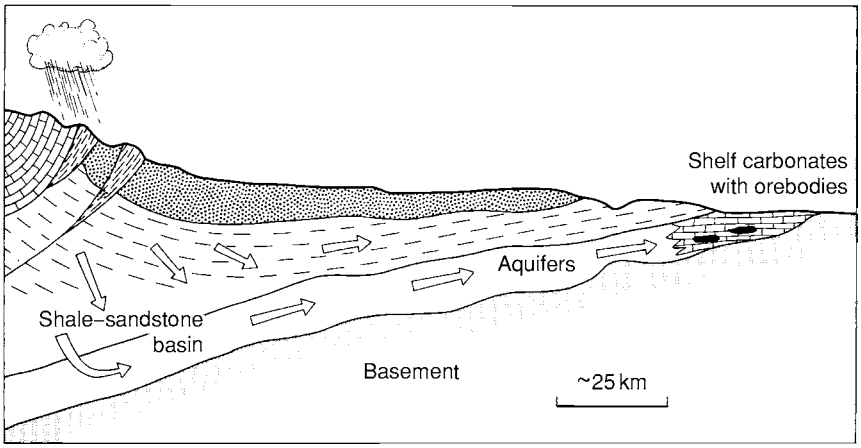

Figure 6 Schematic model for formation of carbonate hosted Mississisppi Valley type Pb Zn ores, via lateral gravity driven flow of basinal brines from an upland region. (Reproduced with permission from Evans AJ (1993) *Ore Geology and Industrial Minerals: An Introduction*, 3rd edn. Oxford: Blackwell.)

compaction and overpressuring of basin sediments, promoting the flow of warm pore fluids.

Pore fluids in deforming sedimentary basins adjacent to uplifting forelands can be forced to flow laterally in response to gravity, a scenario that is best developed during continental plate collisions. A widely accepted theory for the origin of many carbonate-hosted Mississippi Valley-type (MVT) Pb–Zn deposits in central and eastern North America is westward gravity-driven flow of warm basinal brines, caused by Late Palaeozoic collisions between the ancient North American and European continents (Figure 6). Compositional and colour banding ('sphalerite stratigraphy'), fluid inclusions, and other geochemical features of the ores are remarkably consistent over long distances between the Pb–Zn deposits, supporting the occurrence of regional fluid-flow events. Gravity-driven lateral flow of basinal brines has emerged as the most effective mechanism that can account for the thermal and mass balances in many MVT systems.

Overthrusting and consequent sediment compression in fold-mountain belts may also drive the flow of deeper, warmer fluids into shallower or more peripheral environments. Shale-hosted stratiform copper deposits such as the Kupferschiefer (Europe) and White Pine (North America) may have formed via this type of mechanism.

Dehydration reactions associated with regional metamorphism can also provide sources of hot fluids, although they are initially low in salinity and high in CO_2. Such fluids may have been responsible for hydrothermal gold deposits associated with CO_2 metasomatism, found in shear zones and faults in Archaean and younger greenstone belts. Earthquake-induced seismic pumping could provide a mechanism of fluid flow along fault zones.

Magmatic Ores

J E Mungall, University of Toronto, Toronto, ON, Canada

Introduction

Magmatic ore deposits may be defined as rocks of igneous origin (*see* **Igneous Processes**), which can profitably be mined for their constituent chemical elements. For example, the worth of annual global production from magmatic ore deposits exceeded $10 billion in 2001, and dominates or contributes significantly to world supplies of elements representing more than a third of the periodic table. This article summarises the petrogenetic controls on the genesis of magmatic ore deposits, with an emphasis on the application of geochemical models. Readers are encouraged to consult the Further Reading Section at the end of this article for detailed descriptions of the multitude of types of magmatic ore deposits (Figure 1).

Fundamental Controls

The generation of a magmatic ore deposit depends upon the successful operation of four fundamental processes. Elements that are normally widely distributed at low concentrations must be extracted from a large volume of rock by a natural melting event. The resulting magma must be collected into or channelled through a relatively small volume of the Earth's crust, such as a conduit or magma chamber. While within the conduit or magma chamber the magma must become saturated with a phase within which the element of interest is highly concentrated. The phase containing high concentrations of the target element must then be mechanically sorted from the remainder of the magma, and collected in sufficient quantity and at sufficient grade to constitute an economically attractive ore deposit (*see* **Economic Geology**). The study of magmatic ore deposits is, therefore, inextricably tied to studies of the partitioning of elements between coexisting phases in magmas, and of the processes of intrusion and differentiation of magmatic systems (Figure 2).

Element Partitioning

The key to a quantitative approach to the description of the evolution of a magmatic system lies in the distribution of chemical components among the coexisting phases. The distribution of an element between two phases at equilibrium may be described through the use of a partition coefficient D, which is defined as the ratio of the concentration of the element in one phase (e.g., mineral or sulphide melt) to its concentration in another (e.g., silicate melt) (*see* **Minerals:** Sulphides); for example, the partition coefficient for Cu between sulphide and silicate melts can be expressed as

$$D_{Cu}^{sulphide/silicate} = \frac{C_{Cu}^{sulphide}}{C_{Cu}^{silicate}} \quad [1]$$

where C denotes concentration of the subscripted element in the superscripted phase. Partition coefficients can be used in quantitative thermodynamic calculations if the element in question is a trace element whose concentration varies through ranges too small to affect D (Henry's Law is obeyed). If the element is a major or stoichiometric constituent of one of the phases, then D loses its utility as a constant. Values of

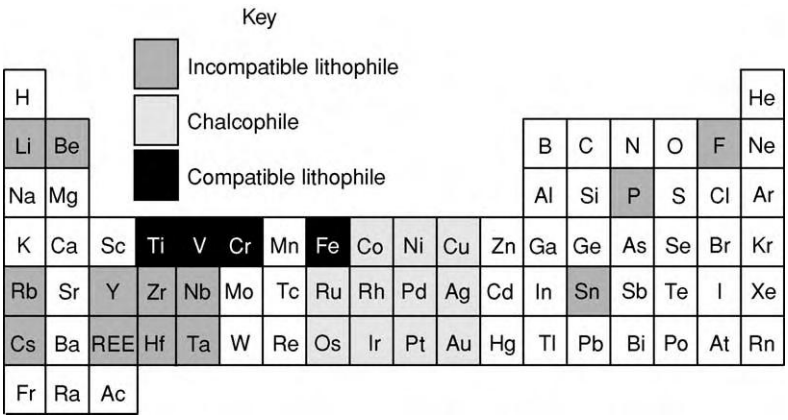

Figure 1 Elements extracted in significant quantities from magmatic ore deposits.

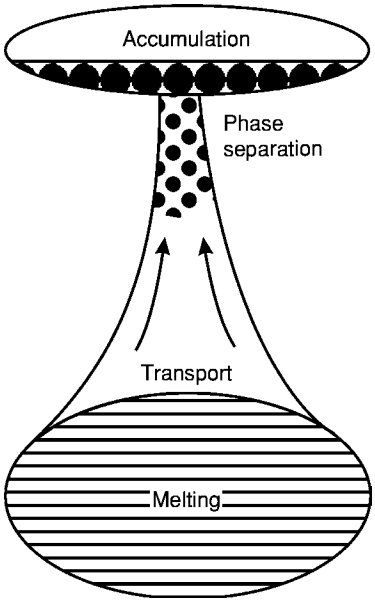

Figure 2 Processes required to generate a magmatic ore deposit.

D quoted in this contribution are intended to be used not as thermodynamic constants but rather as approximate indicators of the affinity of elements for various magmatic phases.

If two phases coexist at equilibrium in a closed system, eqn [1] can be combined with mass balance constraints to give concentration of an element in the melt as a function of the degree of partial melting:

$$\frac{C_i^{melt}}{C_i^{bulk}} = \frac{1}{D_i^*(1-F)+F} \qquad [2]$$

where C_i^{bulk} is the concentration of element i in the entire system, F is the fraction of melt present and D_i^* is a bulk partition coefficient for element i between solids and melt, obtained by summing over all solids the products of the individual phase/melt D and the weight fraction of the phases in the total solid assemblage.

Two processes that may occur during the differentiation of a magma are of critical importance to the generation of magmatic ore deposits. The first is the fractional removal of crystalline phases as the magma loses heat by assimilation of wall rock or by conduction. The second is the separation of an immiscible Fe-S-O liquid if the magma exceeds its carrying capacity for sulphide. Both processes govern the concentration and eventual segregation of ore metals from magmas after melting has occurred.

The effect of fractional crystallization on the concentration of a trace element with constant solid/liquid partition coefficient D_i^* is described by the Rayleigh distillation equation:

$$C_i^{melt} = C_i^o F^{(D_i^* \ 1)} \qquad [3]$$

where C_i^o is the initial concentration of an element and F is the proportion of liquid remaining. Application of eqn [3] to a highly incompatible element in the limiting case of complete solidification would cause the singular occurrence of infinite concentration of a trace element in the last vestiges of melt. What occurs instead is that, at some point, the concentration of a trace element rises to the point at which a mineral that concentrates that element begins to crystallize, effectively increasing D and avoiding the singularity. Depending on the solubility of the concentrating phase, and the value of the element in question, an ore deposit may be generated simply by the intrusion and solidification of a magma that contains sufficient concentration of the element solely through the action of fractional crystallization from a magma which originated by small degrees of partial melting of a

fertile source. Metals which begin to crystallise in a concentrating phase, when the bulk concentration of the element in the magma itself is has not yet attained ore grade, must undergo a final concentrating stage in which the mineral phase carrying the element is physically separated from the magma and collected in one place to form an ore body.

The effect of separation of sulphide melt from silicate melt is usually described using the assumption of batch equilibration of the two phases in a closed system:

$$C_i^{sulphide} = \frac{C_i^{bulk}(R+1)}{R + D_i^{sulphide/silicate}} \qquad [4]$$

where R is the ratio of the mass of silicate melt divided by that of sulphide melt, and C and D are defined as above. Equation [4] can be derived from eqn [2] by redefining some of the terms, and is effectively identical to the equilibrium crystallization equation.

Based upon their relative affinity for the three principal types of phase present in magmatic systems, the elements shown in Figure 1 may be classed into three main groups (*see* Table 1). The chalcophile elements are partitioned strongly into sulphide melt at equilibrium with oxides or silicates, whereas the lithophile elements are those which reside in silicate or oxide phases in preference to metal or sulphide liquids. The lithophile elements may be subdivided into those which are partitioned into oxide or silicate minerals (the compatible lithophile elements) and those which are preferentially retained in silicate melt (the incompatible lithophile elements).

There is considerable overlap between the three groups of elements listed above; for example, V shows variable compatibility because it is an incompatible lithophile element during melting of the mantle, but becomes highly compatible when a magma is saturated with ilmenite or magnetite. Pd is strongly chalcophile, but in the absence of sulphide melt it behaves as an incompatible element.

Incompatible Lithophile Elements

Some combination of very small degrees of partial melting and fractional crystallization to very small residual melt fraction is required to elevate the concentrations of highly incompatible lithophile elements from their trace abundances in the bulk silicate Earth to the weight percent levels necessary for economic extraction. The principal host silicate magmas are granitic pegmatites or highly evolved alkaline or peralkaline felsic plutons. Carbonatites are a related class of rocks derived from carbonate magmas, either through liquid immiscibility with felsic alkaline rocks, or directly by extremely small degrees of partial melting of carbonate-rich mantle.

Incompatible lithophile element deposits may be subdivided into the Li-Cs-Ta (LCT) and the Nb-Y-F (NYF) classes. Deposits of the LCT class are almost exclusively granitic pegmatites associated with highly fractionated intrusions of reduced ilmenite-series (S-type) granites, whereas the NYF class tend to be derived from alkaline or peralkaline felsic intrusions.

LCT pegmatites are thought to originate by fluid-absent melting of pelitic or semipelitic metasedimentary schists in Abukuma-type regional metamorphic belts. Pelitic sediments are generally rich in alkali elements including Li and Cs, and also contain large amounts of F and B. Incongruent melting of white micas and complete melting of tourmaline produces water-poor peraluminous magmas rich in the fluxing components P, F, and B. The compositional undercooling caused by degassing of H_2O as water-rich magmas rise through the crust, causes them to

Table 1 Summary of partitioning behaviour of metals

Element group	*Examples*	D_i^*	*Concentrating phases*	D_i	*Magmatic environments of ore deposition*
Incompatible lithophile	Li, Be, F, Rb, Y, Zr, Nb, Cs, REE, Hf, Ta	<0.1	Melt, rare element minerals	na	Pegmatite fields alkaline intrusions carbonatites
Variable compatibility	P, Ti, V, Cr, Fe	<0.1	Oxide minerals, apatite	10 100	Stratiform intrusions, podiform bodies immiscible oxide melts

Compatible chalcophile	Os, Ir, Ru, Ni	1 10	Olivine, oxide minerals	500 50 000	Chromitites magmatic sulphides

D_i^* is the bulk partition coefficient between mantle minerals and silicate melt during conditions typical of the generation of basaltic magmas. D_i is the partition coefficient for the phase which ultimately concentrates the element (e.g., sulphide melt for chalcophile elements, oxides for Ti, V, Cr). Elements with variable compatibility are those which are generally incompatible during melting but which are concentrated in minerals that crystallize from basaltic to intermediate magmas.

freeze at their eutectic before they can undergo extensive fractional crystallization. In contrast, the water-poor magmas parental to LCT pegmatites do not exsolve a free vapour phase, and do not evolve toward the water-saturated eutectic in the haplogranite system. Instead, LCT magmas are high-variance assemblages that can continue to evolve down to temperatures as low as 450°C, while continously becoming enriched in the fluxing elements F, B, and P as well as the trace elements including Li, Cs and Ta. The residual liquid may be enriched in the lithophile elements to such an extent that its bulk composition may be of ore grade. This magma can then be injected into the country rocks surrounding the cooling pluton and crystallized as swarms of rare-element pegmatite dikes (Figure 3).

The NYF suite of pegmatites and related plutons are probably derived by small degrees of partial melting of upper mantle similar to the sources of ocean island basalts, to produce alkaline magmas or magmas transitional from alkaline to tholeiitic affinity. Such small degree melts are enriched in incompatible elements like Nb, Zr, and Y, and can evolve through a prolonged process of fractional crystallization to peralkaline silica-saturated (pantelleritic) or silica-undersaturated (phonolitic) products. Deposits of the NYF suite of elements may form either directly by crystallization of the rare-element-rich magma. Alternately, the incompatible lithophile elements (e.g., Be, Nb, Y, Zr) may be transported by peralkaline fluids expelled from the cooling pluton, to be deposited where they mix with meteoric or formational waters surrounding the pluton.

There is an immense variety of rare-element pegmatites and related rocks, and there are undoubtedly a number of deposits whose genesis differs in significant ways from the models described here. However, the key requirements for any rare-element magmatic ore deposit must be the essential combination of small degrees of partial melting of fertile source rocks, and extreme fractional crystallization, both processes acting to concentrate these elements in progressively smaller volumes of silicate magma.

Carbonatites (*see* **Igneous Rocks:** Carbonatites) are igneous rocks that contain more than 50% carbonate minerals (*see* **Mining Geology:** Mineral Reserves). They host a great diversity of ore deposits, but the primary commodities extracted from these enigmatic rocks are rare earth elements (REE) and Nb (for which carbonatites are the principal source) as well as Fe, P, F, V, Zr, and Cu. Carbonatite may occur as small, usually concentrically-zoned plutons, or as lavas or pyroclastic deposits of regional extent.

Since carbonate is immiscible with alkaline CO_2-rich magmas, almost any alkaline or peralkaline magma has the potential to form an immiscible carbonatite liquid, given sufficient excess CO_2. Associated carbonatite and alkaline silicate magmas are found in tectonic settings including hotspots and convergent margins. The primary carbonatite magma is thought usually to be calcitic, and concentrates elements with high ionic field strength such as Nb, P, Zr, and F relative to coexisting silicate melt. Carbonatites evolve by fractional crystallization to dolomitic compositions which may become saturated with ore minerals such as pyrochlore, magnetite, and apatite. Late-stage carbonatite magmas may evolve to extremely sodic or ferroan compositions, and can crystallize important volumes of REE minerals such as monazite and bastnaesite within core zones or dykes cutting across carbonatite-alkaline rock complexes.

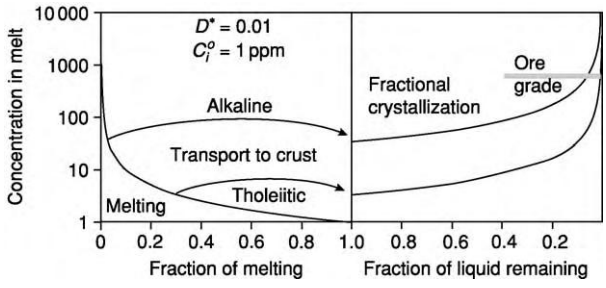

Figure 3 Formation of incompatible element deposits of the NYF class. Melting curve was calculated with eqn [2]; fractional crystallization with eqn [3], for a hypothetical element similar to Nb, Y, or Zr. Arrows represent the extraction of magmas from the mantle to the crust. Only alkaline magmas derived by small degrees of partial melting (left panel) can evolve through fractional crystallisation to very high concentrations of rare lithophile elements (right panel).

Oxides

Cumulates

Oxide minerals hosted by igneous rocks constitute important or principal sources of V, Ti, Cr and, to a lesser degree, Fe. There is considerable controversy surrounding the origins of many magmatic oxide deposits, between proponents of models for their deposition as cumulates from silicate magmas, or as oxide magmas derived by immiscibility with silicate magmas.

There is little doubt that the extremely refractory mineral chromite is deposited as a cumulus phase from silicate melts. Chromite deposits occur either as stratiform horizons in layered intrusions or as podiform accumulations in dunitic rocks. Mixing of two magmas cosaturated with olivine and chromite

will lead to oversaturation of the hybrid magma with chromite alone. Since primitive magmas commonly have only olivine and chromite on their liquidus, each magma recharge event in a large mafic magma chamber will lead to the temporary cessation of olivine accumulation, and the formation of a crystal layer composed solely of chromite. The thickness of the layer that forms will depend upon the temperatures and proportions of the magmas involved as well as the height of the magma column above the cumulate pile. Large layered intrusions, such as the Bushveld intrusion of South Africa, commonly contain numerous chromitite layers in their ultramafic basal series, the largest of which can be mined.

The mode of formation of podiform chromitites has been a more difficult conundrum than that of stratiform bodies. Podiform chromitites are found as wispy, nodular, or layered masses entirely enclosed within pipe- or dyke-like bodies of dunite in the harzburgitic mantle section of ophiolite complexes. Arai recently proposed that the same magma mixing mechanism used to explain the formation of stratiform chromitites can be applied to podiform chromitites. In his model, the more primitive magma is carried by porous flow through the dunite pipe. Melts that have migrated into successively lower-temperature environments farther from the core of the pipe become more evolved. Hybrid, chromite-oversaturated magma forms in places where the flow regime allows some of the cooler, more evolved melt to be drawn back into the core of the system. If the system reaches a steady state, chromitite pods can form and grow to considerable size in the zone of mixing between the two magmas.

Titanomagnetite can be deposited as stratiform horizons in large layered intrusions in much the same manner as chromite. Several processes have been proposed to explain how magnetite can arrive on the liquidus of a basaltic magma, to form monomineralic oxide layers in gabbroic cumulate rocks. The simplest involves magma mixing, analogous to the chromite saturation mechanism. Others include sudden changes in pressure or oxygen fugacity. Whatever the cause, once magnetite begins to crystallize from a basaltic magma, the transition metals Ti and V experience a sudden change from incompatible to strongly compatible behaviour. The first layer of magnetitite to form can constitute an ore of Ti and V, with Fe as an important byproduct. Because magmas form with a range of V and Ti contents, and because the partitioning behaviour of V is extremely sensitive to oxygen fugacity, there is a wide possible range of V abundance in magnetitites, and only a few are of economic grade. Stratiform accumulations of magnetitite are the world's primary repositories of V ore.

Immiscible Oxide Liquids

There are a number of deposits of Fe-Ti oxide (ilmenite and titanomagnetite with or without accessory apatite) worldwide that show textural and structural features, suggesting that they were emplaced as oxide magmas or lavas. There appears to be little doubt that the world's largest Ti deposits (Lac Tio, Canada; Tellnes, Norway) consist of intrusive sills and dykes composed of ilmenite, magnetite, and apatite. More controversial are the magnetite deposits of Kiruna, Sweden, and the El Laco deposit in Chile. In oxide rocks that have mesoscale textures and structures that perfectly replicate shallow subvolcanic and extrusive rocks, including pyroclastic flows, bombs, and lava flows, both deposits present textures closely resembling dendritic quench textures seen in slags. On the other hand, no experimental study has yet demonstrated that iron oxides can exist as liquids at reasonable magmatic temperatures. Furthermore, there is abundant evidence for marginal metasomatic replacement of common lavas and pyroclastic rocks by the same mineral assemblage as is found in the allegedly magmatic oxide rocks, raising the possibility that the oxide deposits may have formed by hydrothermal replacement of pre-existing silicate extrusive rocks. Controversy will likely continue for many years to come.

Chalcophile Elements

The upper mantle is thought to contain about 250 ppm of sulphur in the form of sulphide minerals. Under the conditions of formation of basaltic magmas, the sulphide will be entirely molten, so that the chalcophile elements will be sequestered within the sulphide melt. Under these conditions, the highly chalcophile elements will not enter the basaltic magma in significant quantities, and even the more moderately chalcophile elements such as Cu and Ni will be impoverished in the basalt. Since sulphide is sparingly soluble in basaltic magmas, progressively higher degrees of partial melting will dissolve progressively more of the sulphide. Upon approximately 25% partial melting of the mantle, all sulphide originally present will have been dissolved by the silicate melt, whereupon the chalcophile elements will now reside in a system containing only silicate minerals and silicate melt. Most chalcophile elements behave as incompatible lithophile elements in the absence of a free sulphide phase, so that at high degrees of partial melting of the mantle the chalcophile elements can be extracted into basaltic magmas and transported toward the surface. Such high degrees of melting are generally thought to be related to the melting of

mantle plumes (*see* **Mantle Plumes and Hot Spots**), and result in the extraction of picritic or komatiitic magmas (*see* **Igneous Rocks:** Komatiite).

Suprasubduction zone magmas typically remain sulphide-saturated during melting due to the introduction of sulphide to their source regions by the same fluids that induce partial melting (Figure 4). At best, arc magmas initially saturated in sulphide can generate low-grade Ni-Cu deposits with exceedingly low precious-metal contents.

Once a magma separates from its source and begins to rise toward the surface, it will fall into a state of sulphide-undersaturation due to the inverse dependence of sulphide solubility on pressure in silicate melts. When deeply-sourced mafic or ultramafic magmas reach the Earth's surface, they typically contain less than half the amount of sulphide necessary to induce sulphide saturation.

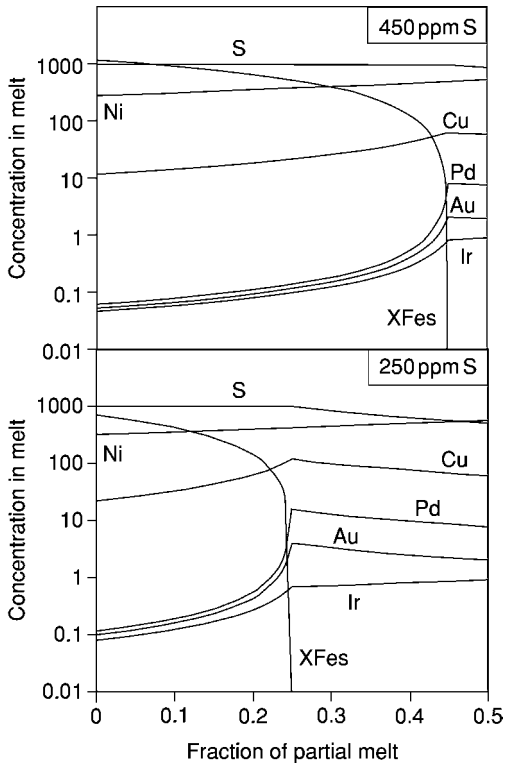

Figure 4 Concentration of chalcophile elements in basaltic magma during partial melting of mantle containing either 450 ppm S (metasomatized sub arc mantle; upper panel) or 250 ppm S (plume head melting; left panel). Chalcophile element concentrations increase as the amount of sulphide remaining in the source (XFes) diminishes. At the moment when sulphide is completely consumed, incompatible chalcophile elements reach their maximum possible concentrations, whereas compatible chalcophile elements (Ni, Ir) continue to increase with further melting.

Magmatic Sulphide Deposits

Magmatic sulphides represent accumulations of immiscible sulphide liquid separated from silicate magmas, and account for the majority of the value of metal produced from magmatic ore deposits worldwide. Although all magmatic sulphide deposits are intrinsically polymetallic concentrations of the base metals Fe, Ni, Cu, and the precious metals Au, Ag, and the platinum group elements (PGE; especially Pt and Pd), it is convenient to categorise them as either precious metal or base metal deposits, each of which yields the elements of the other group as important byproducts.

Precious metal sulphide deposits generally contain less than 1 modal % sulphide, whereas base metal sulphide deposits contain 5 to 100 modal % sulphide. The distinction is an arbitrary one, but it is a consequence of the extreme sensitivity of precious metal concentrations to the mass ratio of silicate to sulphide melt that equilibrate during sulphide segregation, as illustrated in Figure 5. Precious metal sulphide deposits typically form where very small amounts of sulphide have separated from silicate melt and collected in stratiform bodies within large mafic intrusions. Base metal-dominated magmatic sulphide deposits form by the collection of immiscible sulphide liquid

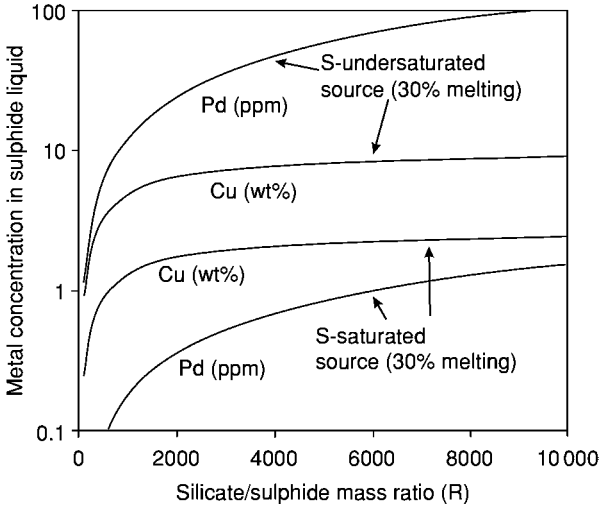

Figure 5 Concentrations of Cu and Pd in sulphide liquid equilibrated with basaltic liquids as functions of the silicate/sulphide mass ratio (R in eqn [3]). The curves are calculated assuming that the initial basalt composition resulted from 30% partial melting of the upper mantle, using the compositions for the sulphide saturated and sulphide undersaturated cases shown in Figure 4. Sulphide rich systems ($100 < R < 1000$) can generate large quantities of base metal rich sulphide which contains relatively low PGE contents. At very high values of R the resulting sulphide is PGE rich, but correspondingly smaller in volume. Magmas derived from sulphide saturated mantle sources can only generate low grade base metal deposits without significant PGE.

from mantle-derived mafic, or ultramafic silicate magmas in lava channels, magma conduits, or places where conduits feed into larger bodies. The Sudbury mining camp, Canada, the world's largest collection of Ni-Cu-PGE deposits, is a unique exception. The Sudbury Igneous Complex and its base-metal sulphide ore deposits formed by the batch equilibration and gravitational segregation of sulphide liquid with several thousand km^3 of shock-melted continental crust following a large meteorite impact into a shallow marine basin filled with sulphidic sediments.

Base Metal Sulphide Deposits

A more common path to sulphide saturation in fertile, previously sulphide-undersaturated magmas is the assimilation of crustal rocks rich in sulphide. This has the combined effect of lowering the temperature of the magma while sharply increasing the amount of sulphur it contains. Addition of large quantities of sulphide can drive a magma into a state of extreme sulphide-oversaturation, so that the sulphide equilibrates at a relatively low silicate/sulphide ratio ($100 < R < 5000$; eqn [3]). The result can be the generation of sulphide in sufficient quantity to separate and form economically attractive tonnages of the base metal sulphides, however, at these relatively lower silicate/sulphide ratios, the concentrations of the precious metals in the resulting sulphide tend to contribute a relatively small part of the total value of the ores.

Emplacement of magmatic sulphides The dominant mode of transport of magmas in the crust is by the emplacement of dykes and sills. Figure 6 provides schematic illustrations of the most important mechanisms for sulphide segregation. Two phenomena related to dyke and sill emplacement are of particular importance in the generation of magmatic sulphide deposits. These are the formation of long-lived conduits, and the formation of channelized lava flows. Because thin, tabular sheets of magma cool rapidly, flow along dykes and sills tends to become focused along their widest portions, which then enlarge themselves by heating and assimilating their wall rocks. The result is the generation of long-lived blade-shaped or tubular magma conduits in which flowing magma cools relatively slowly. Similarly, large fissure-fed lava flow fields are thought to develop distributary systems resembling deltas, in which deeply incised lava channels proximal to the vent feed smaller branching channels and distal sheet or pillowed flow lobes. Within either a conduit or a lava channel, it is possible for a steady state to be reached, in which the temperature of magma passing a given point remains constant for extended periods of time. If the rate of supply of sulphide by degassing or erosion of the channel floor or conduit walls, and the rate of cooling and crystallization also approach a steady state, then sulphide liquid first reaches saturation in the magma always as it passes a single point within the conduit or channel. Sedimentation of sulphide droplets from the flowing lava, perhaps also with a co-saturated phenocryst phase (olivine or pyroxene), can thus lead to highly efficient sorting of the phase and the elements it concentrates from a very large volume of magma into a small, localized volume of rock.

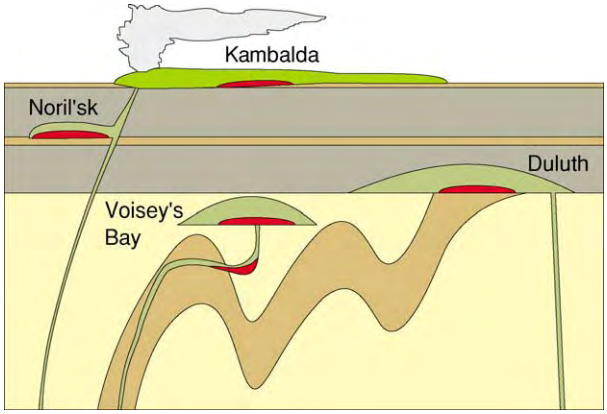

Figure 6 Cartoon of principal mechanisms for the generation and segregation of magmatic base metal sulphides. The image shows a cross section of the upper crust, with brown areas representing sulphur rich crustal rocks which act as sources of sulphur for dykes and plutons of mantle derived magma (darker green) or lava flows (lighter green). Sulphide liquid collects where it formed (Duluth), in traps within conduits or where con duits enter magma chambers (Voisey's Bay), in subvolcanic sills (Noril'sk), or in lava channels cutting through sulphidic sediments (Kambalda).

A related possibility with a similar result is that a magma which has become saturated with sulphide liquid may carry the exsolved sulphide suspended as small droplets in the rapid and turbulent flow within the conduit. A transition within the dyke to laminar flow or a sudden drop in flow velocity due to its passage through a magmatic breccia or a widening of the conduit will then cause the entrained sulphides to settle together in one place within the conduit.

In practice it may be impossible to distinguish between the two sulphide collection mechanisms described above. Classic examples of valuable sulphide deposits accumulated from flowing magma in conduits or lava channels are given in Table 2, with the Sudbury Camp for comparison.

If sulphides are deposited in the place at which sulphide saturation occurred, without being transported and collected from a large volume into a small concentration, then a low-grade disseminated

Table 2 Characteristics of major base metal sulphide deposits*

Deposit or camp	Structural setting	Host magma type	Grades		Production and reserves (Mt)

deposit like those of the Duluth Complex (USA) will result.

Precious metal magmatic sulphide deposits An initially sulphur-undersaturated magma may become sulphur-saturated because crystallization of silicate minerals causes an enrichment of sulphur in residual melt while cooling simultaneously lowers the solubility of sulphide. Highly evolved basaltic magmas may thus passively evolve into a state of sulphide saturation in large magma chambers, causing the separation of extremely small fractions of sulphide melt, as may have occurred in the Great Dyke of Zimbabwe and the Munni Munni intrusion of Australia. Recharge of a large magma chamber by a fresh pulse of magma is another popular explanation for the sudden onset of sulphide saturation in large magma chambers (Figure 7). However, the magma body does become saturated with sulphide, removal of sulphide melt at high R value (eqn [4]) from a silicate magma barely saturated in sulphide may efficiently scavenge precious metals from the entire magma chamber into a single thin stratabound layer. The sulphides thus generated will also be highly enriched in the base metals, but at total sulphide abundances on the order of 1 modal %, the deposits are only valuable for their precious metals.

An alternate possibility for the generation of stratiform sulphide horizons in a layered intrusion involves migration of deuteric fluids in the cooling cumulate pile (Figure 6). As the initially vapour-undersaturated intercumulus melt cools and approaches its solidus it will eventually exsolve an aqueous fluid. Orthomagmatic fluids are capable of dissolving considerable amounts of precious metals and sulphur as they rise through the cumulate pile. If such fluids remain sulphide-saturated and equilibrate with the small quantities of sulphide that exist within the intercumulus liquid, then they will carry

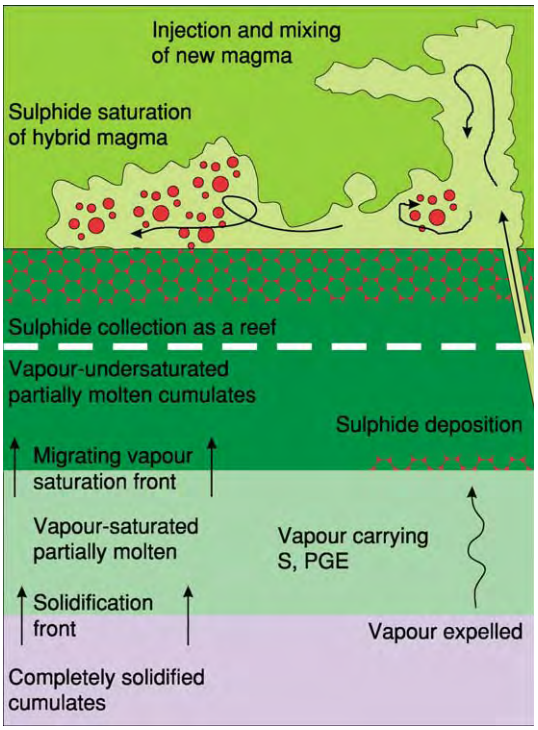

Figure 7 Schematic view of two popular models for the generation of reef type PGE sulphide mineralization in layered intrusions. The orthomagmatic model proposed by Campbell and co workers is illustrated above the white dashed line. The deuteric fluid model proposed by Boudreau and coworkers is illustrated below the line.

considerable amounts of dissolved sulphide and precious metals upward through the pile of cumulates. When such fluids reach the top of the vapour-saturated zone and encounter vapour-undersaturated intercumulus liquid, they will redissolve within it. Dissolution of the vapour phase will cause reprecipitation of the entrained sulphide and precious metals at the level of the transition to vapour-undersaturated conditions. As a vapour-saturation surface migrates

upward through a cumulus pile it will bring with it a sulphide- and precious metal-rich zone akin to a chromatographic front. Such fronts may be frozen in place by the eventual solidification of the cumulate pile, to form stratiform PGE-rich sulphide horizons.

Although there is a potential for the generation of a precious metal sulphide deposit wherever small volumes of sulphide liquid reach equilibrium with large volumes of formerly sulphur-undersaturated silicate magma, nearly all production from precious metal sulphide deposits comes from just two large layered intrusions; the Bushveld complex of South Africa and the Stillwater intrusion of the USA. About half of world production of Pd is generated as a by-product of base metal sulphide mining at Noril'sk in Russia.

MOHO DISCONTINUITY

P Giese, Freie Universität Berlin, Berlin, Germany

Introduction

A century ago, instrumental seismology began to reveal the internal structure of Earth. Analysing seismic data in 1909, following an earthquake 39 km south-east of Zagreb, the Austro-Hungarian meteorologist Adrija Mohorovičić discovered the boundary between the crust and mantle of south-eastern Europe. During the following decades, it turned out that this discontinuity, now known as the 'Mohorovičić discontinuity' (or simply 'Moho-discontinuity' or 'M-discontinuity' or Moho), is present worldwide in continental as well as in oceanic regions. The following discussion focuses on the morphology, structure, and age of the European Moho-discontinuity and the bearing that these features have on the structure and evolution of the crust. The data are largely based on the results of national and international projects carried out during the past 50 years. The European Geotraverse (EGT) project, from 1983 to 1990, involved studies of the European lithosphere along a north- and south-trending corridor from the North Cape of Scandinavia down to the northern coast of Africa (Tunisia), an ambitious

enterprise, in that it attempted to resolve a geodynamic evolution from ~3.5 billion years ago to the present. The EGT project was followed by the EUROPROBE project, which aimed at analysing the structure, properties, and evolution of 'deep Europe' and exemplary cases of crustal accretion, thickening, and extension. The summary of data from these projects covers the geophysical tools used, the petrological significance of the data, and the main structural features of the European Moho-discontinuity.

Geophysical Tools

Geophysical methods are indispensable for the recognition and interpretation of structures in Earth's crust and mantle. Among the numerous geophysical methods suitable to explore structure and composition of the lithosphere, seismic techniques provide the best tools for detailed crustal and upper mantle investigations (*see* **Seismic Surveys**). In explosion seismology, the use of deeply, nearly vertical, reflected waves (P waves) in the subcritical range provides detailed information about the internal structure of the crust and the uppermost mantle (Figure 1A). Another method is based on recording P waves termed 'PmP' wide-angle arrivals; these are recorded as overcritical reflected waves from the Moho-discontinuity and/or as diving waves generated by a strong velocity gradient zone in the model of the crust/mantle transition (Figure 1B). Tomographic studies using travel times of waves generated by earthquakes or by big explosions allow determination of the velocity field of the lithosphere (Figure 1C). During the past decade, a new 'receiver function method' has been developed (Figure 1D). It is based on earthquake records of broadband stations and makes use of P-to-S converted phases that are created at the Moho-discontinuity or other prominent boundaries in the lithosphere. For the study of the lithosphere/asthenosphere system, analysis of surface waves is another powerful seismic tool. The data discussed here are mainly based on recordings of P waves (compressional waves).

Nature and Stability of the Moho-Discontinuity

From a seismological point of view, the Moho-discontinuity is defined as the depth at which the velocity v_P of compressional waves increases from normal crustal velocity values of $<7.2\,km\,s^{-1}$ to typical upper mantle values of $>7.6\,km\,s^{-1}$. Modern studies see the Moho-discontinuity as a sandwich-like mix of crust and mantle materials (i.e., low- and high-velocity materials). In addition, the Moho-discontinuity is not only a compositional boundary,

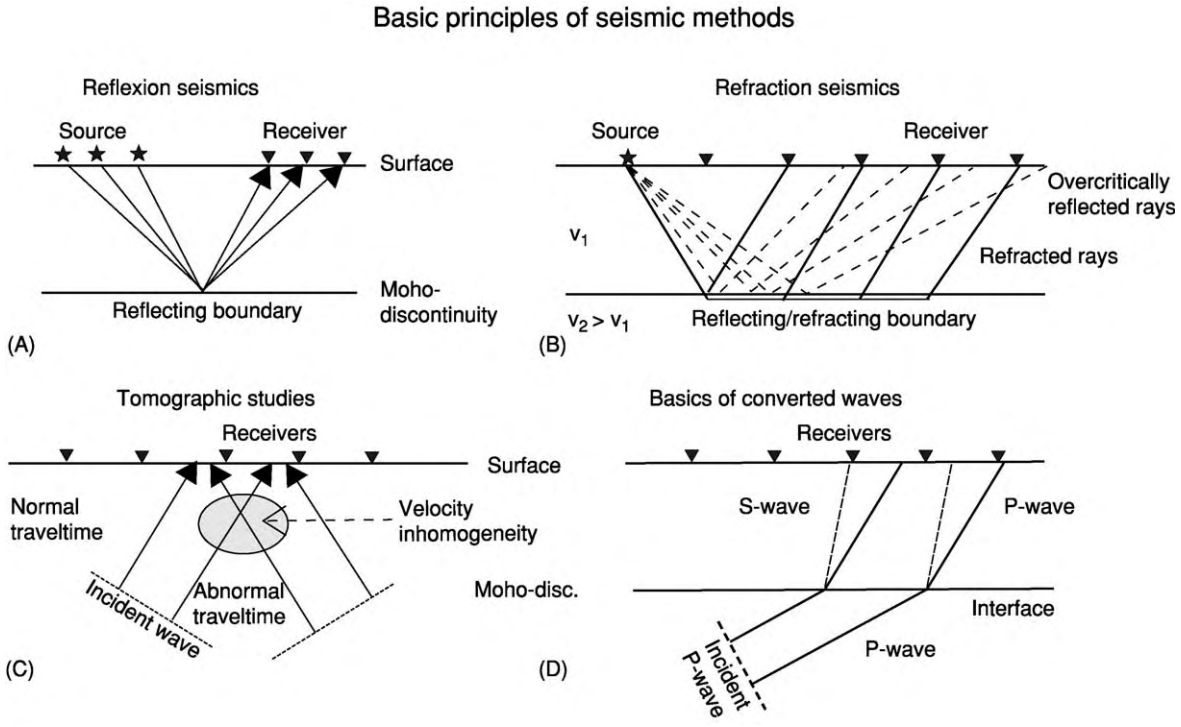

Figure 1 Basic principles of deep seismic sounding methods: (A) reflection seismology, (B) refraction seismology, (C) tomographic seismology, and (D) receiver function analysis.

but is additionally characterized by an abrupt change in the length scale of heterogeneities between the lower crust and upper mantle, and therefore also images various geodynamic processes (Figure 2). In many regions, the Moho depth derived from reflected waves generated at the base of the lower crust coincides with the depth of the Moho-discontinuity as determined from seismic refracted and wide-angle reflected waves. The difference between both results does not exceed a few kilometres. On the other hand, petrologists define the Moho-discontinuity between the crust and the uppermost mantle as a petrological boundary. The lower crust consists of high-temperature/high-pressure metamorphic rocks (granulite facies) with an average mafic composition approaching that of a primitive basalt (*see* **Ultra High Pressure Metamorphism**). As evidenced by mantle fragments brought to the surface by volcanism (xenoliths), the lower crust shows an interlayering of felsic and intermediate lithologies, causing a high degree of seismic reflectivity in the lower crust, as observed in many regions. The layer beneath the Moho-discontinuity, the uppermost mantle, is built up of rocks rich in olivine (*see* **Minerals:** Olivines).

The ambiguity between the geophysical and petrological definitions of the Moho-discontinuity causes problems of interpretation. If lower crustal rocks such as pyroxene granulite or gabbro are subducted to depths below 50–60 km, they are metamorphosed into the high-pressure rock type, eclogite, which shows the same density (3300 kg m ^{3}) and the same P-wave velocity (>7.6 km s ^{1}) as normal mantle rocks (peridotites) show. From this geophysical perspective, eclogites would be interpreted as upper mantle rocks underlying the Moho-discontinuity. Geological, petrological, and geophysical studies reveal that the Moho-discontinuity is not a permanently stable boundary and that it can be destabilized during all stages of the orogenic cycle by tectonic, magmatic, and metamorphic processes:

- Collision of continental blocks causes crustal thickening, associated with the formation of a surface topography and the generation of crustal and lithospheric roots. Intrusion of magmas may also cause crustal thickening.
- When the crust of a thickened mountain belt is reduced by erosion, the crustal root will be buoyantly uplifted until the crust has attained the same thickness as in the surrounding areas.
- When deeper levels of the crust are heated by the underlying mantle, crustal rocks may become mechanically soft and the crustal root may spread laterally over the Moho-discontinuity, much like oil on water.
- A pseudo-thinning of the crust may be caused by metamorphic processes in the lower crust, such as the transformation of gabbroic rocks into eclogite. Such 'pseudo-mantle' rocks might represent portions of subducted and metamorphosed lower crust, so that the true (petrological) crustal thickness would be higher than expected from the study of the recent seismic velocity distribution. Furthermore, such high-density layers may delaminate and sink downward into the deeper lithosphere and asthenosphere due to their negative buoyancy.

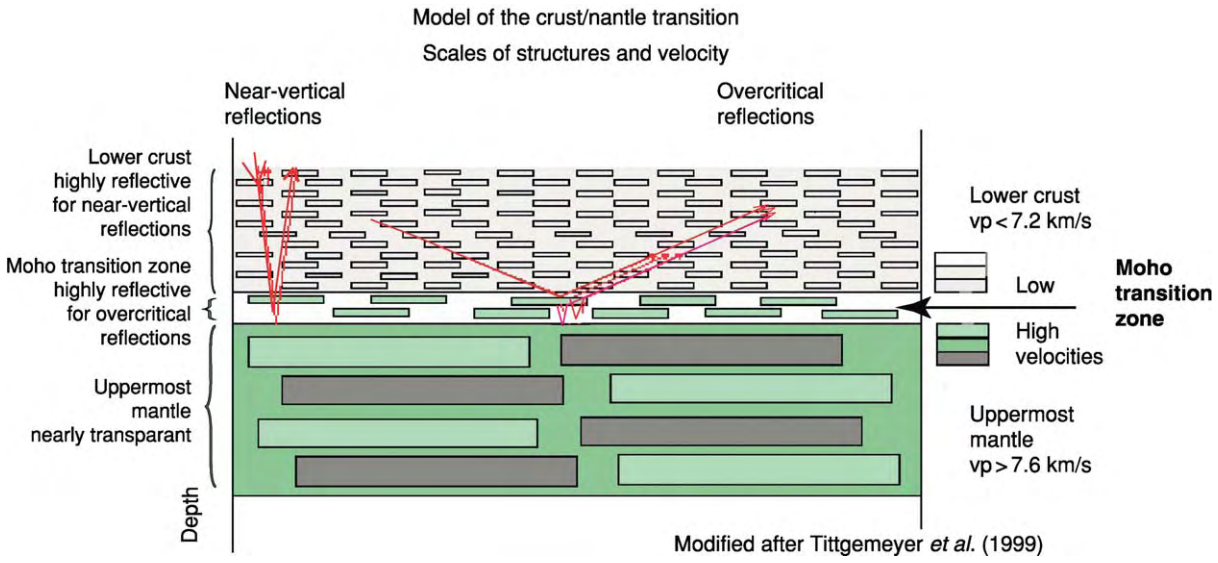

Figure 2 Material properties around the continental Moho discontinuity and their response to seismic signals. The thickness of the transition zone between the lower crust and the upper mantle may vary between ~100 m and a few kilometres. Modified from Tittgemeyer *et al.* (1999).

- The thickened orogenic crust may be thinned by syn- to post-orogenic extension driven by mantle convection, which creates new continental rifts and oceanic basins.

This brief overview demonstrates that the Moho-discontinuity is a sensitive indicator for the detection of past and recent geodynamic processes.

Main Tectonic Units of the European Continent

Present-day Europe forms the western part of the large continental Eurasian Plate. It is bordered in the east by the mountain belt of the Urals and in the north and west by the Atlantic Ocean, which opened in the Triassic. The southern border of Europe is formed by the Mediterranean Sea, the Black Sea, and the Caspian Sea (Figure 3). The growth of the European continent started in the northern region of the Baltic Shield, and the European crust becomes younger and younger from north to south and from east to west. Five main tectonic domains can be distinguished: (1) The East European (Russian) Platform and the Baltic Shield, the north-western part, were formed during Precambrian times, 3.6 Ga to 660 Ma (*see* **Europe:** East European Craton). The western margin of the East European Platform is formed by the complexly structured Trans-European Suture Zone (TESZ), which separates the Variscan mobile belts of Central Europe from the stable platform of Eastern and Northern Europe. This suture zone extends over 2000 km from the North Sea down to the north-western Black Sea. (2) The north-western margin of the Baltic Shield is marked by the Caledonide Orogen, which was formed during the Late Silurian to Early Devonian (*see* **Europe:** Scandinavian Caledonides (with Greenland)). The Caledonides continue into northern parts of England and Ireland (*see* **Europe:** Caledonides of Britain and Ireland). (3) On the eastern side of the East European Platform, the Uralian Orogen (380–250 Ma) marks the tectonic boundary

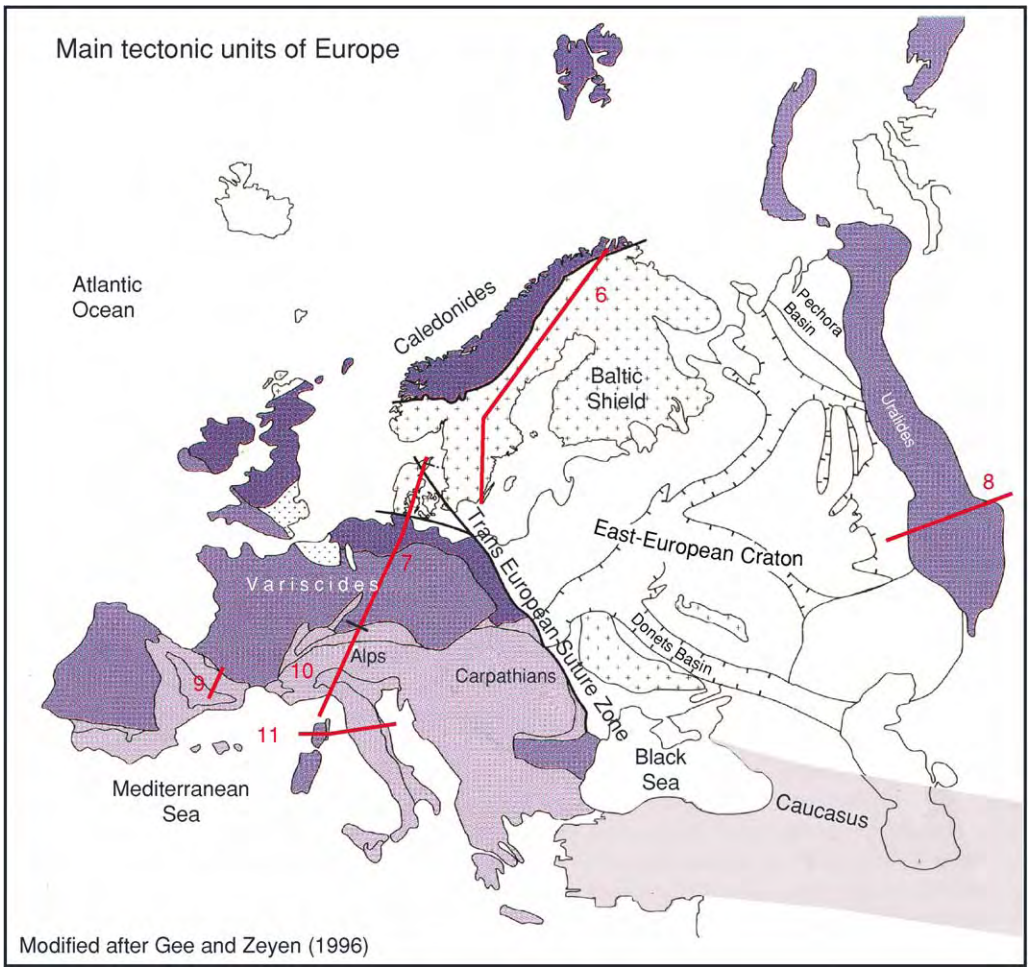

Figure 3 Main tectonic units of Europe. The position of the crustal cross sections described in this paper is marked by red lines. Modified from Gee and Zeyen (1996).

between the East European and the Siberian Plates (*see* **Europe:** The Urals). (4) Central and Western Europe were formed during the Cadomian (~620–540 Ma) Orogeny and severely were overprinted by the Variscan (or Hercynian) Orogeny (400–295 Ma) (*see* **Europe:** Variscan Orogeny). (5) In Southern Europe, the Cenozoic Alpine–Mediterranean mountain belts resulted from the convergence between Africa and Europe during Mesozoic to Cenozoic times (220 Ma). The Mediterranean Sea contains relicts of the oceanic crust of the Tethys and young back-arc basins that are partly built up by young oceanic crust (*see* **Europe:** Mediterranean Tectonics). Besides these compressional structures, there are also some prominent extensional regions in Europe. The formation of the North German and Polish basins and the evolution of the Central European Rift System were generated by post-Variscan extensional processes (*see* **Europe:** Permian to Recent Evolution).

Main Features of the Moho-Discontinuity in Europe

During the past five decades, a large amount of seismic data (active and passive seismology) has provided detailed information on regional and local crustal structures and resulting geophysical anomalies. Figure 4 is a contour map of the depth of the Moho-discontinuity of the Eurasian plate, extending from the Atlantic Ocean in the west to the Siberian Platform in the east. A more detailed Moho contour map of Central, Western, and Southern Europe is presented in Figure 5, which is based on seismic data measured in Europe from 1958–1988. This map comprises large parts of Pre-Caledonian, Caledonian, Variscan, and Alpine domains in Europe. There are very pronounced variations of crustal thickness within and between the different tectonic units. The most prominent structural features are as follows:

- The crust of the Baltic Shield and the East European Platform shows a rather large thickness, with an average of 40–50 km.
- The Trans-European Suture Zone is one of the most important geological boundaries in Europe north of the Alpine Orogen. This suture zone forms a graben-like structure with a thickened crust and a depth of the Moho-discontinuity between 45 and 55 km.
- In contrast to the Baltic Shield and the East European Platform, the depth of the Caledonian and Variscan Moho-discontinuity in Central and

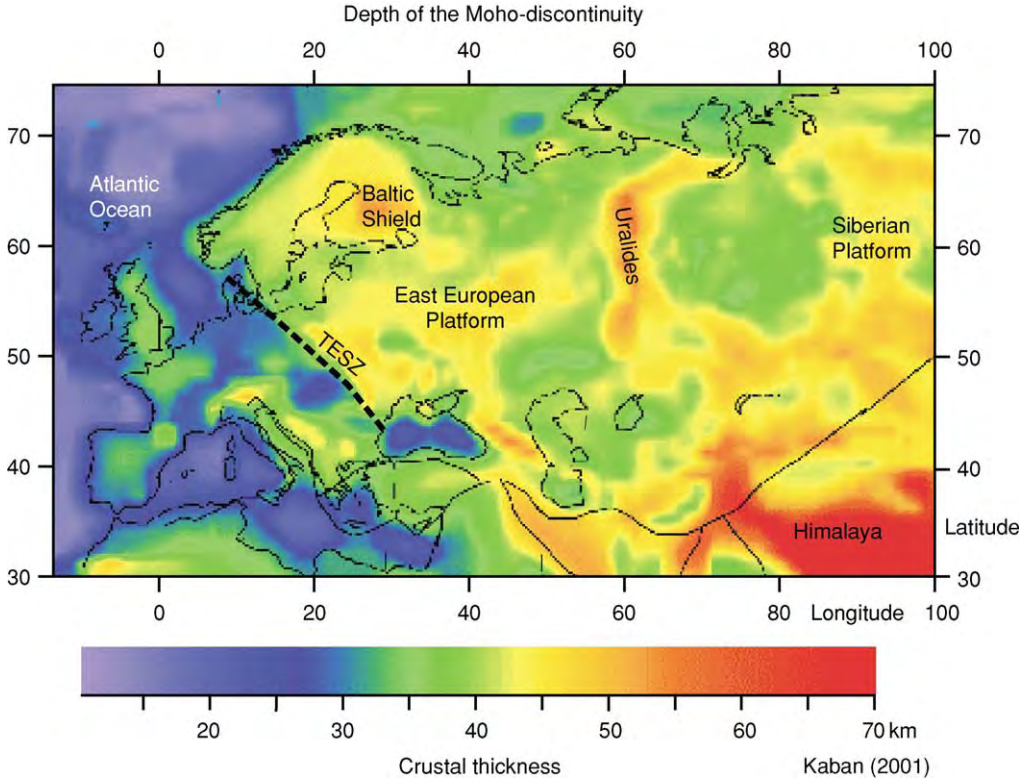

Figure 4 Crustal thickness of the European continent and the West Siberian platform, derived from numerous seismic profiles (mainly from deep seismic sounding studies) and gravity data. Modified and reproduced from Kaban (2001).

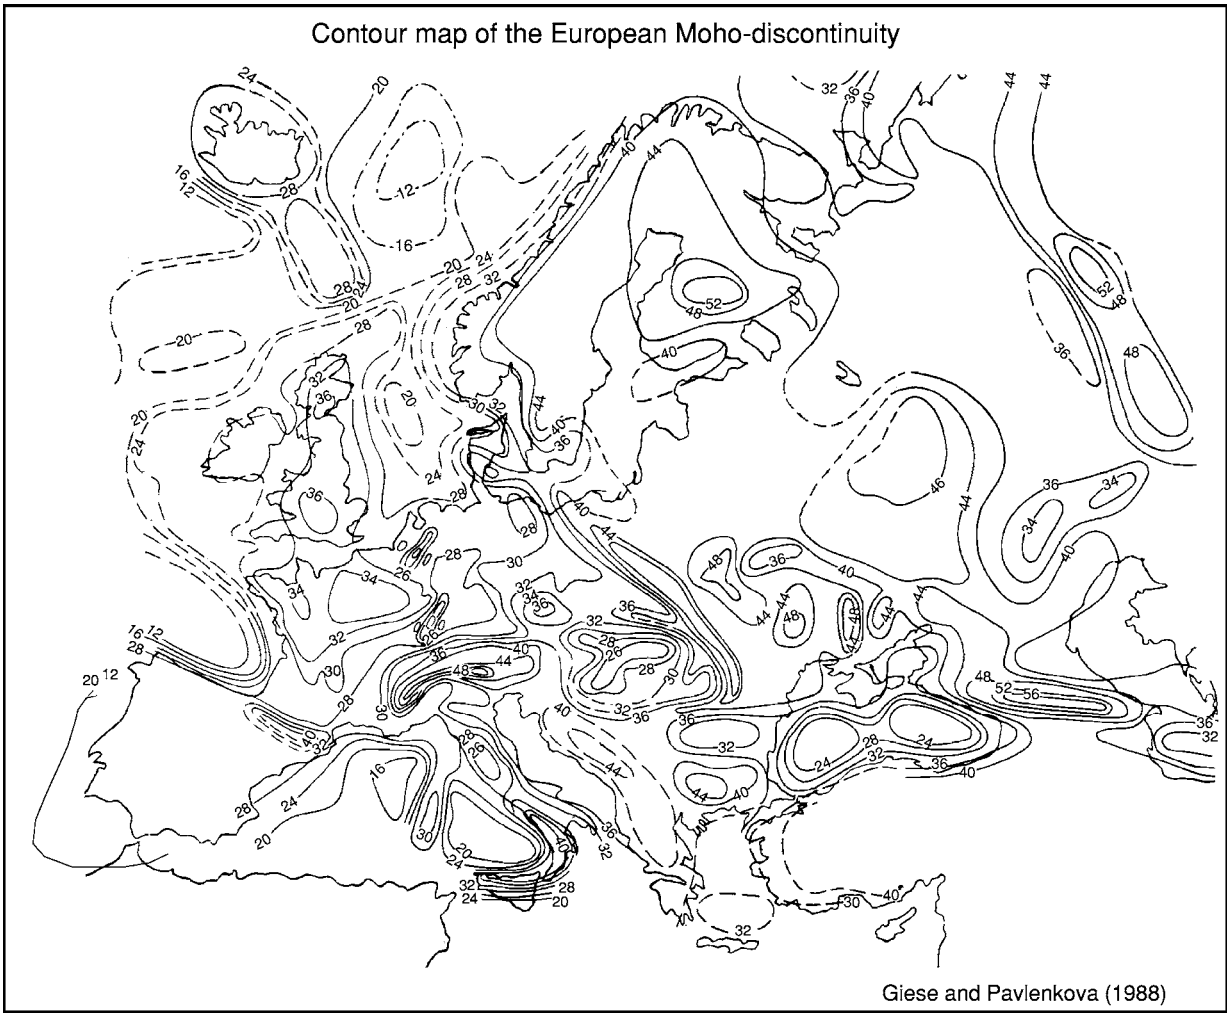

Figure 5 Morphology of the Moho discontinuity in Central, Western, and Southern Europe. The contours (spacing, 2 to 4 km resp) reveal the main geological structures of young orogens such as the Alps, the Apennines, and the Pyrenees. Giese and Pavlenkova (1988).

Western Europe measures only 30–35 km. No crustal roots are recognizable.

- The picture is distinctly different in the Variscan Uralides, where the crustal root or parts of the root have been preserved since the Late Palaeozoic. In the root zone, the Moho-discontinuity has been detected at a depth of 50–60 km.
- The southern (Mediterranean) region of Europe presents a very heterogeneous set of crustal structures. This region is built up of a system of several Cenozoic orogenic belts with thick mountain roots up to 60 km deep.

Other regions were formed by extensional processes and are characterized by a shallow Moho-discontinuity. Extension in continental crust is documented in the Permo-Mesozoic basins of Northern Germany and Northern Poland, in the Cenozoic European rift system. The Cenozoic Pannonian Basin with a crustal thickness of only 24 km was formed by back-arc spreading. Oceanization of continental crust is also observed in back-arc regions of the western Mediterranean, where the Moho-discontinuity is found at a depth of only 10 km. Atlantic Ocean crust borders the western and north-western margin of the European continent. Oceanic crust is also present in the central Black Sea and in the Bay of Biscay, which was formed by counterclockwise rotation of the Iberian peninsula with respect to mainland Europe.

Main Structural Features of Pre-Variscan and Variscan Europe

Northern and Eastern Europe

Precambrian Europe is built of the Baltic Shield and the East European Platform (*see* **Europe:** East European Craton; Scandinavian Caledonides (with

Greenland)). The Baltic Shield is a collage of cratonic blocks and island arcs. The orogenic belts resulting from multiple collision have been levelled out by erosion at the surface and partial re-equilibration of the Moho-discontinuity. Seismic studies reveal variations of crustal thickness ranging from 40 km in Sweden to more than 55 km in southern Finland. This anomalously large crustal thickness is mainly caused by a relatively thick lower crust (15–20 km). Figure 6 shows a north to south crustal cross-section through the Baltic Shield between the North Cape and the southern tip of Sweden at the Baltic Sea. Along this section, the average crustal thickness is about 40 km. Lateral inhomogeneities with several distinct offsets of the Moho-discontinuity may be related to fault zones in the upper crust. These probably reflect amalgamation of microplates that were derived from the fragmentation of Late Archaean megacontinents and that were welded together along Proterozoic collisional belts. The large thickness of the Baltic Shield and the Eastern European Craton requires an average crustal density of 2900–3000 kg m ^{3} By comparison, the average crustal density in Central Europe amounts only to about 2800 kg m ^{3}. Thinned crust is present only in the Dniepr–Donets Basin, which is a product of intracratonic rifting in the Devonian and Early Carboniferous times. Parts of the Caledonian belt are exposed along the coast of Norway and in Scotland and central England. Another branch of the Caledonides is suspected beneath the Northern German and Polish basins. The recent average crustal thickness is about 28–34 km and no orogenic roots are visible (Figure 5). As in the Variscides, the Caledonian crust is distinctly thinner than that of the Baltic Shield, which again suggests crustal thinning by delamination of lower crust.

The Trans-European Suture Zone

The Trans-European Suture Zone is one of the most prominent geological boundaries in Europe. It separates the East European Platform from the mobile Variscan Domain in Central Europe. This zone, with its graben-like structure and a crustal thickness of 40–50 km, extends from the western coast of the Black Sea up to the western Baltic Sea. Here this system splits into two branches, the northern Sorgenfrei–Tornquist Zone (STZ) and the southern Trans-European Fault Zone (Figure 3). This zone is well recognizable in the contour map of the Moho-discontinuity in Figure 5.

The Variscides of Central and Western Europe

The main part of Central and Western Europe has a Late Proterozoic (Cadomian) fundament, but the present-day structure is controlled by a strong Variscan overprint (*see* **Europe:** Variscan Orogeny). This region extends between the North Sea and Baltic Sea to the north and the Alpine mountain belts to the south and, in the west to east direction, between the Atlantic Ocean and the Trans-European Suture Zone (Figure 3). The upper section of Figure 7 shows the crustal structure of the transition from the Baltic Shield to the Variscan Domain in Central Europe (*see* **Europe:** Variscan Orogeny). The lower section of shows the crustal structure of the area between the

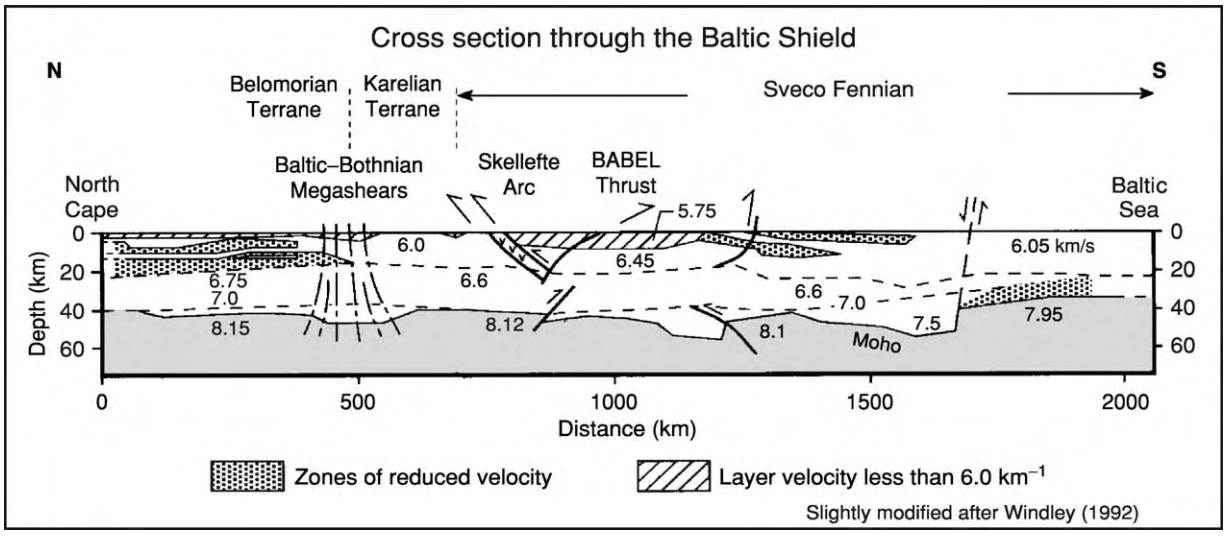

Figure 6 N S cross section through the Baltic Shield with the main crustal structures, displayed as an isoline velocity model (vertical exaggeration: 5:1). Modified after Windley *et al.* (1991) in Blundell *et al.* (1992).

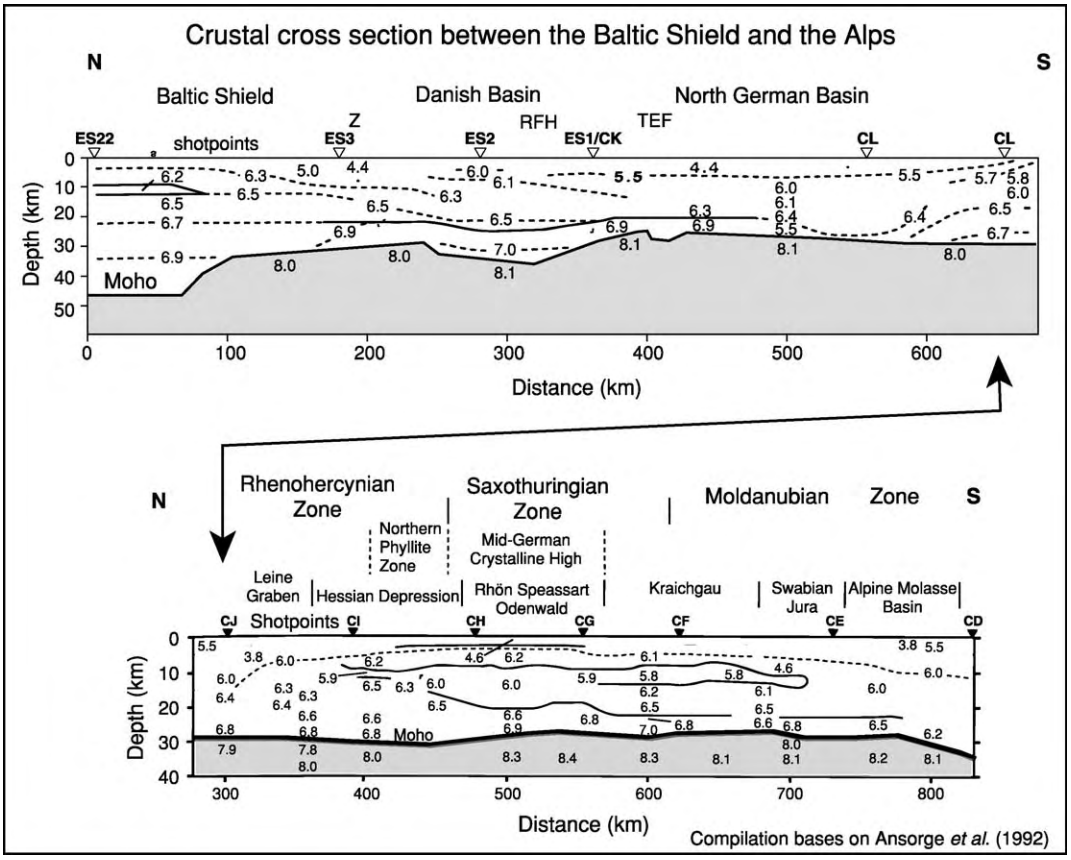

Figure 7 (Upper part) Structure of the transitional zone between the Baltic Shield and the Variscan crust adjacent to the south, which has undergone Permo Mesozoic extension. STZ, Sorgenfrei Tornquist zone; RFH, Ringkbing Fyn High; TEF, Trans European Fault. (Lower part) North south section from the northern margin of the Rhenohercynian zone to the northern margin of the Alps. Although the internal crustal structure is very heterogeneous and the section cuts prominent suture zones, the crustal thickness is rather constant (28 30 km). Modified from Ansorge *et al.* (1992).

North German Basin and the northern margin of the Alps. Along this profile, the recent Moho-discontinuity lies at a depth between 28 and 30 km The depth increases to 34 km at the northern margin of the Alps. The present-day morphology of the Moho-discontinuity does not show any significant relicts of Variscan roots. Velocities in the uppermost mantle change significantly from a minimum value of 7.8 km s ^{1} in the north to as much as 8.4 km s ^{1} under the southern margin of the Mid-German Crystalline High; from there it decreases again to a more normal value of 8.1 km s ^{1}. The Variscan orogenic systems were formed during Late Palaeozoic times by the collision of numerous continental fragments or terranes of different size with the Baltic Shield and the East European Platform. Because seismic reflection profiles provide evidence of important crustal stacking, compressional deformation must have formed thick and deep crustal roots, comparable with the mountain roots of the recent Mediterranean orogens. These roots have not survived. Destruction of the Variscan roots is usually referred to as 'collapse' of the orogen. This comprehensive term summarizes a variety of processes, including erosion and isostatic uplift; gravitational spreading of hot, low-viscosity materials; extension by active rifting; and delamination of dense lower crust and mantle lithosphere.

Spectacular Crustal Root of the Uralides

The Ural Mountains are the product of collision of the East European Craton with the Siberian Shield (*see* **Europe:** The Urals). Figure 8 shows the results of a seismic profile across the southern Uralides. The Moho-discontinuity, well defined by seismic reflection data, dips from the west and east under the central part of the belt, down to a depth of 50 km. Wide-angle reflections in the central part of this belt reveal a still existing crustal root, with the Moho-discontinuity situated at a depth of 50–60 km. This unusual preservation of an orogenic root may be explained by the small density contrast (only 100 kg m ^{3}) between the root and the surrounding

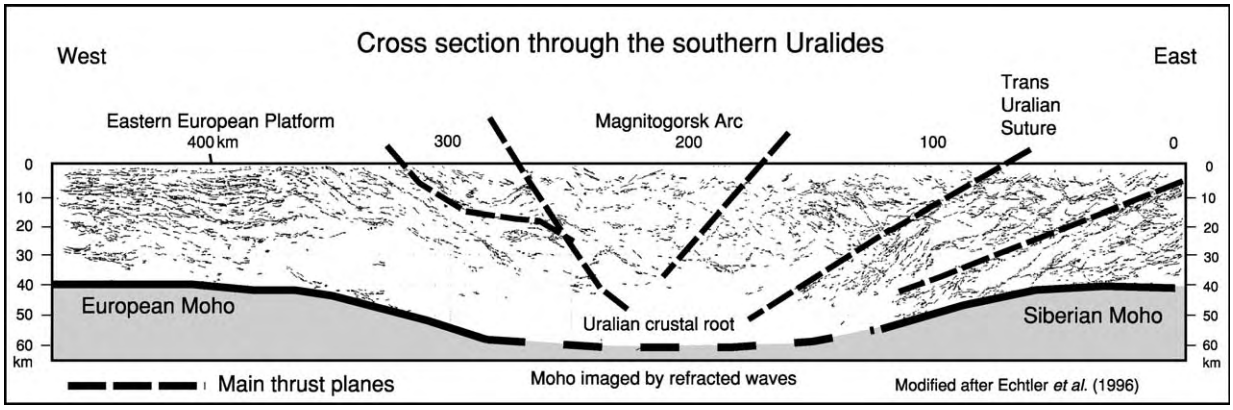

Figure 8 (Upper part) West to east directed section across the southern Uralides, based on seismic reflection and refraction measurements. Note the bilateral symmetry of reflections dipping from either side under the thick root. Modified from Echtler *et al.* (1996).

mantle, which was not sufficient to drive buoyant lateral spreading. In addition, there is no indication of post-orogenic active rifting in the Uralides.

The Post-Variscan Basins of Central and Western Europe

The post-Variscan regions of Central and Western Europe are characterized by an average crustal thickness of only 28–32 km (Figures 5 and 7). In these regions, the post-Variscan evolution is dominated by extensional tectonics, with formation of a new Moho-discontinuity at depths around 30 km. The main extensional elements are the Permo-Carboniferous basins in northern Germany and Poland and the Cenozoic European Rift System (*see* **Europe:** Permian to Recent Evolution). In the North German and Polish basins, the thickness of the post-Variscan sediments may attain 10 km, and the base of the crust has been detected at depths between 23 and 30 km. This implies crustal thinning, decreasing from a thickness of ~30 km to 13–23 km. Basin development started in Early Permian times and was probably caused by a combination of strike–slip and extension along the south-western margin of the East European Platform, and thermal subsidence subsequent to an Early Permian episode of mantle-derived magmatism. A second magmatic event occurred during the Cretaceous.

The Cenozoic European Rift System traverses Western and Central Europe up to the southern border of the Baltic Shield. Over a distance of about 1800 km, this north–south-oriented rift system is composed of a sequence of separated segments (Figure 5). This rift system starts in southern France in the Rhône Graben. Northwards, the Limagne Graben, west of the Rhône Valley, is a very significant segment of the rift that traverses the Massif Central and is flanked by volcanic chains. Further north, the Bresse Graben system continues from the Rhône Valley. Both the Limagne Graben and the Bresse Graben systems terminate again in the Burgund transform fault system, which links the grabens of south-eastern France with the Rhine Graben near Basel. The Rhine Graben (Figure 5) between Basel and Frankfurt/Main forms the central segment of the European Cenozoic Rift System. At the northern end of the Rhine Graben, at a triple junction near Frankfurt, the rift system splits into two branches. To the north, it follows the Hessen depression and the Leine Graben near Göttingen and disappears beneath the North German Basin. The Oslo Graben forms the northernmost segment of this rift system. The western branch starts at the northern end of the Rhine Graben near Frankfurt and continues in a north-west direction through the Rhenish Massif into the Lower Rhine Basin and disappears beneath the North Sea.

As shown in Figure 5, the total crustal thickness along the Central European Rift System is distinctly reduced, from 30 to 32 km outside the rift to about 28 km on top of the rift. Even the splitting of the rift near Frankfurt is recognizable in the contour map of the Moho-discontinuity. (Figure 5). The creation of the layering in the lower crust has been widely discussed in the literature. Deep seismic reflection profiles suggest that the layering of the lower crust resulted in an extensional regime, and that magmatic intrusions caused partial crustal melting and the transformation of deep crustal mafic rocks into eclogite. The unusual large amplitudes of the Moho reflections and the presence of anomalously high seismic velocities in the lowermost crust beneath Tertiary rifts (e.g., the Rhine and Rhône Grabens) imply that the Moho-discontinuity and part of the layering

of the lower crust are comparatively young features, related to interactions between the lower crust and the mantle.

Crustal Structure of the Mediterranean Region

Towards the south, Europe is flanked by Mesozoic–Cenozoic orogenic systems created by the convergence and collision of the European continent with the African/Arabian Plate. During their evolution, since the early Mesozoic, the Alpine–Mediterranean orogenic belts underwent a more or less complete cycle of extension, subsidence, subduction, collision, topographic buildup, extensional collapse, and back-arc spreading associated with the creation of new oceanic basins. The morphology of the Moho-discontinuity shows that this discontinuity was strongly involved in these compressional and extensional deformation processes.

All Mediterranean mountain belts show the typical subdivision into three main tectonic zones, each with its own specific crustal structures: the foreland (fore-arc), the central zone, and the hinterland (back-arc). In all the studied cases (Alps, Apennines, Betic Cordillera, Carpathians, Caucasus, Hellenides, and Pyrenees), this basic picture is clearly expressed in the asymmetric geometry of the Moho-discontinuity. The Moho-discontinuity of the foreland dips under the central zone and in some cases even beyond, under the hinterland, down to a depth of 60–70 km. Still deeper crustal rocks cannot be excluded, but have been metamorphosed into eclogites, which owe their thickness to tectonic stacking of sedimentary and crystalline units, including mantle slices, as well as to magmatic additions to the crust. The hinterland, with its thin crust, overlies the underthrusted continental lithosphere of the foreland and oceanic crustal fragments of the central zone. In this case, there is no continuity between the Moho boundary of the foreland and the Moho boundary of the hinterland. The vertical offset between the two Moho-discontinuities may attain 10–30 km. In the closely spaced array of Mediterranean microplates (*see* **Europe:** Mediterranean Tectonics), the tectonic role of a crustal block may change across a short distance: the Adriatic Microplate (*see* **Europe:** The Alps) is the upper plate in the Alpine system, whereas it represents the lower plate in the Apennines. Three typical crustal cross-sections (Pyrenees, Western Alps, and Northern Apennines) highlight the main characteristics of the Moho topography in the Mediterranean belts (Figures 3, 9, 10, and 11).

Pyrenees

The Pyrenees are situated between the Iberian continental block and the European Plate. Extensional deformation was active from the Triassic through the Cretaceous. This extensional phase was followed by convergence between Iberia and Europe that occurred from the Late Cretaceous through the Middle Miocene, creating the Pyrenees. The present-day crustal structure across the Pyrenees displays a well-preserved crustal root created by the collisional process (Figure 9). The seismic reflection profile reveals how the Iberian crust was subducted below the European crust. A Moho offset of about 30 km has been detected beneath the North Pyrenean fault zone, and the reflecting lower crust of the Iberian crust can be traced down to a depth of 60 km.

Central Alps and Northern Apennines

The Alps are considered as a classical example of an orogen formed by the convergence between the continents of Europe and Africa, including the intervening Adriatic Microplate (*see* **Stratigraphical**

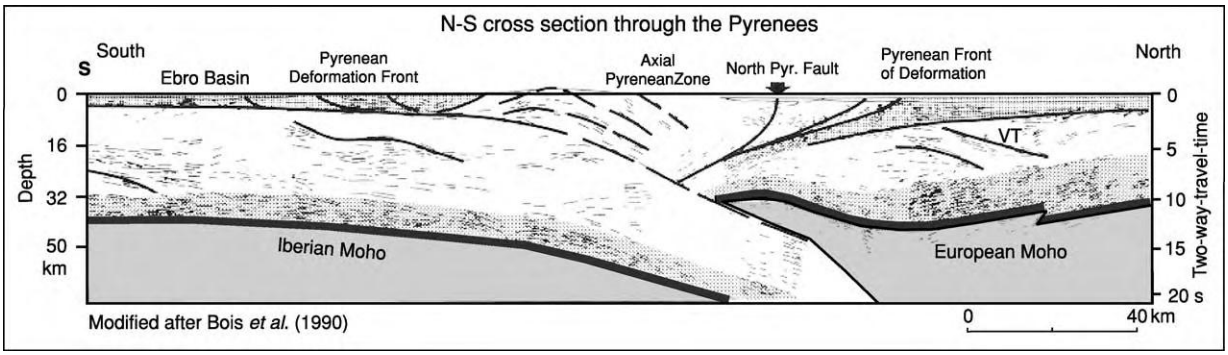

Figure 9 Line drawing and tectonic interpretation of a deep seismic profile across the Pyrenees. Beneath the central zone the offset of the Moho discontinuity is clearly recognizable. Modified from Bois and ECORS (1994).

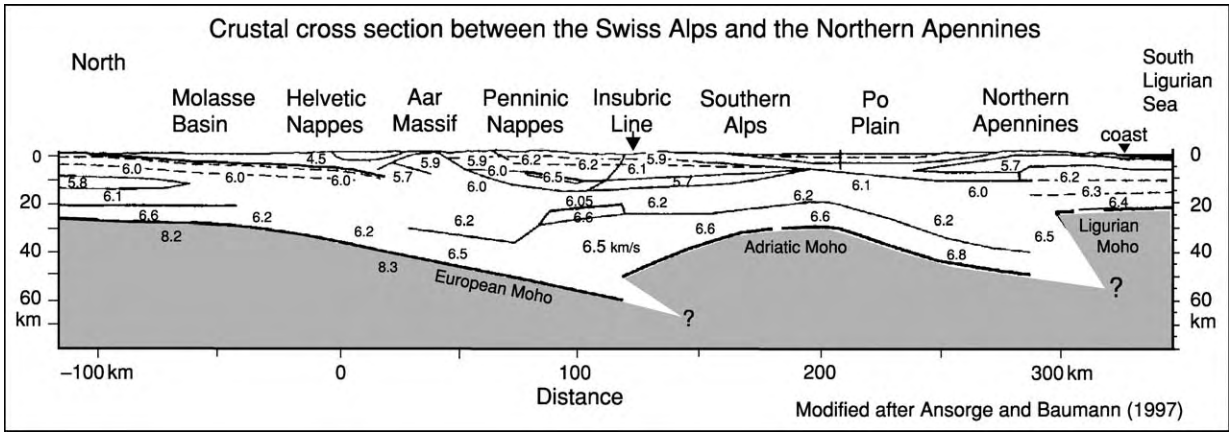

Figure 10 North to south directed crustal section between the Central (Swiss) Alps and the Ligurian Sea. This section shows two clearly expressed offsets of the Moho discontinuity. Thus three separated Moho discontinuities can be defined from north to south (the European, the Adriatic, and the Ligurian sea Moho). Modified with permission from Kissling (1997) in Pfiffner *et al.* (1997).

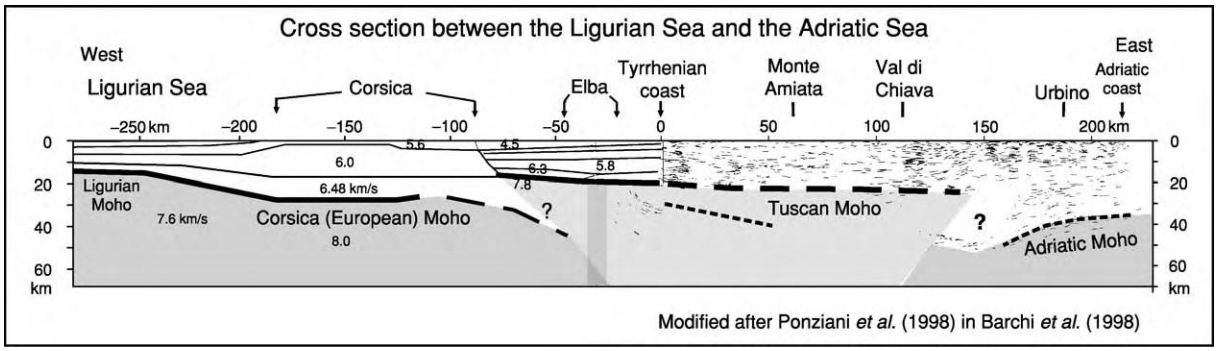

Figure 11 West to east directed crustal section across the Northern Apennines between the Ligurian Sea and the Adriatic Sea. This section is based on seismic refraction data in the western part and on seismic reflection observations in the eastern part. Note the different Moho discontinuities from west to east: the thin oceanic crust of the Ligurian Sea, the European crust of Corsica (and Sardinia) with a normal Variscan crustal thickness of 30 km, the thinned crust in the Tuscany region, and the subducting crust of the Adriatic foreland. Reproduced from Ponziani *et al.* (1998).

Principles). After the Variscan Orogeny, a vast embayment in the eastern margin of Pangaea propagated westwards during the Mesozoic to produce the Tethys Ocean. In the Alps, convergence started in the mid-Cretaceous with the consumption of ocean crust and was followed by overthrusting of the marginal units of the Adriatic Microplate onto the European continental margin. In the Southern Alps (the Alpine hinterland), thrusting of the sedimentary cover was directed southwards towards the Po Plain. South of the Po Plain, along the southern and western margins of the Adriatic Microplate, the mountain belt of the Northern Apennines was formed in the Cenozoic. These repeated collisions have strongly affected the geometry and depth of the Moho-discontinuity. Figure 10 shows a north–south crustal cross-section between the Swiss Alps in the north and the northern Ligurian Sea in the south. This section traverses the Central and Southern Alps, the western Po Plain, and the Northern Apennines. The complex shape and geometry of the Moho-discontinuity are clearly imaged in the records of the seismic reflected and refracted waves. The seismic section shows the well-developed structural asymmetry of both mountain belts. From the Alpine foreland (the lower plate), the Moho-discontinuity dips southwards, from 30 km at the northern Alpine front to about 60 km beneath the Central Alps. Under the Southern Alps, the Adriatic Moho-discontinuity situated at a depth of about 40 km is clearly separated from the European Moho-discontinuity overlap of both Moho-discontinuities. The southern part of the section (Figure 10) traverses the Southern Alps and the Po Plain, the Northern Apennines, and the northern part of the Ligurian Sea. The continental crust of the Southern Alps and of the Po Plain must be related to the margin of the Adriatic Microplate. Beneath the Po Plain, the Adriatic Moho-discontinuity shows a minimum

depth of 35 km. Towards the north and south, the Adriatic Moho-discontinuity dips down to 40–50 km beneath the Southern Alps (as the upper plate) and also beneath the Northern Apennines (as the lower plate). Beneath the Northern Apennines, there is a clear offset of 20–30 km between the deep northern and the shallow southern Moho-discontinuity. The thinned crust of the Northern Apennines (about 20–25 km) must be regarded as an extended marginal part of the Adriatic Microplate. Southwards, the thin crust of the Northern Apennines passes into the thin oceanic crust of the Ligurian Sea.

Ligurian Sea, Tuscany, and Adriatic Sea

Figure 11 shows a WSW–ENE-trending cross-section between the Ligurian Sea in the west and the Adriatic Sea in the east, which passes by northern Corsica, Elba, Tuscany, and the Umbrian Apennines. This profile demonstrates the complex structure of this divergent orogenic belt, which resulted from repeated deformation with changing transport directions along the margin of the Adriatic Microplate. The counterclockwise rotation of the Corsica–Sardinia block has strongly affected the geometry and nature of the Moho-discontinuity west and east of Corsica. Along a south-west and north-east section, four different Moho-discontinuities can be identified (Figure 11): (1) a young oceanic Moho-discontinuity beneath the Ligurian Sea and Provençal Basin is situated at a depth of 14–18 km; (2) beneath the Variscan continental crust of Corsica, the European Moho-discontinuity has been detected at a depth of 25–30 km; (3) the young Moho-discontinuity beneath Elba and Tuscany is situated at a depth of only 20–25 km (the structural relations between the Corsican and the Tuscany Moho are a matter of debate: there is probably no direct link between the discontinuities); and (4) a well-expressed offset of 20–30 km separates the shallow Tuscan Moho-discontinuity from the deep Moho-discontinuity beneath the Northern Apennic Arc (this offset defines the crustal root of the Apennines).

Along the section (Figure 11), there are three different zones in which the crustal thickness changes. In the westernmost part, the transition from the thin and young oceanic crust of the Ligurian Sea to the Variscan continental crust of Corsica can be interpreted as a passive continental margin. The situation is completely different in the contact zone between Corsica and Tuscany. Due to the counterclockwise rotation of Corsica, an eastward-dipping subduction zone must be postulated beneath Elba and western Tuscany. In the reflection profile CROP03 beneath Elba and western Tuscany, weak, eastward-dipping reflections indicate the existence of an interface that may be interpreted as the top of an eastward-dipping subduction zone. Very probably there is no direct link between the Moho-discontinuity beneath Corsica and the Moho-discontinuity beneath Tuscany. The Tuscany crust in the hinterland of the Northern Apennines is characterized by back-arc extension that has reduced the crust to a thickness of only 20 km. The third change in crustal thickness occurs beneath the Apenninic Arc. In this area, the Tuscany Moho-discontinuity terminates and another deeper Moho has been detected at a depth of 40–50 km. There is no link between the shallow Tuscany Moho and the deep Moho-discontinuity of the Adriatic Microplate. The offset between the two Moho-discontinuities amounts to about 20 km. This break can be interpreted as a continent–continent collision zone. A normal crustal thickness of 30–35 km has been measured beneath the Adriatic coast, the foreland of the Apenninic Arc.

The Subcrustal Lithosphere in Europe

The lithosphere is defined as the rigid outermost shell of Earth, comprising continental and oceanic crust and the uppermost mantle. The Moho-discontinuity is an intralithospheric interface. The lithosphere is a strong, elastic layer overlying the weak, ductile asthenosphere with a more or less gradual transition. The ductile asthenosphere is believed to represent the zone in the mantle where the melting point is most closely approached by the actual temperature curve. Because it transmits shear waves, this layer cannot be completely molten, but small amounts of melt may be present. The thickness of the lithosphere, like that of the crust, exhibits important variations. The thickness of the European lithosphere is depicted by the contour map in Figure 12. The cross-section reveals four main features. First, beneath the Baltic Shield and the Eastern European Platform, the thickness of the lithosphere is about 200 km. This feature correlates with the thick continental crust and low heat-flow values (40–50 mW m ^{2}). Second, a thin lithosphere of about only 50 km exists beneath the western region of Central Europe, especially along the Rhine and Rhône rivers. Here, also, the crust is relatively thin ($\leq$30 km) and the heat flow is distinctly higher than in Northern and Eastern Europe (80–90 mW m ^{2}). Third, in the Mediterranean region, the thickness of the lithosphere is very heterogeneous. A thick lithospheric root has been detected beneath the Alps and the Northern Apennines. This feature is at least partly explained by sinking delaminated lithospheric slabs, subsequent to continental collision. Under the young oceanic basins such as the

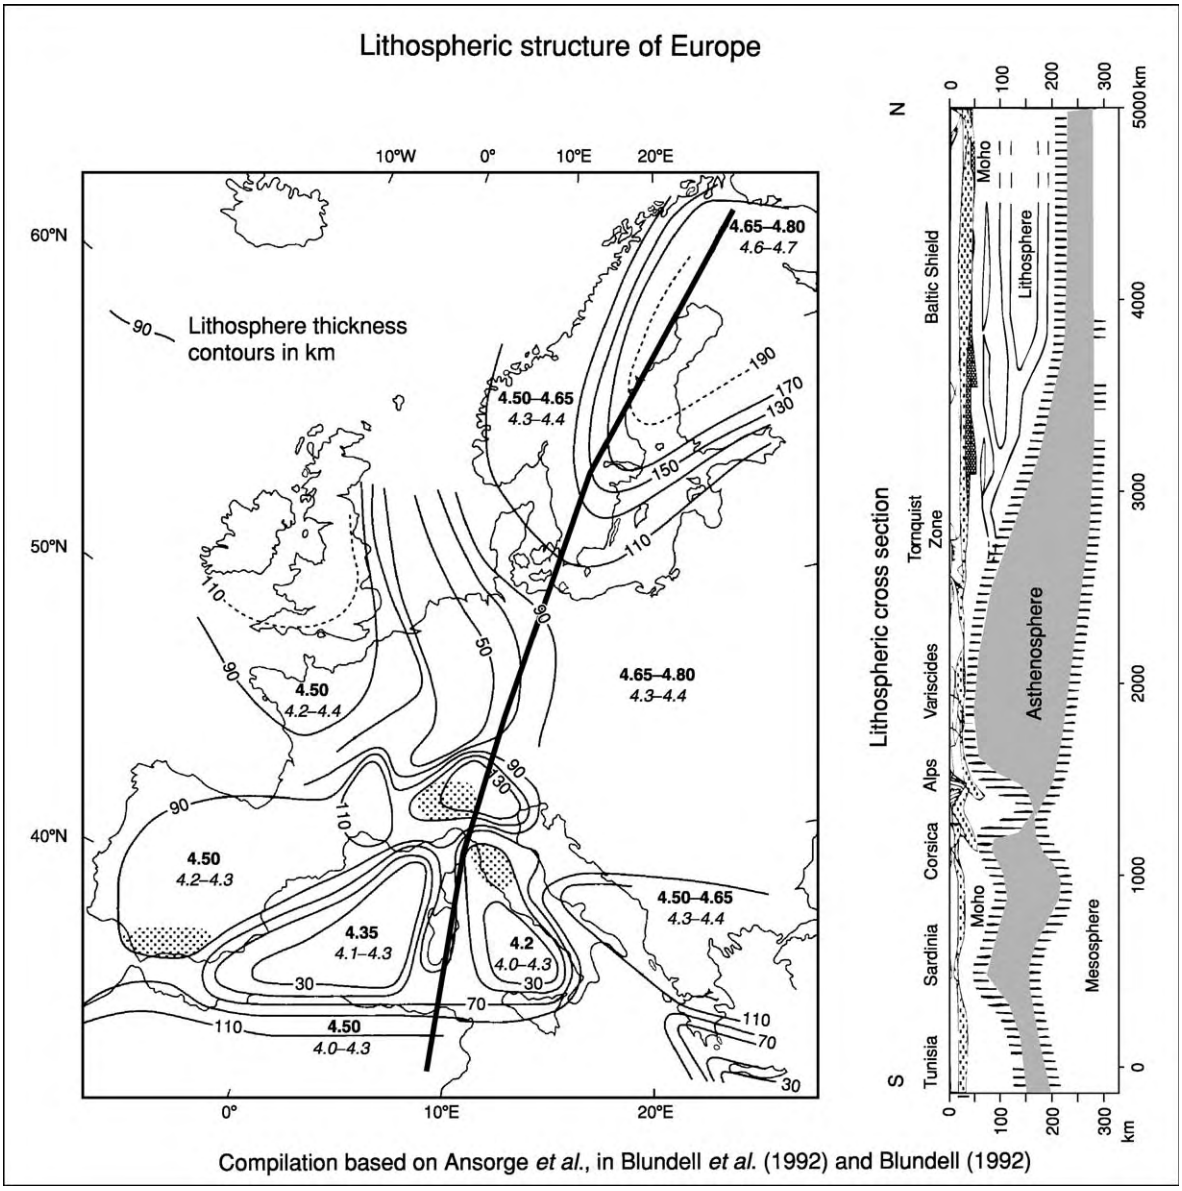

Figure 12 (Left) Contour map of the depth to the base of the lithosphere of Europe, derived from an interpretation of surface wave data. Numbers refer to S wave velocities above and below the base of the lithosphere. Shaded areas indicate thickened lithosphere. Reproduced with permission from Panza (1992). (Right) North to south cross section of Europe, demonstrating very clearly the basic differences of lithospheric thickness between the Baltic Shield in the north and the Variscan and Alpine part in Central and Southern Europe. Note the lithospheric root beneath the Alps. Modified from Blundell *et al.* (1992).

Tyrrhenian Sea, the asthenosphere is thin (10–20 km). Due to the very different tectonic situation, the heat flow varies strongly between 50 and 150 mW m $^{-2}$. Fourth, there is relatively thin lithosphere (about 50–80 km) in the Baltic Shield, but a thick one (about 200 km) exists beneath Central Europe.

Although recent tectonic and magmatic events in Europe are mainly concentrated in the Mediterranean region, there has been some recent activity in Central and Western Europe. Late Cretaceous to Holocene volcanism is found in an east- to west-trending belt that extends from western Poland to western Germany, continuing southwards across the French Massif Central to the Mediterranean. Recent seismological studies in the Eifel region and in the northern Massif Central have revealed low-velocity anomalies in the lithosphere and down to at least depths of 300–400 km. These findings support the concept that deep-seated mantle plumes can produce intraplate mantle volcanism.

Analysis

Studies of the European Moho-discontinuity offer the possibility to compare crustal structures of very different ages and evolutionary stages. The Moho-discontinuity is not a static feature in the lithosphere, but rather evolves geodynamically. In Europe, the Moho-discontinuity in each of the four main regions is distinguished by a specific nature and geometry. The Baltic Shield, including the East European Platform, is characterized by a 40- to 50-km-thick continental crust. In the shield regions, the average crustal velocity and density are relatively high due to a thick lower crust with mafic components. These shield regions have remained rather stable and undeformed in the Phanerozoic Eon, during which the crust of Central, Western, and Southern Europe has been repeatedly reworked. A relatively thin crust, only 30 km thick, characterizes the Variscan belts in Central and Western Europe. The Variscan Orogen was formed in Devonian and Carboniferous times by the sequential collision of continental fragments, producing a thickened crust such as that in the recently formed Alps. The Variscides subsequently collapsed and then re-equilibrated in Permian times with extensional overprinting. This re-equilibration was associated with widespread crustal melting, extensive volcanism, and the formation of late- to post-orogenic sedimentary basins. Consequently, the post-Variscan Moho image is mainly related to post-orogenic pervasive subhorizontal shearing associated with magmatic underplating. This layered structure of the lower crust is imaged by the highly reflective crust under sedimentary basins. An exception to this general evolution exists in the Palaeozoic orogen of the Urals, which have preserved their collisional structure with a crustal root. Apparently, this root was never destabilized by major fluid flow and heating.

The third main European region was formed by the young orogens in the Mediterranean regions of Southern Europe, which are characterized by a very heterogeneous crustal and Moho-discontinuity structure, morphology, and composition. Finally, spreading along the Mid-Atlantic Ridge since the Early Jurassic produced oceanic crust and an oceanic Moho-discontinuity.

The differences between the Baltic Shield and west-Central and Western Europe do not require different plate tectonic mechanisms, but can be explained by higher temperatures and rheological softening of the Variscan crust. This may ultimately be due to the repeated emplacement of melts rich in heat-producing radioactive elements. The Variscides have passed the three stages typical of an orogenic cycle: compression and crustal thickening, metamorphism and extensional collapse of the orogen. By comparison with the Variscides, the evolution of most of the young Mediterranean mountain belts has advanced only to the second stage or to an early part of the third stage. The mountain roots of these young orogenic belts are still preserved and are clearly recognizable in the seismic records. In all orogenic belts, it cannot be excluded that lower crustal rocks are present in eclogite facies and therefore escape detection by geophysical methods.

Introduction

The south-west Pacific Ocean is a region of isolated islands and submerged plateaus and ridges (Figure 1). The three main islands of New Zealand (North, South, and Stewart) make up the largest landmass group in the region. Schists, greywackes, and granitoids are exposed in islands on the Challenger Plateau and Chatham Rise and have been sampled in dredges on the Campbell Plateau and Norfolk Ridge, thus demonstrating their continental geological character. Abyssal Pacific oceanic-crustal floor typically lies at water depths of about 5000 m, and the boundary between continental crust and oceanic crust is marked by a generally pronounced slope break at about 2500 m water depth. The wider area of continental crust in the New Zealand region (Figure 1) is about one-third the area of on-land Australia and is commonly referred to as Zealandia.

On-land New Zealand contains a wide variety of Phanerozoic rocks (Figure 2), which preserve a detailed record of the Cambrian to early Early Cretaceous convergent margin of southern Gondwana, late Early Cretaceous rifting, a Late Cretaceous–Palaeogene passive margin, and the Neogene–Holocene active convergent and strike-slip margin. So much of continental Zealandia is submerged because of the widespread Cretaceous extension and rifting. It was only with the development of the Neogene–Holocene convergent plate boundary that about 10% of Zealandia emerged above sea-level.

A distinction is generally drawn in New Zealand between pre-late Early Cretaceous (more than 105 Ma) 'basement' rocks, which are commonly metamorphosed and generally highly deformed, and 'cover' rocks, which are younger than 105 Ma, poorly indurated, well stratified, and less deformed.

Palaeogeographical Reconstructions

The shape of the continental crust of Zealandia has changed throughout the Phanerozoic. From the Cambrian to the Early Cretaceous, the New Zealand part of the Gondwanan margin grew by the magmatic and tectonic addition of batholiths and terranes. In the last 100 Ma this continental crust has been thinned, rotated, and translated in response to multiple tectonic events. Reconstructions (Figure 3) involve subtracting the 480 km Neogene dextral strike-slip movement on the Alpine Fault, the 45° Oligocene–Miocene rotation between the Pacific and Australian plates, and 4000 km of northwards drift. Small crustal blocks within 100 km of the Alpine Fault (i.e. most of on-land New Zealand) have undergone strong Cenozoic deformation. In the pre-rift (100 Ma) palaeogeography (Figure 3A) Zealandia is in a near-polar position and contiguous with Tasmania and Antarctica. By 10 Ma, some movement on the Alpine Fault had taken place and modern-day New Zealand had been isolated by seafloor spreading.

Geological Basement

At a regional scale, the volcanic, sedimentary, plutonic, and metamorphic basement rocks of New Zealand can be described in terms of a number of western and eastern tectonostratigraphic terranes, composite regional batholiths intruding these terranes, and schist, gneiss, and mélange overprints on

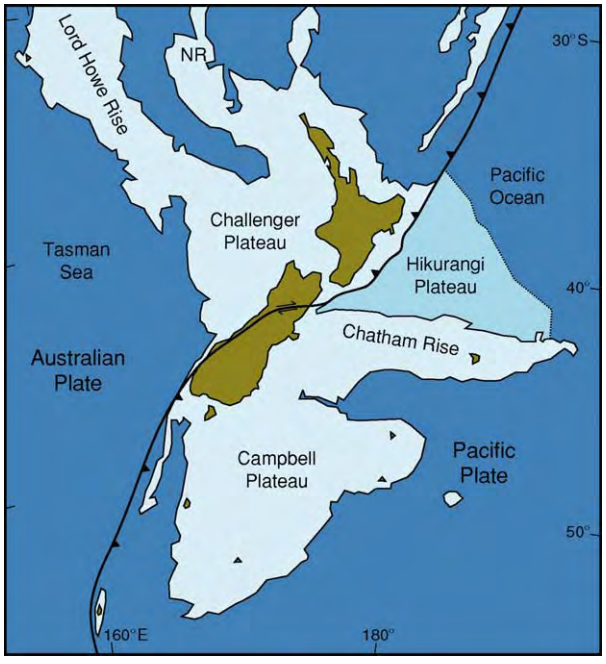

Figure 1 The outline of the area of continental crust in the New Zealand region (Zealandia). Land and major islands are pale brown; water less than 2500 m deep is pale blue. Deep ocean floor is dark blue and Hikurangi plateau large igneous province is intermediate blue. The present day Pacific Australian plate boundary is shown by the thick black line, with teeth on the over riding plate. Only about 10% of Zealandia is emergent above sea level as the North and South Islands. NR, Norfolk Ridge.

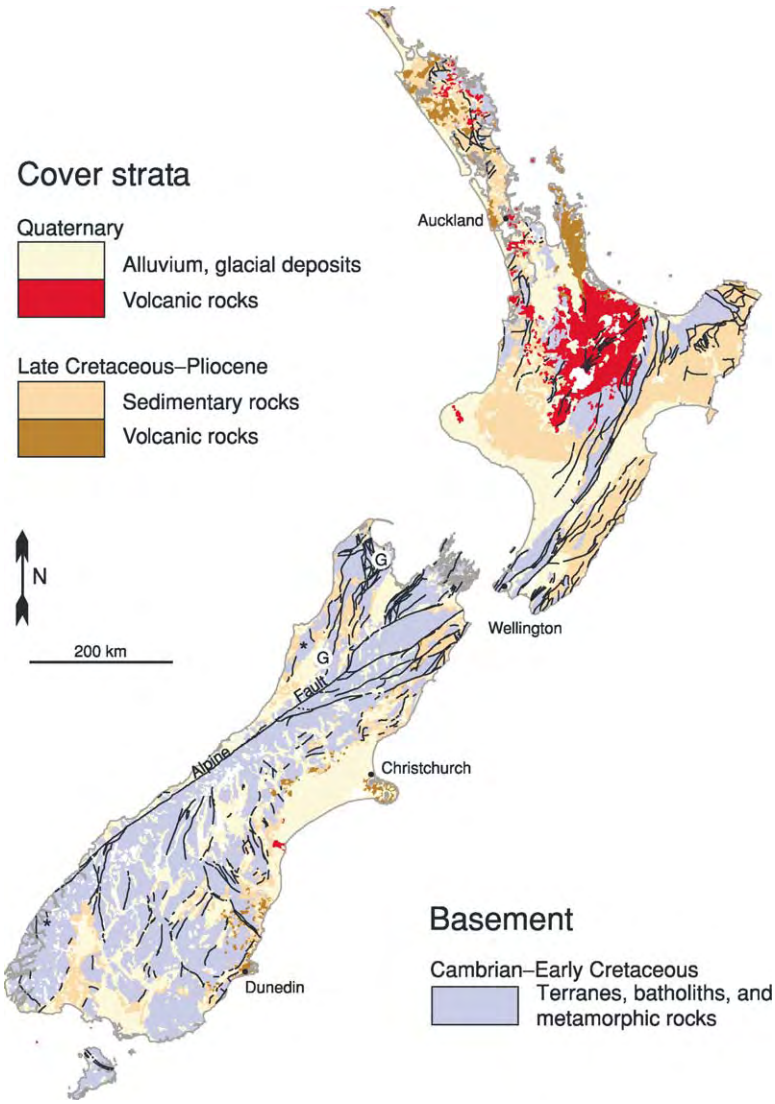

Figure 2 Simplified present day on land geology of New Zealand. The black lines are faults. Many of the lakes and valleys of the South Island are the result of Quaternary glacial erosion. the terranes and batholiths (Figure 4). Figure 5 shows the names, age ranges, and mutual geometric relationships of the constituent basement units on an Early Cretaceous reconstruction (Figure 3A). No Precambrian rocks are exposed; New Zealand has been near a continent–ocean margin throughout the Phanerozoic.

Western Province Terranes

The Western Province terranes lie west of the Median Batholith and comprise the Early Palaeozoic Buller and Takaka terranes. The Buller Terrane consists of variably metamorphosed siliciclastic sandstones and mudstones, of continental Gondwanan provenance, and is the westernmost recognized terrane in New Zealand (i.e. the terrane closest to the Gondwanan cratonic core). Rare fossils are of Ordovician age, but a Buller Terrane paragneiss contains detrital zircons as old as 3400 Ma (Archean; New Zealand's oldest known geological material). Intercalated volcanics are absent. The Takaka Terrane consists of siliciclastic, carbonate, and volcanic rocks. Middle Cambrian trilobites in the Takaka Terrane are New Zealand's oldest known fossils. The Takaka Terrane is generally well stratified and lithologically diverse, and includes Cambrian ultramafics and boninites, Ordovician limestones, and Silurian orthoquartzites. The Buller and Takaka Terranes were accreted to Gondwana by the Devonian.

Eastern Province Terranes

The Eastern Province terranes lie east of the Median Batholith and comprise the Brook Street, Murihiku,

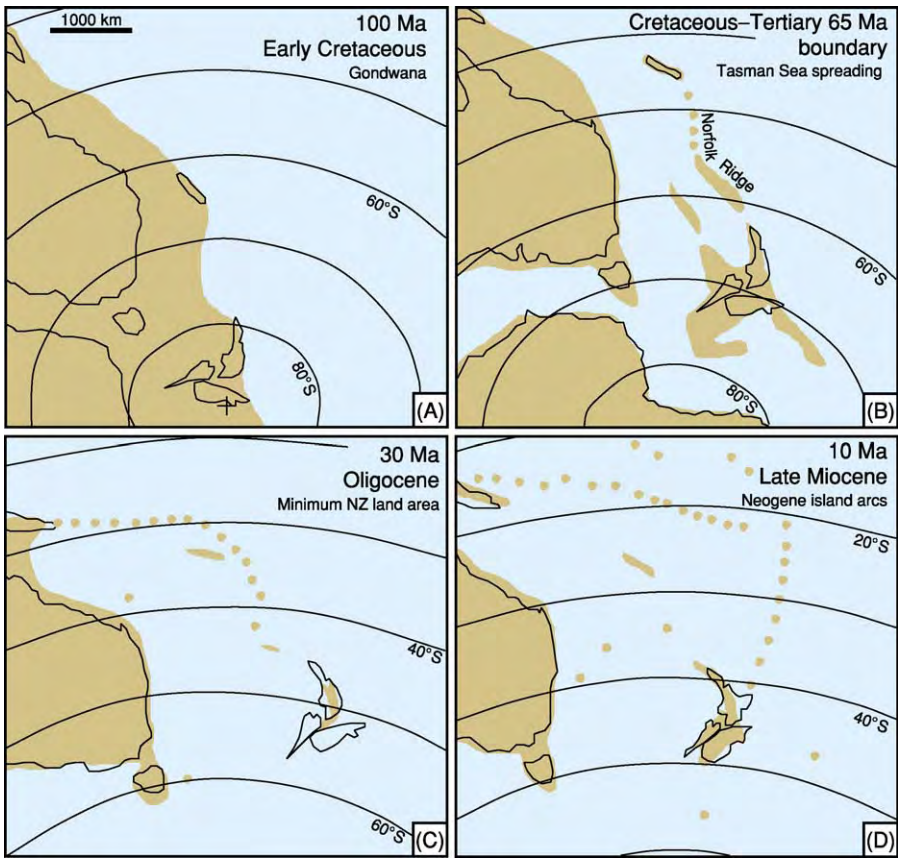

Figure 3 Palaeogeographical reconstructions of New Zealand at approximately (A) 100 Ma, (B) 65 Ma, (C) 30 Ma, and (D) 10 Ma. Brown, inferred land including schematic island arc chains; black lines, present day coastlines of North and South Islands and the Alpine Fault. On these reconstructions, the Alpine fault divides the South Island into eastern and western parts. (Reproduced with permission from Lee DE, Lee WG, and Mortimer N (2001) Where and why have all the flowers gone? Depletion and turnover in the New Zealand Cenozoic angiosperm flora in relation to palaeogeography and climate. *Australian Journal of Botany* 49: 341 356.)

Maitai, Caples, Rakaia, and Pahau terranes. Carboniferous conodonts are known from a limestone in the Rakaia Terrane, but the age range of clastic rocks in Eastern Province terranes is from Permian to Early Cretaceous (Figure 5). The Eastern Province terranes are thus entirely younger than the Western Province terranes and represent accretion of material to Gondwana in the Mesozoic.

The Brook Street Terrane is a Permian subduction-related isotopically primitive pyroxene-rich basalt-dominated volcanic pile and volcaniclastic apron, in places up to 14 km thick, which is intruded by Permian layered gabbros and trondhjemite plutons that are now part of the Median Batholith. New Zealand's only known *Glossopteris*, a Gondwanan leaf fossil, occurs in the Brook Street Terrane. The Murihiku Terrane comprises a 9–13 km Late Permian to Late Jurassic volcaniclastic marine succession of sandstone with lesser conglomerates, mudstones, and tuffs. It has the simplest internal structure of all the Mesozoic New Zealand terranes, a broad synclinorium that is traceable for 450 km through the North and South Islands.

The Maitai Terrane consists of the eastern Early Permian (285–275 Ma, according to uranium–lead dating of zircon) Dun Mountain Ophiolite Belt, which is unconformably overlain by 6 km of well-stratified Late Permian to Middle Triassic volcaniclastic sedimentary rocks. The ophiolite originated in a near-arc setting. The Brook Street, Murihiku and Maitai terranes are adjacent to each other as a Permian–Triassic arc, fore-arc, and exhumed near-arc ophiolite, respectively.

The Caples, Bay of Islands, and Rakaia terranes contrast with the aforementioned Eastern Province terranes in that their Permian–Jurassic clastic sequences are tectonically imbricated with ocean-floor basalt, chert, and limestone associations; all three terranes grade into the pumpellyite–actinolite to amphibolite facies Haast Schist. Deposition occurred as submarine-fan deposits in lower trench-slope basins, before juxtaposition in an accretionary

prism. Compositional and provenance differences are used to discriminate the three terranes: Rakaia sandstones are quartz rich, plutoniclastic, and of average rhyodacitic composition and are thus compositionally distinct from the more dacitic to andesitic volcaniclastic-dominated sandstones in Caples and the Bay of Islands. The Pahau Terrane has a similar lithology and structure to the Rakaia Terrane, but its depositional ages extend into the Late Jurassic and Early Cretaceous and it contains tuffs. Much of the Pahau clastic detritus is probably recycled from Rakaia rocks, but a volcanic input, probably from the Median Batholith, is also required. The Pahau Terrane probably represents trench deposits that

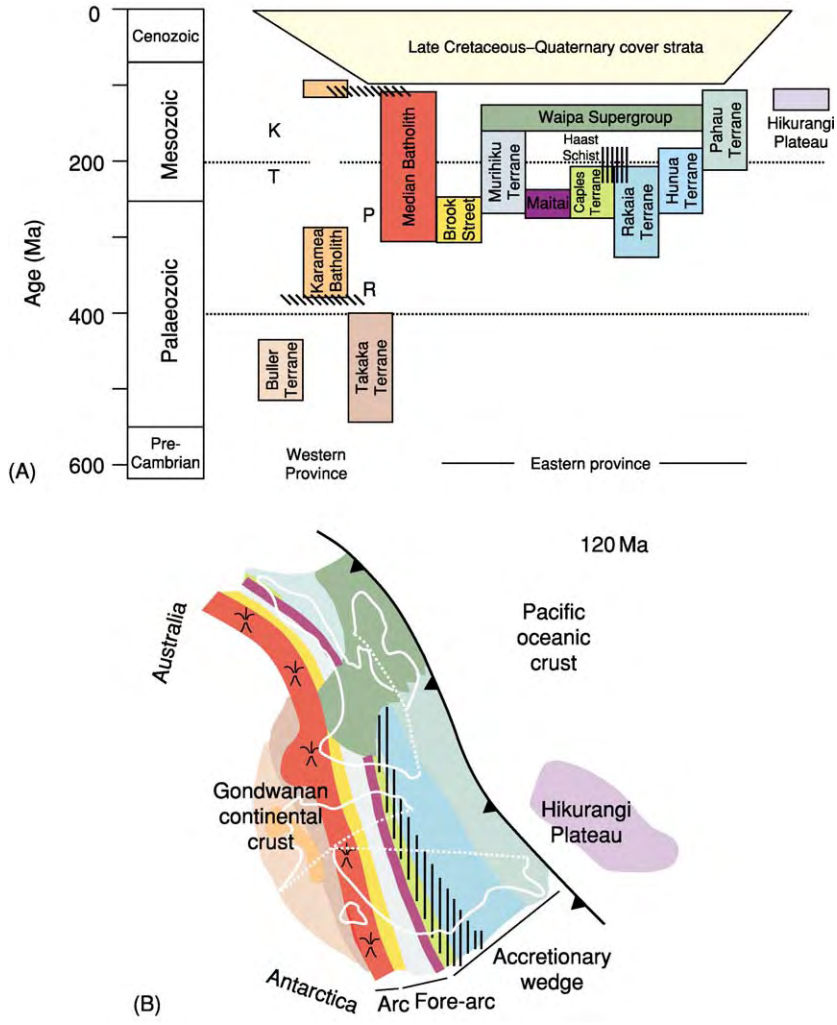

Figure 5 (A) Summary of the age ranges of New Zealand's basement terranes (green, blue, brown, yellow), batholiths (red, orange), and metamorphic rocks (overprint stripes). Gondwana Sequence rocks are shown by letters: K, Kirwans Dolerite; T, Topfer Formation; P, Parapara Group; R, Reefton Group. The terranes can be grouped into Eastern and Western provinces. (B) One possible palaeogeographical reconstruction of south eastern Gondwana at about 120 Ma (the end of the convergent margin phase). The present day New Zealand coastlines are shown as white lines; the Alpine Fault and other faults are shown as white dotted lines. (Reproduced with permission from Mortimer N (2004) New Zealand's geological foundations. *Gondwana Research* 7: 261 272. © International Association for Gondwana Research.)

were laid down and deformed towards the end of Cretaceous subduction.

These nine terranes make up the bulk of the New Zealand volcanosedimentary basement. Smaller tectonostratigraphic units can be regarded as components of the larger terranes. The Median Tectonic Zone is still used by some New Zealand geologists to describe a zone of terrane shards and igneous complexes of uncertain status and correlation that lies between the Brook Street and Takaka terranes (see Plutonic Rocks, below).

Overlap Sequences

Overlap sequences of varying ages can be recognized by their lesser deformation and metamorphism and distinctive petrofacies, as compared with older immediately underlying rocks. Lateral correlatives are used to constrain models of terrane amalgamation and accretion. The only New Zealand rocks that have been correlated with autochthonous Gondwanan sequences occur in two small outliers in northern South Island (marked G in Figure 2). Four units – the Reefton Group (marine Devonian), Parapara Group (marine Permian–Triassic), Topfer Formation (nonmarine Triassic), and Kirwans Dolerite (a Middle Jurassic low-titanium tholeiite sill intrusion) – indicate that the Buller and Takaka terranes had been accreted to Gondwana by the end of the Palaeozoic. In North Island, a postulated Late Jurassic overlap sequence – the Waipa Supergroup, possibly sourced

from the Median Batholith – may indicate that most of the basement terranes had accreted by this time. The post-105 Ma cover sediments provide a firm minimum age for the mutual juxtaposition and accretion of the basement terranes.

Plutonic Rocks

There are three composite regional batholith-sized belts (more than 100 km^2) of plutons in New Zealand, and numerous smaller isolated plutons. The Median Batholith is a composite Cordilleran batholith with intrusive contacts against the Brook Street and Takaka terranes. It comprises dozens of 1–10 km Carboniferous to Early Cretaceous gabbroic to granitic subalkaline I-type plutons. The eastern half of the Median Batholith has also been called the Median Tectonic Zone. The ages and average compositions of the rocks change across the batholith axis: Permian gabbroids dominate the eastern edge, Triassic to early Early Cretaceous dioritoids dominate the central part, and late Early Cretaceous adakitic granitoids are found on the western margin. Roof pendants of petrologically related volcanosedimentary rocks occupy about 5% of the batholith area. How much of the Median Batholith is allochthonous is debatable.

The Karamea–Paparoa Batholith lies entirely within the Buller Terrane. Its constituent plutons are dominated by Devonian–Carboniferous I-type and S-type granites. The Hohonu Batholith, also within the Buller Terrane, represents 105–82 Ma plutonism associated with the change from convergence to rifting.

Metamorphic Overprints

Regionally extensive metamorphic overprints include Devonian and Cretaceous polymetamorphic amphibolite–granulite facies gneisses (formed from Buller, Takaka, Median, and Karamea–Paparoa protoliths). Some of the gneisses are confined to the lower plates of two Cretaceous metamorphic core complexes in the South Island (stars in Figure 2). The Haast Schist of Jurassic–Cretaceous pumpellyite–actinolite to amphibolite facies overprints the Caples, Bay of Islands, and Rakaia terranes. Metamorphism probably took place in the deep parts of a Jurassic–Early Cretaceous accretionary wedge. Exhumation of the Haast Schist belt was episodic, with most of the schist being at the surface by 105 Ma and deeper levels being exhumed along the Alpine Fault from 20 Ma to the present day. The third major kind of regional tectonic overprint is the Early Cretaceous mélange that is present as belts in and between the Rakaia and Pahau terranes. In part this mélange is probably coeval with the Haast Schist mineral growth, but it formed in the shallower parts of the accretionary wedge. The steep mélanges may represent zones of strike-slip deformation.

Episodes of tectonic activity were previously described as orogenies. In the early 1980s it was realized that the Mesozoic Rangitata Orogeny was probably a composite of an older subduction-related event and a younger extension-related event. With the recognition that much of the intrusion, metamorphism, and deformation in the Buller and Takaka terranes ('Tuhua Orogen') occurred during the Cretaceous (of 'Rangitata' age), the orogen terminology became obsolete.

Cover Strata

Late Early Cretaceous to Holocene rocks rest unconformably on all the older basement units. The last 100 Ma of New Zealand's geological history can conveniently be divided into four periods, which are discussed in the following sections.

Late Early Cretaceous Intracontinental Rifting

Estimates of the timing of the end of Palaeozoic–Mesozoic subduction range from 125 Ma to 85 Ma. The youngest clearly subduction-related plutonic suites are 125 Ma old, and the oldest rift-related alkaline volcanics are about 100 Ma old. Detrital zircon dates of about 100 Ma have been obtained from sandstones imbricated in the accretionary wedge of the Pahau Terrane, but ignimbrites that fill extensional half-grabens are 105–100 Ma old. The two metamorphic core complexes, Paparoa and Fiordland, also attest to extreme local continental extension at around 105 Ma. Hypotheses about the reason for the cessation of subduction in the Cretaceous include migration of a spreading ridge along the trench, stalling of spreading outboard of the trench, and collision of the Hikurangi Plateau large igneous province (Figure 1) with the Gondwanan margin. Late Early Cretaceous sedimentary rocks typically comprise synrift non-marine deposits succeeded by passive-margin marine transgressive strata.

Late Cretaceous–Palaeogene Passive Margin

The oldest oceanic crust adjacent to the Challenger and Campbell Plateaus is about 85 Ma old. Spreading in the Tasman Sea ceased at about 55 Ma. New Zealand moved north (Figure 3) due to continuing spreading on the Pacific–Antarctic Ridge. Marine basins developed across Zealandia as a result of post-rift thermal subsidence. The maximum marine inundation of Zealandia, with widespread limestone deposition, occurred in the Oligocene, but local fluvial and coal deposits dating from throughout the

Late Cretaceous–Cenozoic (albeit in different parts of North and South islands) indicate that Zealandia was never entirely submerged.

Miocene–Pliocene Active Margin Development

By earliest Miocene times, a new plate boundary (in broadly the same place as the present-day boundary; Figure 1) had propagated through Zealandia and cut across the trend of the basement terranes. The development of the Pacific–Australian plate boundary had profound geological consequences. The Northland and East Coast allochthons, consisting of Late Cretaceous–Palaeogene ophiolitic and sedimentary rocks, were thrust onto North Island from the north-east at the end of the Oligocene (*ca*. 25 Ma). Subduction-related arc volcanism started at about 25 Ma and became widespread in Northland and the Coromandel between 15 Ma and 5 Ma. On South Island, intraplate stratovolcanoes developed along the east coast. The Neogene succession is generally thick, clastic-dominated, and regressive.

Quaternary

Although they are part of the continuing Neogene volcanotectonic phase, Quaternary rocks are shown separately in Figure 2 because of their wide areal extent and strong association with present-day landforms. The subduction-related Quaternary volcanoes of North Island have erupted extensive ignimbrite sheets, which blanket the older rocks. In South Island large fluvioglacial outwash plains issue from glacially eroded valleys.

Conclusions

The Phanerozoic geological history of New Zealand can be interpreted in terms of the progressive Pacificwards growth of Gondwana by terrane accretion and batholith intrusion at an obliquely convergent margin. Continental growth was terminated by widespread extension in southern Gondwana from about 105 Ma and was followed by seafloor spreading from about 85 Ma in the Tasman Sea and Southern Ocean. The entire basement and its cover of passive-margin Late Cretaceous to Palaeogene sediments were subjected to renewed deformation in the Neogene with the inception of the modern Australia–Pacific plate margin.

NORTH AMERICA

Contents

Precambrian Continental Nucleus

W Bleeker, Geological Survey of Canada, Ottawa, ON, Canada

Introduction

North America is a large continent and much of it is ancient (Figure 1). Fringed along several of its coastlines by younger mountain ranges, the broad interior of the continent is underlain by crust that ranges in age from >4.0 Ga to <1 Ga. This ancient crust (Figure 2) formed and progressively amalgamated during several broad 'orogenic' or mountain-building cycles. Although recording net crustal growth, this protracted history of orogenic cycles was far from linear – it involved numerous crust-forming (e.g., growth of volcanic islands) and crust-destroying (e.g., partial subduction) events, punctuated in time. It also involved a complex choreography of tectonic collisions between small lithospheric plates, subsequent rifting and dispersal events, re-aggregation, associated deformation, partial melting and metamorphism, and large-scale rearrangements along faults. Ultimately, at about 1 Ga, this protracted crustal evolution culminated in the growth of a large supercontinent known as Rodinia. In essence, the ancient core of continental North America, which is generally referred to as Laurentia, is a large fragment of this vast late Proterozoic supercontinent (*see* **Precambrian:** Overview).

Between 800 and 600 Ma, supercontinent Rodinia started to break up, resulting in the plate tectonic dispersal of about a dozen large continental fragments. This event liberated the large North American fragment (Laurentia) out of the parental landmass of Rodinia. Since this breakup, the west coast of Laurentia (present coordinates) has been a long-lived active margin facing oceanic plates and colliding island arcs, whereas its eastern margin was modified by yet another major collision and rifting cycle, first forming the Appalachian-Caledonian Mountain (*see* **North America:** Southern and Central Appalachians) Belt, and finally rifting, starting at *ca*. 200 Ma, to form the present-day Atlantic Ocean basin. (*see* **North America:** Atlantic Margin) These events have modified the margins of Laurentia and added marginal terranes of mostly younger crust, such as the Coast Mountains of British Columbia, large parts of Alaska (*see* **North America:** Northern Cordillera), and Gondwana-derived terranes along the eastern seaboard. Nevertheless, North America remains dominated by Precambrian crust, with a mean isotopic age >2 Ga.

The ancient crustal core of the continent, parts of which are exposed in the Canadian Shield (Figure 2), is underlain by subcontinental mantle lithosphere of above average thickness, which locally reaches down to a depth of 200–300 km into the hotter, convective mantle. This 'mantle keel' developed during or shortly after the amalgamation events in the crust, either by thermal growth (i.e., cooling from the top downwards) or by lateral accretion of buoyant slabs of depleted peridotite. The lithospheric keel is currently a reservoir of diamonds, a high-pressure polymorph of carbon. Transported to the surface by exotic volcanic rocks known as kimberlites, these valuable gemstones are now being produced from several mines across northern Canada (Figure 3). The mantle keel is mechanically coupled with the overlying crust, forming a thick and somewhat cooler lithosphere that enhances the strength and

long-term stability of the ancient continental core of Laurentia.

Modern Plate Tectonic Context and Extent of Laurentia

The continent of North America is an integral part of the North American plate, one of about 12 large lithospheric plates that presently form the segmented outer mechanical and thermal boundary layer of the Earth. These plates float on a solid but convecting mantle. Due to forces acting on their bounding surfaces (e.g., 'slab pull', but also 'ridge push', 'basal drag', and frictional forces), plates drift and interact laterally. Typical absolute plate velocities on the modern Earth are on the order of 1–10 cm year, with the North American plate moving in a west-south-westerly direction at *ca*. 2 cm year (centre of the continent), around a rotation pole located in north-western Equador.

Along its leading edge, the North American plate overrides subducting oceanic plates (Juan de Fuca, Cocos), which fuel arc volcanism along the Cascade and Central American margins. Elsewhere, relative plate motion, with respect to the main Pacific plate, is oblique or sideways, resulting in a transform fault boundary with right-lateral motion (the San Andreas and related faults). Collectively, these processes cause

deformation and modification of the Precambrian crust and lithosphere, which locally extends up to 1000 km inboard of the margin.

The eastern margin of the North American plate is the slow-spreading mid-Atlantic ridge, which runs north through Iceland and to the east of Greenland into the Arctic basin. Hence, Greenland, almost entirely underlain by Precambrian crust, is geologically part of North America and, more specifically, part of its Precambrian core, Laurentia. With progressive northward opening of the North Atlantic rift, Greenland started to rift apart from the main part of Laurentia at about 80 Ma, opening up the Labrador Sea. This rifting was subsequently aborted in favour of propagation of the mid-Atlantic ridge to east of Greenland, along the present trace of the ridge. Here, ridge propagation split off a fragment of Precambrian crust from Laurentia, which remained attached to the Eurasian plate and now underlies parts of Scotland, Ireland, and the adjacent continental shelf. This Precambrian sliver, known as the Lewisian Gneiss Complex, is equally part of Laurentia. Other Precambrian crustal elements may have rifted and drifted off Laurentia with the opening of a proto-Arctic basin (i.e., prior to the Innutian Orogeny, see **Figure 1**), but here relationships are presently less well understood.

The stable Precambrian lithosphere underlying much of North America responds to far-field boundary forces by gentle flexing and arching. As a consequence, Precambrian crust in the north-central parts of the continent is gently arched up, giving rise to the physiographic province of the Canadian Shield. The latter is characterized by scattered rocky outcrops of generally low relief (**Figure 2**), although, locally, rift

(I) Tilted strata of Proterozoic fluvial sandstones overlying the *ca.* 1.8 Ga crustal collage of Laurentia; 100 m high cliffs along the Brock River, North west Territories. Deposits such as these form widespread overlap assemblages as early as 1.75 Ga.

flank uplift has created significant new relief, exposing up to 1000 m-high sections through Precambrian rocks, particularly along the coasts of Labrador, Baffin Island, and Greenland. Minor rejuvenation of relief is currently taking place along arctic coastlines in response to post-glacial rebound. Elsewhere, peneplaned Precambrian basement dips gently beneath a thin Phanerozoic sedimentary cover, giving rise to interior platforms (*see* **North America:** Continental Interior). Presence or absence, and thickness, of this sedimentary cover was, of course, further modulated by changes in global sea-levels, either expanding or shrinking the extent of interior seaways.

In a number of localities, subsidence of the Precambrian lithosphere has been more pronounced, resulting in downwarped intra-continental basins filled with thicker sedimentary successions. One example is the Hudson Bay Basin in the middle of the Canadian Shield, which has been subsiding intermittently during the Phanerozoic. The processes responsible for this intermittent subsidence are poorly understood. Much better understood is the Western Canada Basin, a broad foreland basin forming in response to downflexing of Precambrian lithosphere in advance of the marginal load of the North American Cordillera.

In addition to the broad exposure of the Canadian Shield, crust of Precambrian age is also exposed in more restricted tectonic or plateau uplifts within the Cordilleran and Appalachian-Alleghanian mountain chains that fringe Laurentia. Important examples are the Laramide uplifts in the western United States (e.g., the Wind River Ranges in Wyoming) (*see* **North America:** Southern Cordillera), thrust sheets in the Rocky Mountains, and domal 'core complexes' throughout the internal Cordillera. Deep incision of the Colorado River in the uplifted Colorado Plateau also exposes an important window of Precambrian crust. The Blue Ridge Mountains of the south-eastern United States and the Long Range inlier of Newfoundland are examples of major thrust-related uplifts of Precambrian basement of Grenvillian age in the Appalachians (*see* **North America:** Northern Appalachians). In general, the subsurface edge of Precambrian basement can be traced with isotopic ratios of younger granitoids. An example is the $^{87}Sr/^{86}Sr$-isotopic line of the Cordillera (Figure 1).

Precambrian Nucleus of North America: General Structure

The basic architecture of the Precambrian nucleus of North America is that of a 'collage' comprising crustal elements of different ages (Figure 1). Many of the crustal elements involved in this collage were exotic with respect to each other, having originated in different places around the globe before being amalgamated. Other elements represent crustal growth along the margins of previously assembled continental crust. In places, the crustal collage is truncated by younger rifted margins, providing evidence that, originally, the collage must have extended well beyond its currently preserved margins.

Although the internal structure of the collage is complex, the complexity is far from random. In some ways, the overall architecture can be compared with the 'nested' structure of 'Russian dolls' (Figure 4):

- North America, in its present form, is a fragment of the latest supercontinent in Earth history, Pangaea (Figure 5) (*see* **Pangaea**), which existed from about 300 to 200 Ma and is currently still in the process of progressive breakup and dispersal, although a number of plates have already started their collisional history (e.g., India with Eurasia).
- The North American fragment of Pangaea hosts within itself a large fragment of the earlier supercontinent Rodinia (Figure 4), which was amalgamated from 1200 to 980 Ma. As discussed earlier, this fragment of Precambrian crust, several thousand kilometres in diameter, is commonly referred to as Laurentia.
- On a smaller scale, Laurentia hosts within itself 6–7 large fragments of Archaean (>2.5 Ga) crust, the Archaean 'cratons' (*see* **Precambrian:** Overview). Among these, the Superior, Wyoming, and Slave cratons are some of the better-known examples. These crustal fragments are called cratons because they show long-term stability, having been affected by younger deformation only around their edges. The typical length scale of these Archaean cratons is *ca.* 1000 km. The Superior Craton is the largest preserved Archaean craton on Earth.
- Furthermore, the larger Archaean cratons are typically composite, consisting of a number of domains with disparate crust formation ages. Included among these domains are ancient crustal fragments that are dominated by gneissic granitoids with ages of crystallization or inheritance of >2.9–3.0 Ga. Such ancient gneiss domains (e.g., the Central Slave Basement Complex of the Slave Craton; or the North Caribou Terrane of the Superior Craton; see Figure 4) have typical length scales of 100–300 km.
- Finally, these ancient gneiss domains are themselves heterogeneous. Embedded within them are found Earth's oldest rocks, including, for instance, the 4.03 Ga Acasta gneisses of the Slave Craton (Figures 2A and 4). Individual examples of these

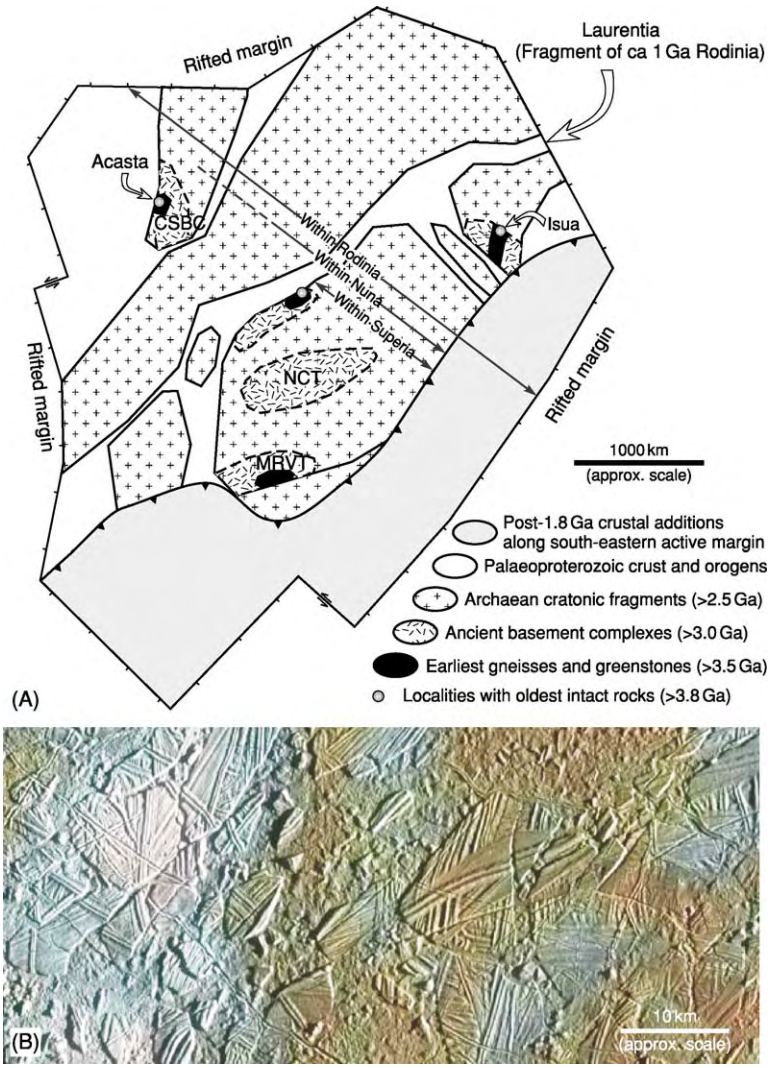

Figure 4 (A) Cartoon illustrating the systematic fractal architecture of the Precambrian crust. The Precambrian record consists of a collage of 'nested' fragments across a variety of scales. At the largest scale, Laurentia itself represents a rifted fragment of Rodinia, a *ca* 1 Ga supercontinent. Its margins formed between 780 600 Ma, when Rodinia started to break up. At the smallest scale, we find individual gneiss complexes consisting of some the oldest intact rocks on Earth (e.g., Acasta, Isua), nested within larger Archaean cratons. The overall fractal structure is one of preservation and reflects repeated cycles of fragmentation and re aggregation, with smaller older fragments preserved in larger younger fragments. Abbreviations: CSBC, Central Slave Basement Complex, Slave Craton; NCT, North Caribou Terrane, Superior Craton; MRVT, Minnesota River Valley Terrane. (B) An identical fractal pattern of nested fragments, but at smaller scales, is seen in this picture of the icy crust of Europa, one of Jupiter's large moons (source: NASA, Galileo Orbiter PIA01127). Linear features are ridges formed by upwelling and subsequent freezing of water along cracks.

Early Archaean gneiss complexes are typically preserved at the 1–10 km scale, in some cases ranging up to *ca*. 100 km.

Hence, the structure of the Precambrian nucleus of North America, and that of the geological record in general, is self-similar (fractal) in nature, repeating a basic motif across a variety of scales, ranging from the size of modern plates to that of individual ancient gneiss complexes or the greenstones belts embedded within them. As plate tectonics is the dominant process in shaping this pattern on the modern Earth, it is tempting to conclude that plate tectonics must have been equally dominant since at least *ca*. 4.0 Ga, the time of the Earth's oldest preserved crust (Figure 6). One might also conclude that plates have grown in size over time. These conclusions seem reasonable but there are a number of important caveats.

The similarity in basic pattern strongly suggests repeated fragmentation and dispersal events of pre-existing crust, with fragments becoming incorporated in new crustal collages through time. However, similarity in pattern and implied kinematic processes

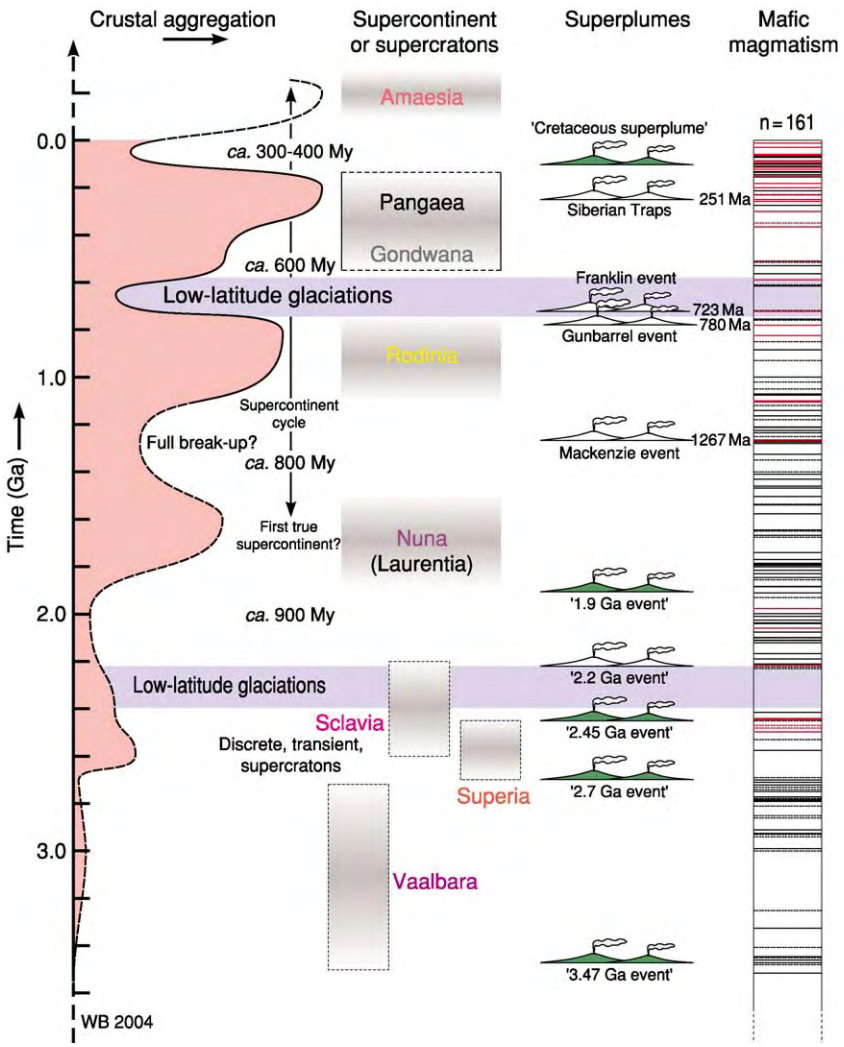

Figure 5 The history of crustal aggregation states (supercratons, supercontinents) through time (vertical axis; modified after Bleeker, 2003). Mid Proterozoic Nuna, including the large 1.8 Ga core of Laurentia, was probably the first true supercontinent in Earth history. The Late Archaean may have been characterized by several discrete, transient, aggregations referred to as super cratons: Vaalbara, Superia, Sclavia and possibly others. The diachronous break up of these supercratons, in the Palaeoproterozoic, spawned the present ensemble of *ca.* 35 Archaean cratons, which now are variably incorporated into younger crustal collages. Since the assembly of Nuna, the time gaps between successive crustal aggregation maxima appear to have become shorter. Note the correlation of intervals of global glaciation with two periods of continental breakup and dispersal, and with possible minima in the frequency of mafic magmatic events in the continental record (legend for the latter: red line, well established mantle plume event; black line, other mafic magmatic event; dashed line, poorly dated event; modified after Ernst and Buchan (2001).

does not necessitate similarity at a dynamic process level. Modern lithospheric plates tend to be large and relatively rigid, and negative buoyancy of subducting, old and cold oceanic plates ('slab pull') is a major component in the overall force balance driving plate motions. At present, it is controversial whether in a hotter Archaean Earth, with 2–4 times the present heat production and a more substantial fraction of the primordial heat budget still preserved inside the Earth, thinner and smaller lithospheric 'plates' interacted the same way as their modern counterparts. A key question is whether the return flow of oceanic mafic-ultramafic material was by rigid slab subduction (i.e., 'plate tectonics') or whether residues, after tonalitic melt extraction, descended back into the convecting mantle by more disorganized gravitational sinking ('drip tectonics')?

Attempts to answer this question from the geological record, as preserved in Archaean cratons, leaves little doubt that the cratons preserve a record of interaction between different crustal fragments. Nevertheless, Archaean cratons lack a fully diagnostic set of criteria confirming modern plate behaviour (e.g., passive margins, flexural basins, accretionary prisms, uncontested ophiolites, high pressure-low temperature metamorphic rocks and

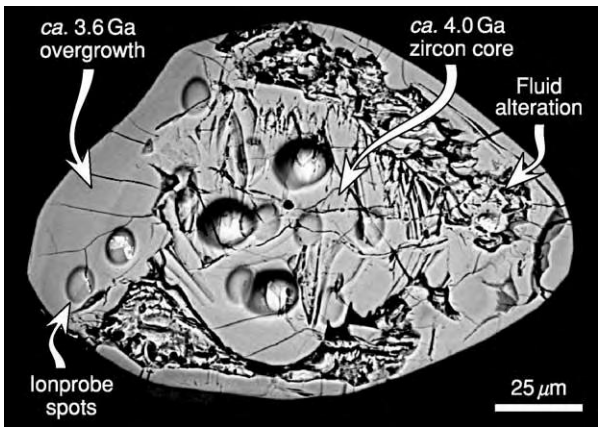

Figure 6 Backscatter electron image of a *ca.* 4.0 Ga zircon crystal from the Acasta gneisses, Earth's oldest intact rocks (see also **Figure 2A**). Metamorphic rims formed at *ca.* 3.6 Ga. Oval spots are scars from the ion probe beam (from Stern and Bleeker, 1998).

paired metamorphic belts, etc.). Hence, it is useful to consider alternative explanations. In doing so, it is also instructive to consider other planetary bodies and their unique pathways of lithospheric evolution. For a comparison with the fractal pattern of repeated fragmentation and amalgamation in the Earth's crust, the icy crust of Europa, one of Jupiter's large moons (**Figure 4B**), is of particular interest (*see* **Solar System: Jupiter, Saturn and Their Moons**). Europa's crust of water-ice, overlying an interior ocean, shows a fractal pattern that is essentially similar to that of Earth's crust, requiring repeated fragmentation events, upwelling and freezing of water along cracks, and lateral mobility of fragments. Yet it is not the product of plate tectonics driven by rigid slab subduction of dense silicate rocks.

Both on Europa and Earth, the fractal pattern of smaller, older fragments embedded in younger crustal collages, is an artefact of the process by which fragments are created and preserved. With each repeated breakup event, crustal fragments can only become smaller, while their number will increase. On the other hand, erosion, tectonic slivering, and partial subduction will, over time, reduce the number of fragments or hide them in the lower crust. Furthermore, a fragment of a certain size and age can only be preserved in a younger fragment that is either the same size or larger. Hence, the negative correlation between fragment size and age, as illustrated in **Figure 4**, is primarily a function of how continental crust is preserved, and may not provide information on whether continental plates have grown in average size over geological time.

Nevertheless, it is intriguing that few of the Archaean cratons come close in size to even the smallest of the major continental plates today. The Superior Craton of North America, the largest extant Archaean Craton, with a surface area of *ca.* $1.57 \times 10^6\,km^2$, is about half the size of the Arabian Plate. Indeed, several independent lines of evidence suggest that Archaean continental aggregations may have been smaller and more transient than their modern counterparts:

- A hotter Archaean Earth, with a substantially higher radiogenic element budget, favours smaller and faster plates to dissipate the increased heat production and avoid catastrophic heating of the planetary interior.
- The record of $^{87}Sr/^{86}Sr$ isotopic compositions of Precambrian seawater, as measured from marine carbonates, shows that prior to 2.6–2.5 Ga, Sr ratios were buffered by dominant interaction with oceanic crust and young mantle-derived mafic rocks. Only after *ca.* 2.5 Ga do we see a rapid rise in the $^{87}Sr/^{86}Sr$ ratios, reflecting more significant input from weathering of aged continental crust.
- Much of the modern detrital sediment load to sedimentary basins and continental shelf-slope systems is provided by large river systems draining large continental hinterlands. The fact that there are few examples of large sedimentary basins of a shelf-slope affinity preserved in the Archaean record, suggests that river systems and their continental hinterlands were smaller, and that large, emerged continental plates were rare or absent.
- As attested by Laurentia, once large cratonic landmasses have aggregated and become underlain by a lithospheric keel, they tend to resist breakup. So, as noted above, the observation that none of the Archaean fragments, with their lithospheric keels, approaches modern continents in size may be significant after all.
- Characteristics of the supercontinent cycle (**Figure 5**) suggest that the successive time lags between breakup and dispersal of one supercontinent (e.g., Rodinia) and the re-aggregation of a subsequent supercontinent (e.g., Pangaea) have become shorter over the last 2.5 billion years. The easiest explanation for this observation is that, following supercontinent breakup and dispersal, modern continental plates, due to their large average size, quickly run out of room and start colliding. More substantial time lags in the past suggest smaller continental plates.
- And finally, Earth's present rate of heat loss is about twice the rate of internal heat production, while at the same time heat production (mainly from K, Th, U) is undergoing slow exponential decay. Thermal arguments predict therefore that,

over time, the lithosphere will slowly thicken and stiffen, evolving ultimately to a relatively immobile 'one-plate' state. This state has already been reached by our closest sister planet, Venus, which is only marginally smaller than Earth (Venus' radius is 95% that of Earth).

Precambrian Nucleus of North America: A Systematic Overview

From 2.0 Ga to 1.8 Ga, over a time-span of about 200 million years, the core of Laurentia formed by progressive amalgamation of 6–7 large fragments of Archaean crust and intervening island arcs into a broad orogenic collage (Figure 1). Crustal shortening and thickening accompanying the various accretion and collision events led to uplift and exhumation and, ultimately, stabilization of the newly formed crust, as indicated by the initiation of widespread intracontinental sedimentary basins that overstep the boundaries between different crustal blocks as early as *ca* 1.75 Ga. Interestingly, the time-frame of relatively rapid crustal aggregation and growth implied for Laurentia is of a similar order to that for the progressive development of the most recent supercontinent, Pangaea, which started with assembly of the large southern continent Gondwana in the latest Proterozoic and terminated with final collision of Gondwana and Laurasia in the Carboniferous to Permian (i.e., an overall time-frame of *ca*. 250 Ma).

The widespread 2.0–1.8 Ga orogenic events in Laurentia, known in North America as the Hudsonian Orogeny, have counterparts in most other continents (e.g., the Amazonian Orogeny in Brazil; the Svecofennian Orogeny of the Baltic Shield; the Capricorn Orogeny of Western Australia). Through the collective amalgamation of a large number of disparate Archaean cratons or microcontinents into a global collage, this first-order orogenic event may have led to the first true supercontinent in Earth history at about 1.75 Ga named Nuna (Figure 5). Through further crustal growth along its external margins, and final continent–continent collision to form the Grenville Orogen along its southeastern margin (Figure 1), Nuna evolved into *ca*. 1 Ga Rodinia.

Clearly, the Archaean cratons are the dominant building blocks in the Palaeoproterozoic assembly of Laurentia, and the core of Nuna. Hence, they form a logical starting point for a brief systematic overview of the Precambrian crust.

The Archaean Cratons

Individual Archaean cratons that constitute the core of Laurentia are: the Superior, Slave, and Wyoming cratons; the highly reworked Rae and Hearne cratons, collectively known as the Churchill structural province; the enigmatic Sask Craton, which underlies much of the Palaeoproterozoic Trans-Hudson Orogen in central Canada; and the Nain or North Atlantic Craton underlying southern Greenland (Figure 1). These cratons represent a subset out of a total ensemble of about 35 large Archaean crustal fragments preserved around the world.

The independent nature of some of the component cratons of Laurentia is still a matter of debate. Clearly, the well-studied Superior and Slave cratons are two pieces of crust that are exotic relative to each other and most likely originated from unrelated ancestral landmasses – the Late Archaean supercratons Superia and Sclavia, respectively (Figure 5). The ancestry of some of the other cratons is less clear.

A putative suture between the Hearne and Rae cratons, the Snowbird Tectonic Zone (Figure 1), remains controversial. Hence, it is possible that the Hearne and Rae cratons represent a contiguous fragment of Archaean crust. The Hearne Craton is locally overlain by an Early Proterozoic cover sequence, the *ca*. 2.4–2.1 Ga Hurwitz Group, which shows similarities to the Huronian Supergroup overlying the southern Superior Craton. Both sequences contain evidence for *ca*. 2.3 Ga low-latitude glaciations. Futhermore, both cratons are cross-cut by *ca*. 2450 Ma mafic dykes. Palaeomagnetic data from these dykes suggest that the Hearne Craton may have originated, at 2450 Ma, from just south of the 'Huronian margin' of the Superior Craton (Figure 7). Thus, both cratons likely originated from within supercraton Superia, possibly along with others such as the Karelia, Nain and Yilgarn cratons.

Whether the Wyoming Craton, underlying much of the north-western United States, is truly distinct or just a southern continuation of the Hearne Craton also remains unclear. The proposed suture between the Hearne and Wyoming cratons is buried underneath thick platform strata. The Sask Craton may be an exotic piece of crust or, alternatively, a partially detached piece of either the neighbouring Hearne or Superior Craton, incorporated in the Trans-Hudson Orogen. Interestingly, many of these fundamental questions can be resolved, in principle, with detailed palaeomagnetic studies and high-precision age dating of the Palaeoproterozoic mafic dyke swarms that cut the cratons, in conjunction with stratigraphic comparisons of the Archaean cratons and the Palaeoproterozoic cover sequences that overlie them.

The Slave Craton

As an example of the Archaean components of Laurentia, the Slave Craton is described in more detail.

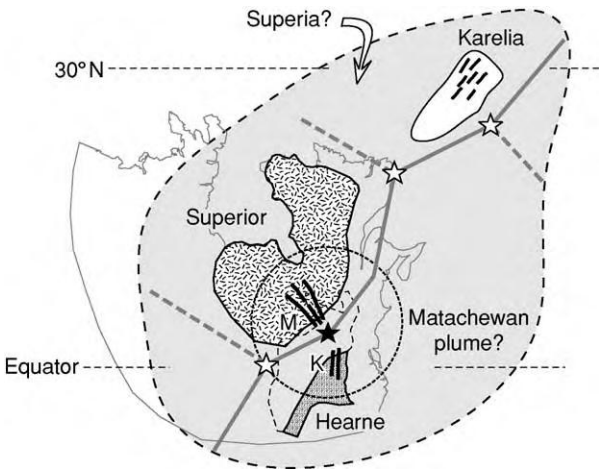

Figure 7 Possible reconstruction of the relative position of the Superior and Hearne crustal fragments at *ca.* 2450 Ma, prior to the inferred break up of their ancestral supercraton, Superia. Both cratons are cut by *ca.* 2450 Ma mafic dykes that are petrographi cally similar, the Kaminak dykes (K) of the northern Hearne and the Matachewan dykes (M) of the southern Superior, respect ively. Palaeomagnetic data from both dyke swarms allow the reconstruction shown here. Both dyke swarms and the inferred break up of Superia may have been consequences of the *ca* 2450 Ma Matachewan plume (black star). Karelia, another Ar chaean craton now embedded in the Baltic Shield, also hosts *ca* 2450 Ma mafic dykes and, thus, may have been part of Superia. Also shown is a possible topology of intracontinental rift zones along which supercraton Superia broke up, liberating individual cratons. Plumes or hotspots along this rift zone (open stars) may have had ages spreading out over a 100 200 million year interval, similar to those along the mid Atlantic rift during progressive break up of Pangaea.

This well-exposed fragment of Archaean crust measures about 500 (E–W) by 700 (N–S) km and is surrounded by orogens of Palaeoproterozoic or younger age (Figures 1 and 8).

The west-central part of the craton is underlain by an ancient gneiss complex that hosts some of the oldest intact rocks in the world, the *ca.* 4.03 Ga Acasta Gneisses (Figure 2A). This basement complex is overlain by a thin, *ca.* 2.8 Ga quartzite and banded iron formation sequence (Figures 2B and 8), which in turn is overlain by the main cycle of *ca.* 2.73–2.62 Ga volcanic and sedimentary rocks (Figures 2C,D and 8). Very similar stratigraphic relationships are seen in other cratons of Laurentia and around the world.

The Neoarchaean supracrustal rocks of the Slave Craton, known as the Yellowknife Supergroup, were intruded by voluminous granitoid rocks that range in age and affinity from *ca.* 2.71–2.67 Ga, synvolcanic, tonalite-granodiorite plutons to *ca.* 2.58 Ga, post-tectonic, granite plutons. The supracrustal and pre-tectonic granitoid rocks are deformed by several discrete folding events, resulting in complex fold interference structures (Figure 2D) and high-amplitude basement-cored domes. The overall result is an archetypical Archaean 'granite-greenstone terrane'.

The younger granites are part of a craton-wide, *ca.* 2.59–2.58 Ga 'granite bloom', which transported heat, partial melt fractions, and aqueous fluids, as well as most of the incompatible heat producing elements (K, U, Th), from the hot lower crust to the upper crust. This critical and irreversible step allowed the lower crust to cool and to mechanically couple with the mantle lithosphere. Shortly following this terminal granite bloom, Slave crust stabilized and became 'cratonic'.

Following cratonization, from 2.58 Ga to 2.2–2.0 Ga, Slave crust was gradually exhumed by *ca.* 10–15 km (on average) through slow uplift and erosion. This is indicated by the onlap of unconformably overlying Palaeoproterozoic cover sequences onto exhumed Archaean basement (Figure 2E). Starting at about 2230 Ma, the Slave Craton, still within the larger context of its host supercraton Sclavia, was intruded and weakened by numerous mafic dyke swarms and anorogenic alkaline complexes. These events eventually led to rifting and breakup of Sclavia and independent drift of the Slave Craton as a small microcontinent. In general, these Early Proterozoic rifting and dispersal events resulted in some of the first true sediment-rich passive margin sequences in the geological record (e.g., the Coronation Supergroup overlying the western margin of the Slave Craton, Figure 2E).

Proterozoic Orogens: the Glue of the Laurentian Collage

The oldest Palaeoproterozoic orogen within Laurentia is the Taltson-Thelon Orogen along the western margin of the Rae Craton. It is marked by a *ca.* 2.02–1.95 Ga magmatic arc, with a conspicuous aeromagnetic signature that allows it to be traced for several thousand kilometres (Figure 1). This magmatic arc suggests significant consumption of oceanic lithosphere below the western edge of the Rae Craton, leading to collision and eventual suturing of the Slave Craton to the Rae. Partial subduction of Slave crust below the Rae led to flexural subsidence of the Slave and its overlying platform sequence, resulting in one of the best examples of a Palaeoproterozoic foreland trough—the Kilihigok Basin. The short flexural wavelength of this basin suggests a low flexural rigidity of Slave lithosphere at 1.9 Ga, and hence argues against a thick lithospheric keel at that time.

During the Slave–Rae collision, subduction is also active on the western side of the Slave Craton, underneath an outboard Hottah Arc. This arc accreted to

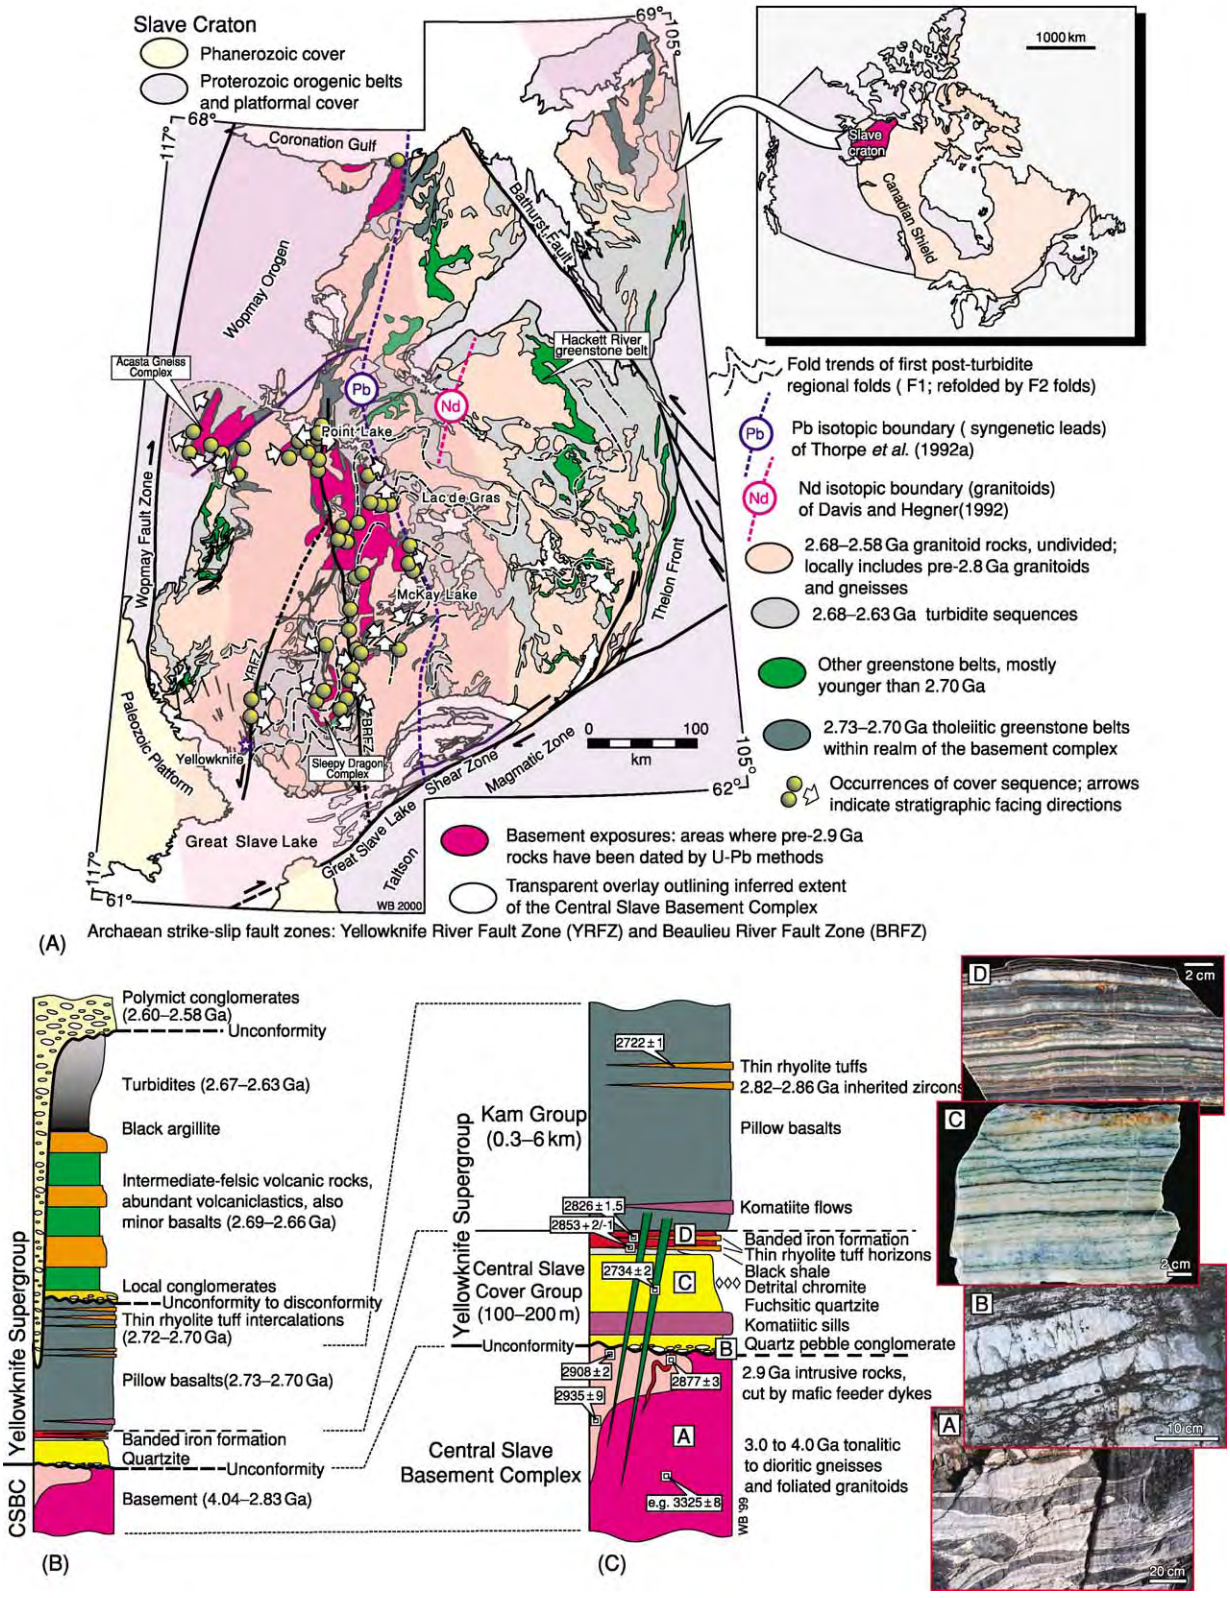

Figure 8 Geology and generalized stratigraphy of the Slave Craton. (A) Geological map; transparent overlay (light purple) outlines minimum extent of the Mesoarchaean to Hadean basement complex of the Slave Craton. (B) Generalized stratigraphy for large parts of the craton. (C) Typical stratigraphy immediately overlying the Mesoarchaean basement complex; photos A D illustrate different units in the section.

the Slave Craton, followed by a subduction polarity flip and building of a new arc on the Hottah–Slave Suture at *ca*. 1.88 to 1.86 Ga.

Elsewhere, the eastern margin of the Rae-Hearne block (already assembled or always contiguous?) started to interact with outboard island arcs, representing the early stages of the Trans-Hudson Orogen (Figure 1). Similar processes were occurring around the margins of the other cratons, some still at remote locations (e.g., the onset of arc accretion along the southern margin of the Superior Craton, initiating the Penokean Orogen). Then, in a spectacular climax of orogenic activity, between about 1850 Ma and 1800 Ma, the remaining cratons gradually aggregated, collided, and amalgamated. This final stage involved the putative closure of the wide Manikewan Ocean between the Rae-Hearne and Superior cratons to form the >3000 km-long Trans-Hudson Orogen through the centre of the Canadian Shield. Terminal collision in Trans-Hudson Orogen (Figure 9) involved northward indentation of the large Superior Craton into a northern hinterland of the Rae-Nain-Hearne-Slave Collage. This northward indentation caused oroclinal bending of the hinterland and tectonic escape of crustal blocks along large strike-slip faults. The northward movement also caused late-stage transcurrent motion on the lateral margins of the Superior indentor (Figure 1).

Post-1.8 Ga Growth and Modification of Laurentia

Following the climactic growth of Laurentia at *ca*. 1.8 Ga, orogenic activity transferred to the external margins of Laurentia, in the west and the south-east. A complete assessment of growth along the western margin needs to involve a western landmass (most likely a combined Australia-Antarctica continent and its amalgamation history), which has since rifted off.

In the south-east, 1.8 Ga orogenic activity must have left major tracts of oceanic lithosphere along the 'trailing edges' of the plates that carried the Archaean cratons into the Laurentian collage. This oceanic lithosphere was subsequently consumed. A number of successive arcs formed, either as outboard

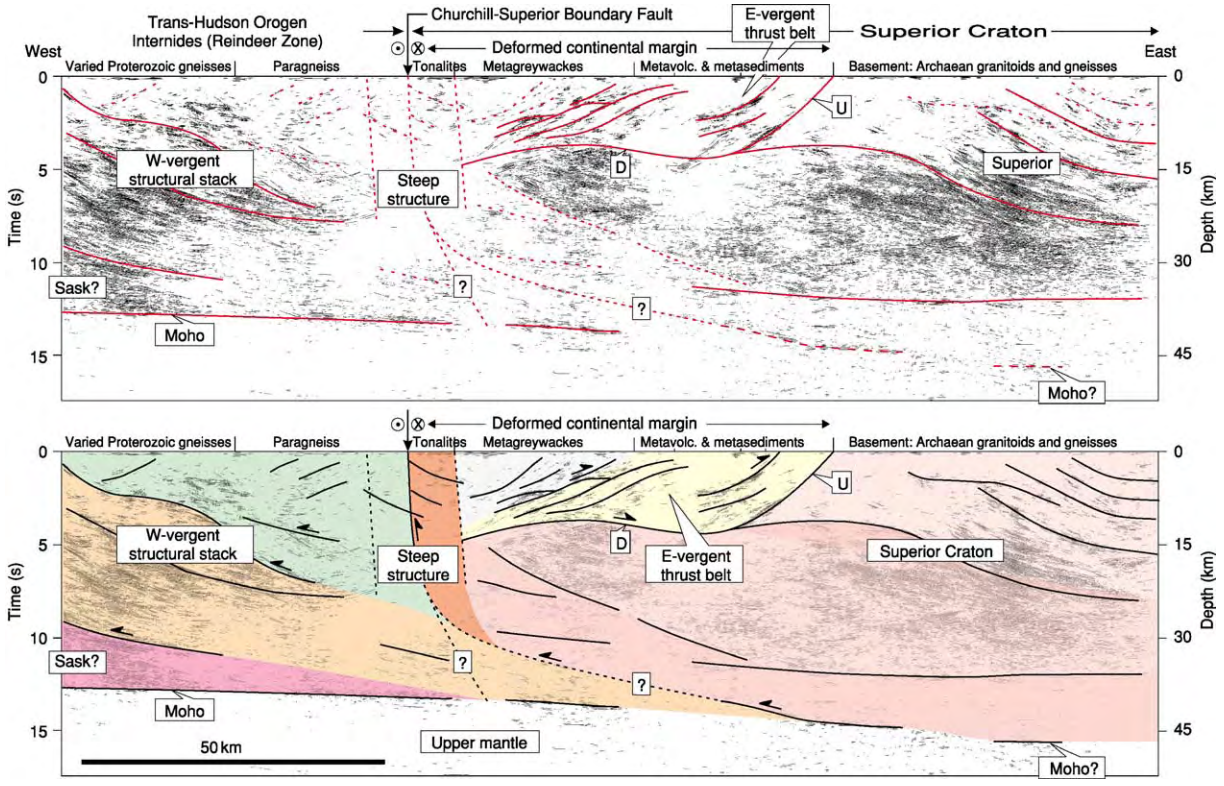

Figure 9 Representative seismic reflection profile (upper diagram) and interpreted cross section (lower diagram) through one of the major *ca*. 1.8 Ga sutures of Laurentia, the 'Churchill Superior Boundary Zone', along the western margin of the Superior Craton (see Figure 1 for location of profile). Early deformation imbricated the continental margin of the Superior Craton, including the *ca*. 2.0 Ga Ospwagan Group (Figure 2F and G) into an E vergent fold thrust belt. During terminal collision, vergence changed and the buoyant Superior margin started to override juvenile Palaeoproterozoic rocks of the internal zone of the Trans Hudson Orogen. Oblique convergence degenerated into late stage sinistral strike slip deformation along the steep Churchill Superior Boundary Fault (modified after White *et al.*, 2002; see also Bleeker, 1990).

island arcs or, at other times, as magmatic arcs on the growing margin of Laurentia. These long-lived active margin processes led to progressive outward growth of and accretion to Laurentia, culminating with the final collisional history of the *ca*. 1.19–0.98 Ga, high-grade, Grenville Orogen (Figure 1).

Significant pulses of outward growth that can be recognized along various parts of the margin are the Yavapai (1.79–1.71 Ga) and Mazatzal (*ca*. 1.70–1.62 Ga) belts of the south-western United States (Figure 1). The latter is broadly coeval with the Labradorian event of north-eastern Laurentia (Figure 1), which involved accetion of a 1.70–1.66 Ga outboard arc to the margin of Laurentia at about 1655 Ma. The Labradorian Arc and a number of younger arcs (e.g., the Pinwarian Arc) were severely reworked during terminal Grenville collisions. The latter involved final suturing of Laurentia to a southeastern landmass (Amazonia?) to form Rodinia.

During its long-lived Proterozoic active margin evolution, lasting from about 1.8 Ga to 1.0 Ga, Laurentia likely faced a 'Pacific-type' ocean to the south-east (present coordinates). Inboard of this margin, several major magmatic events suggest the upwelling of hot mantle underneath the growing continent. Similar processes ultimately led to the rifting and breakup of Laurentia (as part of Rodinia), starting at about 780 Ma. Important examples of mid-Proterozoic igneous events are several pulses of granite-rhyolite magmatism concentrated in south-eastern Laurentia; the intrusion of the 1.3 Ga Nain plutonic suite in Labrador; the 1267 Ma giant Mackenzie dyke swarm; several more localised mafic dyke swarms; and the basalt-rhyolite volcanism of the Keewanawan event in the mid-continent rift (Figure 1).

Glossary

Nuna Earth's first true supercontinent that formed by progressive amalgamation of numerous microplates and intervening island arc terranes towards the end of the Palaeoproterozoic era, from about 1.9 Ga to 1.7 Ga.

Sclavia Late Archaean ancestral landmass of the Slave Craton and allied cratons. This landmass or supercraton amalgamated during Late Archaean orogenic activity, cratonized shortly after 2.6 Ga, and experienced rifting and break-up between 2.2 Ga and 2.0 Ga, spawning several microplates, including its type craton, the Slave Craton of the Canadian Shield. Existence of this late Archaean supercraton is indicated by the Slave Craton being a cratonic fragment surrounded by rifted margins.

Superia Late Archaean ancestral landmass of the Superior Craton and allied cratons. This landmass or supercraton amalgamated during Late Archaean orogenic activity, cratonized shortly between 2.68 Ga and 2.62 Ga, and experienced rifting and break-up starting at 2.48 Ga, spawning numerous microplates, including its type craton, the Superior Craton of the Canadian Shield. Existence of this Late Archaean supercraton is indicated by the Superior craton being a cratonic fragment surrounded by rifted margins.

Supercraton One of several Late Archaean cratonic landmasses, not necessarily a single supercontinent, that on Palaeoproterozoic break-up spawned the present ensemble of *ca*. 35 Archaean cratons with their rifted margins.

Continental Interior

D F Merriam, University of Kansas, Lawrence, KS, USA

> PB King wrote "The [Continental] Interior Lowlands are differentiated from the Laurentian [Canadian] Shield mainly by their retention of a sedimentary cover, so that the tectonic boundary between the two divisions is arbitrary and the differences are not fundamental."
>
> (*The Tectonics of Middle North America*, 1951)

Introduction

The vast country of essentially flat-lying sediments rimmed on three sides by the old Appalachian, Ouachita, and Rocky Mountain mountain chains and to the north the poorly exposed, heavy glaciated, low-lying Canadian Shield (nucleus) composed of Precambrian crystalline igneous and metamorphic rocks, comprises the North American Continental Interior (Figure 1). This immense area, also known as the Central Stable Region, is drained by the mighty Mississippi River and tributaries – and contains the large, relatively shallow, freshwater Great Lakes. This physiography accurately reflects the tectonic provinces (Figure 2). Occasionally, bits of the basement poke through the veneer of this essentially gently-dipping sedimentary cover in the Black Hills of South Dakota, Wichita Mountains of Oklahoma, Ozarks of Missouri, and Baraboo Range of Wisconsin. The shape and form of the sedimentary rocks over the area conform well to the shape and form of the Precambrian basement foundation on which they lie.

Although the topography is subdued and the spectacular scenery is formed for the most part, by erosional remnants or incised valleys, it reflects geological conditions of the region and thus the landforms are a key to understanding recent developments. This part of North America forms the physiographic provinces of the Interior Lowlands and the Great Plains – the bread basket of the continent.

The nucleus of the North American continent is the Precambrian Canadian Shield – the craton, a stable feature around and on which subsequent events took place (*see* **North America:** Precambrian Continental Nucleus). The craton itself had a long and complex history but because of poor exposure and structural complexities it has been difficult to decipher. With a few notable exceptions, the craton is made up of ancient igneous and metamorphic crystalline rocks. The notable exception is the Midcontinent Rift System (MRS), extending from Minnesota to Oklahoma, which is an elongated, younger, faulted, and down-dropped trough containing extrusive igneous rocks interspersed with thick, locally derived, immature sediments (Figure 3). Near the end of the Precambrian, a prolonged period of erosion beveled and smoothed the old fractured/faulted surface prior to it being covered by the younger sedimentary rocks.

Figure 1 Index map of North American physiographic provinces showing location of Interior Lowlands and Great Plains of Continental Interior wedged in between the Appalachian Mountains on the east and the Rocky Mountains on the west. (From Kay and Colbert (1965), John Wiley & Sons.)

This part of the Earth was relatively stable during the next several hundred million years, and as the seas advanced and retreated over the low relief surface, they deposited fairly uniform marine sediments, layer upon layer, over extensive areas. The type and distribution of the sediments responded to the global change in sea-level as well as to changes in local conditions. All of these events were recorded in the sedimentary section, which, as the history unfolded, was sprinkled liberally with long intervals of no record. Because of the sensitivity to conditions in the accumulation of sediments in this type of environment, much of the history is not chronicled; in fact, it has been estimated that as much as 85% of time in any one place is not represented by the rock record. This situation is aptly described as layer-cake geology.

The Foundation

The foundation is the craton, which was formed by adding on (accretion of) material to the original

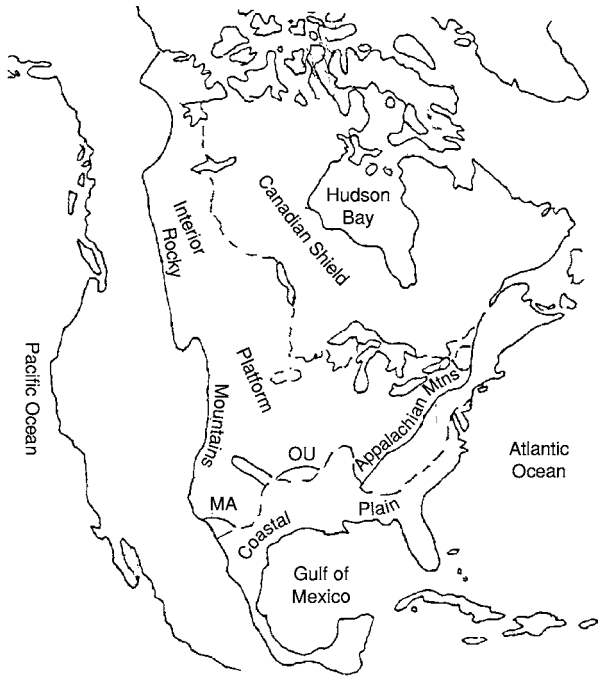

Figure 2 Simplified tectonic map of the North American Continent (MA Marathon Uplift; OU Ouachita Mountains). (Modified from Bally, Scotese and Ross (1989) GSA, The Geology of North America, v. A.) Note physiographic provinces mimic tectonic ones.

primaeval nucleus (Archaean age; 3600 to 2600 Ma) so that the younger Precambrian crystallines (Proterozoic age; 2500 to 900 Ma) rim the nucleus to the south (Figure 3). The Midcontinent Rift System (MRS; 1200 to 1000 Ma) cuts across the older Precambrian terrain. This foundation forms part of the continental crust which ranges in thickness from 40 to 50 km (Figure 4).

In the Continental Interior south of the Canadian Shield, the Precambrian basement complex is exposed in only a few places. Thus, the knowledge of this time period in the Earth's history is known from the thousands of wells drilled in the search for petroleum, water, and mineral resources, plus, of course, geophysical data.

The Sedimentary Veneer

Overlying the Precambrian foundation is the sedimentary veneer, the composition and configuration of these younger sedimentary deposits giving clues to the conditions under which they were deposited and accumulated. Thus, information is contained in the rocks about the location of sea margins, climate, and life at that time.

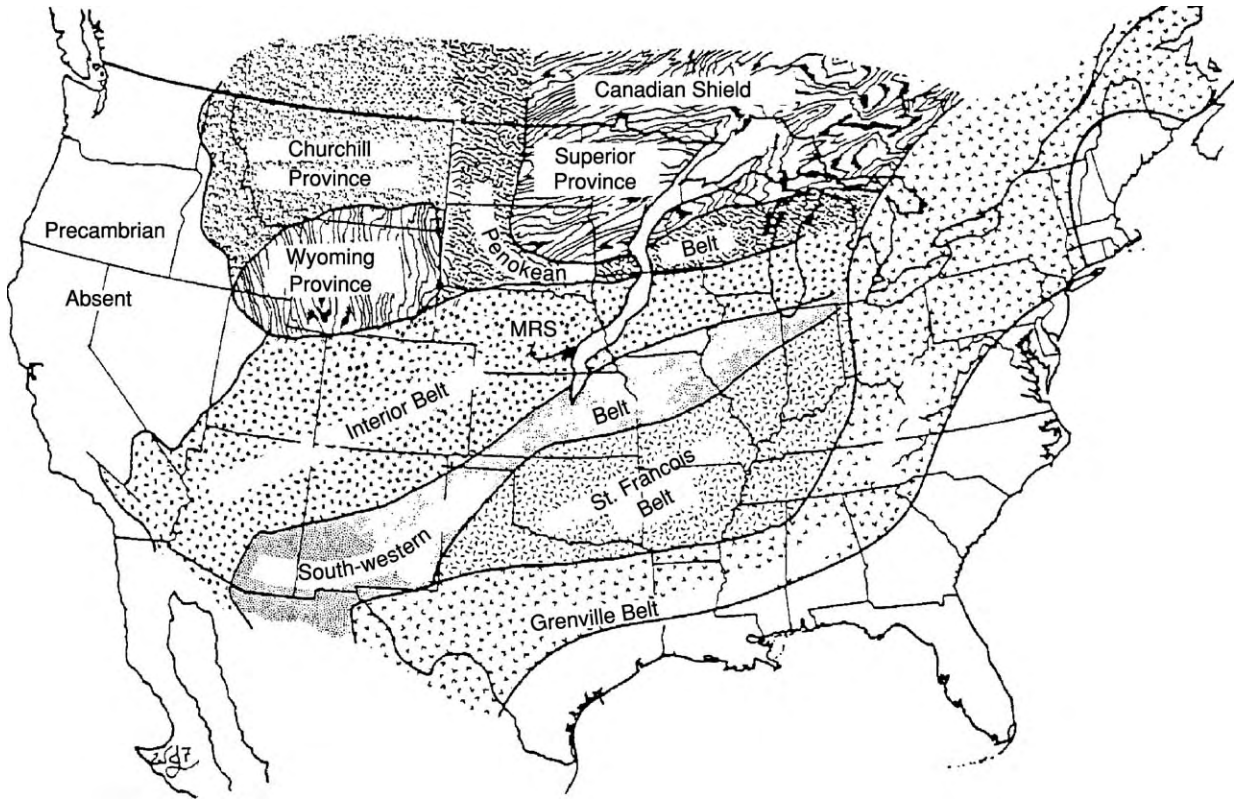

Figure 3 Proterozoic crustal provinces in North America. Archaean: Canadian Shield (>2500 Ma); Proterozoic: Penokean Belt (1900 1820 Ma), Interior Belt (1780 1690 Ma), South western Belt (1680 1610 Ma), St Francois Belt (1480 1380 Ma), Greenville Belt (1000 550 Ma). Midcontinent Rift System (MRS). (Compiled by Van Schmus and Bickford (eds.) (1993) GSA, The Geology of North America, v. C 2.)

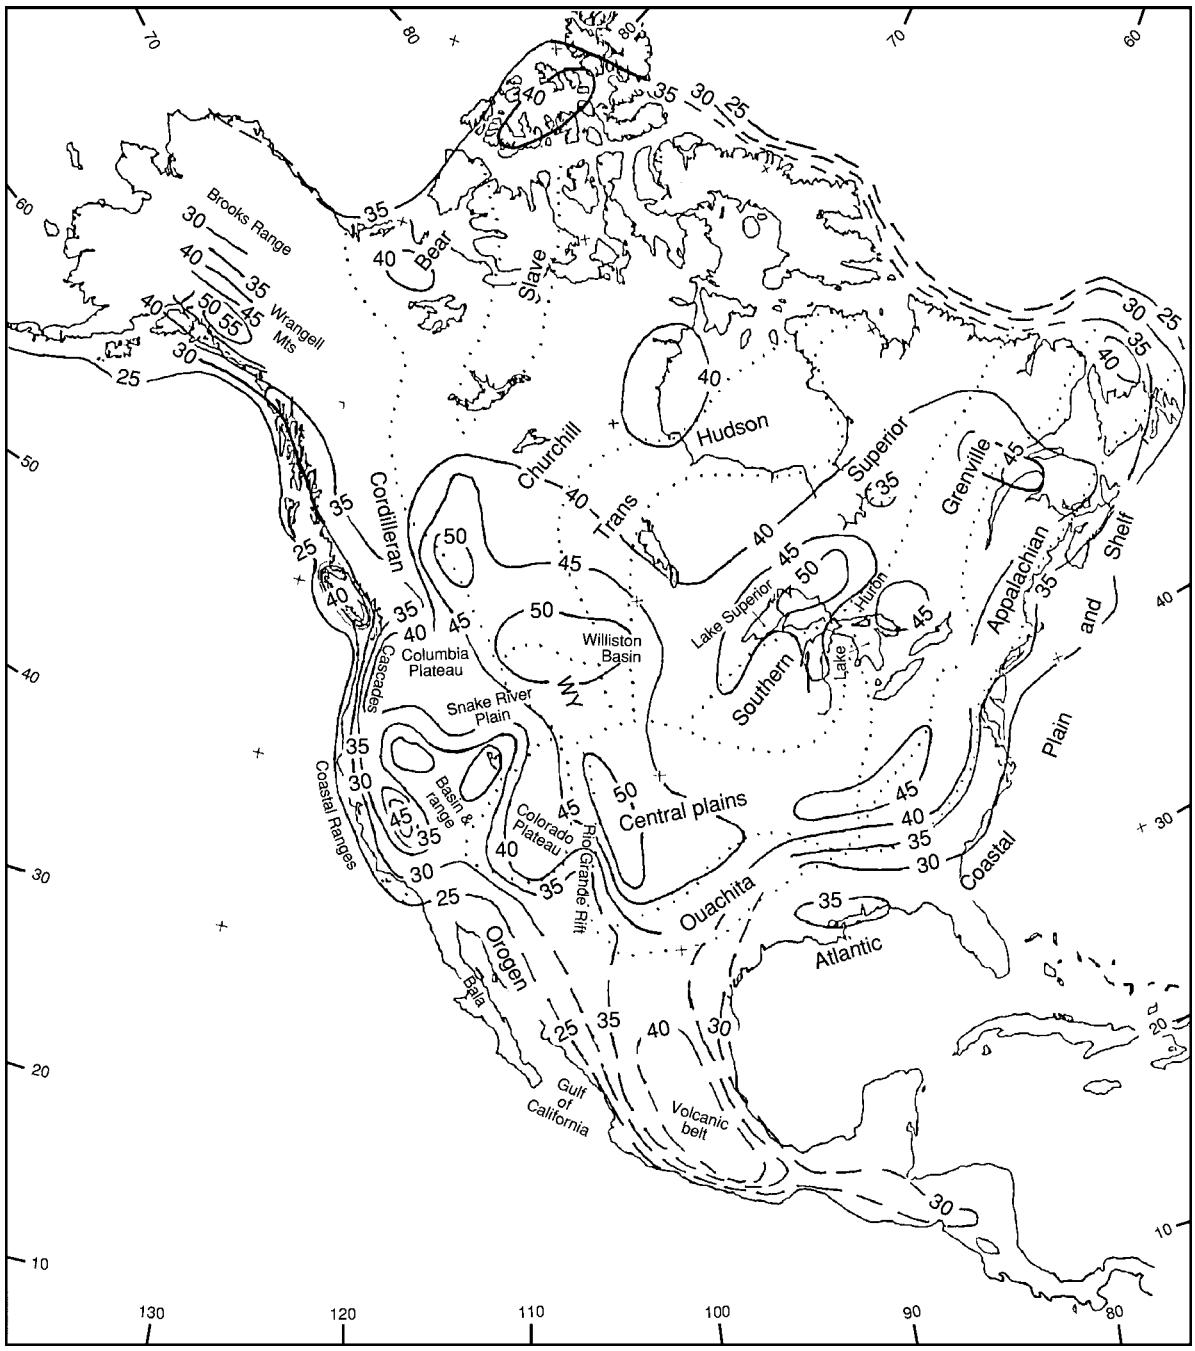

Figure 4 Crustal thickness of North America superposed on simplified geologic province map. Thickness in Continental Interior ranges from 40 to 50 km; Contour Interval = 5 km. (From Houston (1993) GSA, The Geology of North America, v. C 2.)

The original major geological time divisions of the rock sequence were established in Europe and equivalents correlated to North America in the nineteenth Century (Figure 5). It was soon learned, however, that the classic classification of rock units did not always coincide with the major divisions on the craton; these divisions, separated by major gaps in the record, became known as sequences. Sequences (*see* **Sequence Stratigraphy**) are major cycles in the Earth's history recording events on and adjacent to the craton. In a simplistic view, they are records of a significant advance and retreat of the sea lapping on the edge of the craton, ideally starting with a sequence of nonmarine clastics, followed by marine sediments,

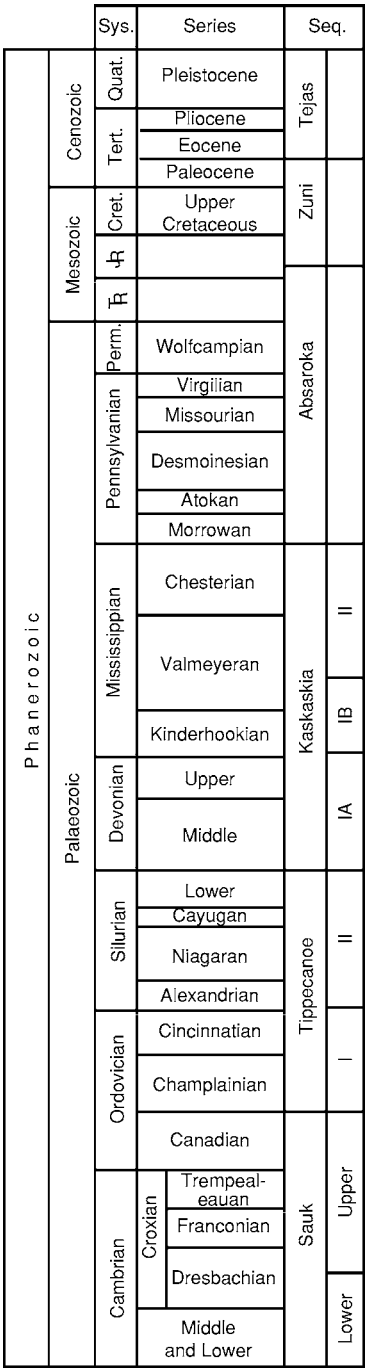

Figure 5 Correlation chart showing relation of sequences and subsequences to standard chronostratigraphic scheme for Phanerozoic. (From Sloss (1988) GSA, The Geology of North America, v. D 2.)

culminating with evaporites and clastics, and ending with a hiatus (gap), then followed by another cycle (Figure 6). All or parts of the sequence may or may not be present at any one location, depending on local conditions.

The craton was never very high above sea-level, a few tens or a couple of hundred metres at most, so that slight changes in sea-level brought inundations or withdrawals of the sea over wide expanses. The seas that spread over the craton, thus, were never very deep, and as the craton gradually foundered, the sediments accumulated. In concert with the rise and fall of sea-level, tectonic forces were busy forming and shaping mountain belts around the edges of the craton. On the craton, the tectonic forces were transmitted through the rigid basement rocks, causing a differential vertical movement of the fractured basement blocks as they readjusted to the stress. A series of uplifts and basins formed as a result of these structural movements and the sediments responded accordingly, filling in the low areas and either not being deposited on the high areas, or deposited and then stripped off. Most of the basins are shallow but some on the margins, such as the Anadarko Basin of Oklahoma and Denver Basin of Colorado, are deeper structural troughs with corresponding thicker sections of sedimentary rocks.

The Phanerozoic Geological Record

As the seas advanced over the low-lying craton, sediments accumulated and thus preserved a record of the history of that episode. The first Phanerozoic sediments on the craton were detrital material derived from erosion of the craton itself. In fact, the exposed part of the craton contributed clastics to the sequence during each episode. The Sauk sequence (latest Proterozoic to Early Ordovician) saw a major inundation as the seas advanced over the craton (Figure 7). The Tippecanoe sequence (Middle Ordovician to Early Devonian) was less widespread and confined mostly to the eastern part of the craton and distribution of the Kaskaskia sequence was similar. However, the early part of the Absaroka sequence (latest Mississippian to Early Permian) was more extensive, and represents a calumination of events, as all but the most northern part of the craton was affected.

Near the end of the Palaeozoic, major changes in the sedimentation and structural history (*see* **North America:** Southern Cordillera) of the central part of North America took place as the result of the Ancestral Rocky Mountain, Ouachita, and Alleghany/Appalachian orogenies (*see* **North America:** Southern and Central Appalachians). The next major inundation of the continent took place in the Zuni sequence, when Cretaceous seas covered much of the craton. Again, major changes in the structural history near the end of the Mesozoic, with the rise of the Rocky Mountains to the west, mark the end to

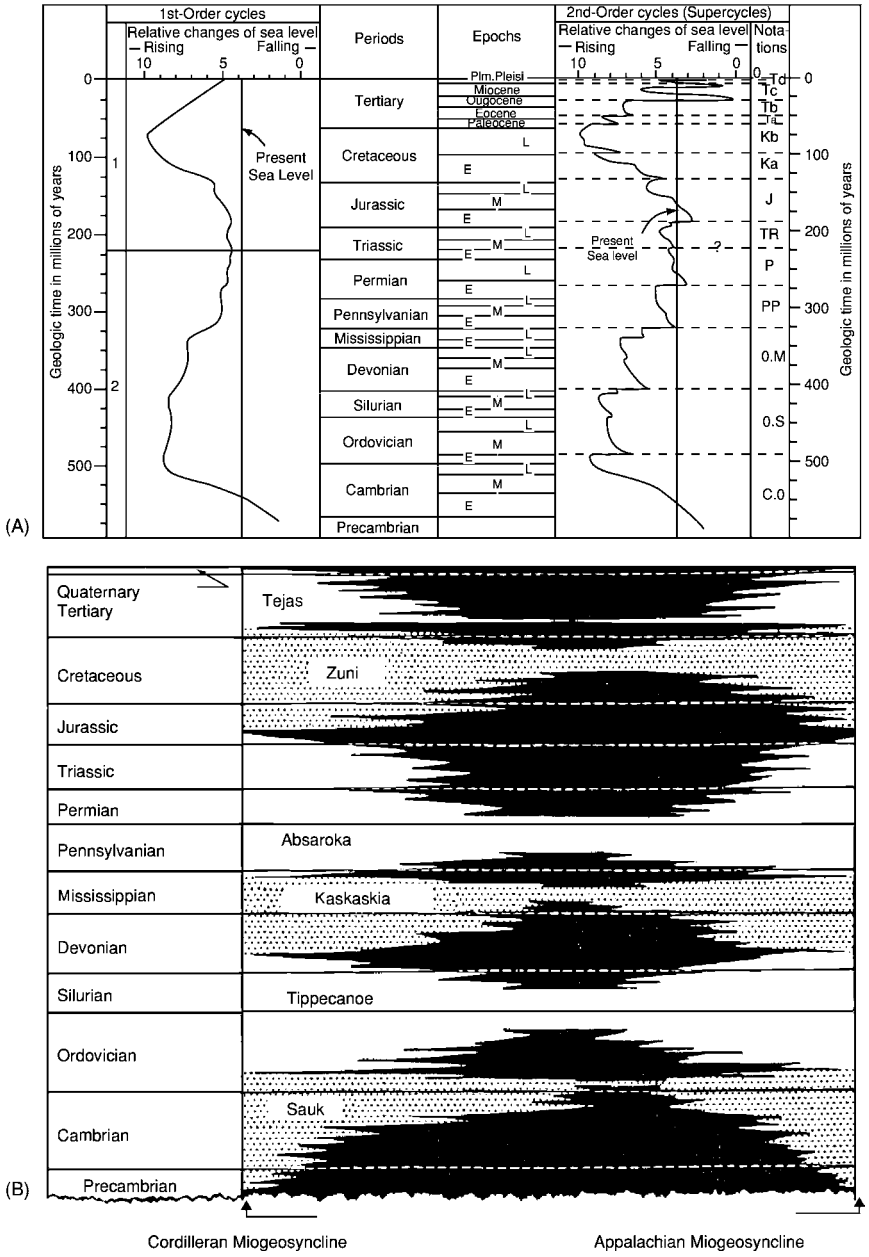

Figure 6 (A) First and second order global cycles of relative change of sea level during Phanerozoic time. (Adapted from (1989) GSA, The Geology of North America, v. A.) (B) Sloss' (1963) diagram of relation of sequences to craton. Black areas are gaps (hiatuses) and white and stippled areas represent deposition of sediments during successive depositional episodes. Note the stratigraphic section is more complete off the craton.

the sea incursions on the continent, so that the Tejas sequence is represented only by terrigenous sediments – material derived from the erosion of the newly-formed Rocky Mountains. This is now the situation remains today – the interior of the continent is high and dry. The end of each episode was marked by withdrawal of the seas and prolific erosion eradicating parts or all of the recorded history of the immediate and preceding chapters.

Several episodes of igneous intrusions into the sediments in the southern part of the Continental Interior took place during the later Cretaceous and Early Tertiary. These small igneous bodies were intruded from the mantle at great depths rapidly along zones of weakness in the continental crust into the sedimentary section. They are of interest, not only for their composition, time of emplacement, and implication for the tectonics, but because some of them, on

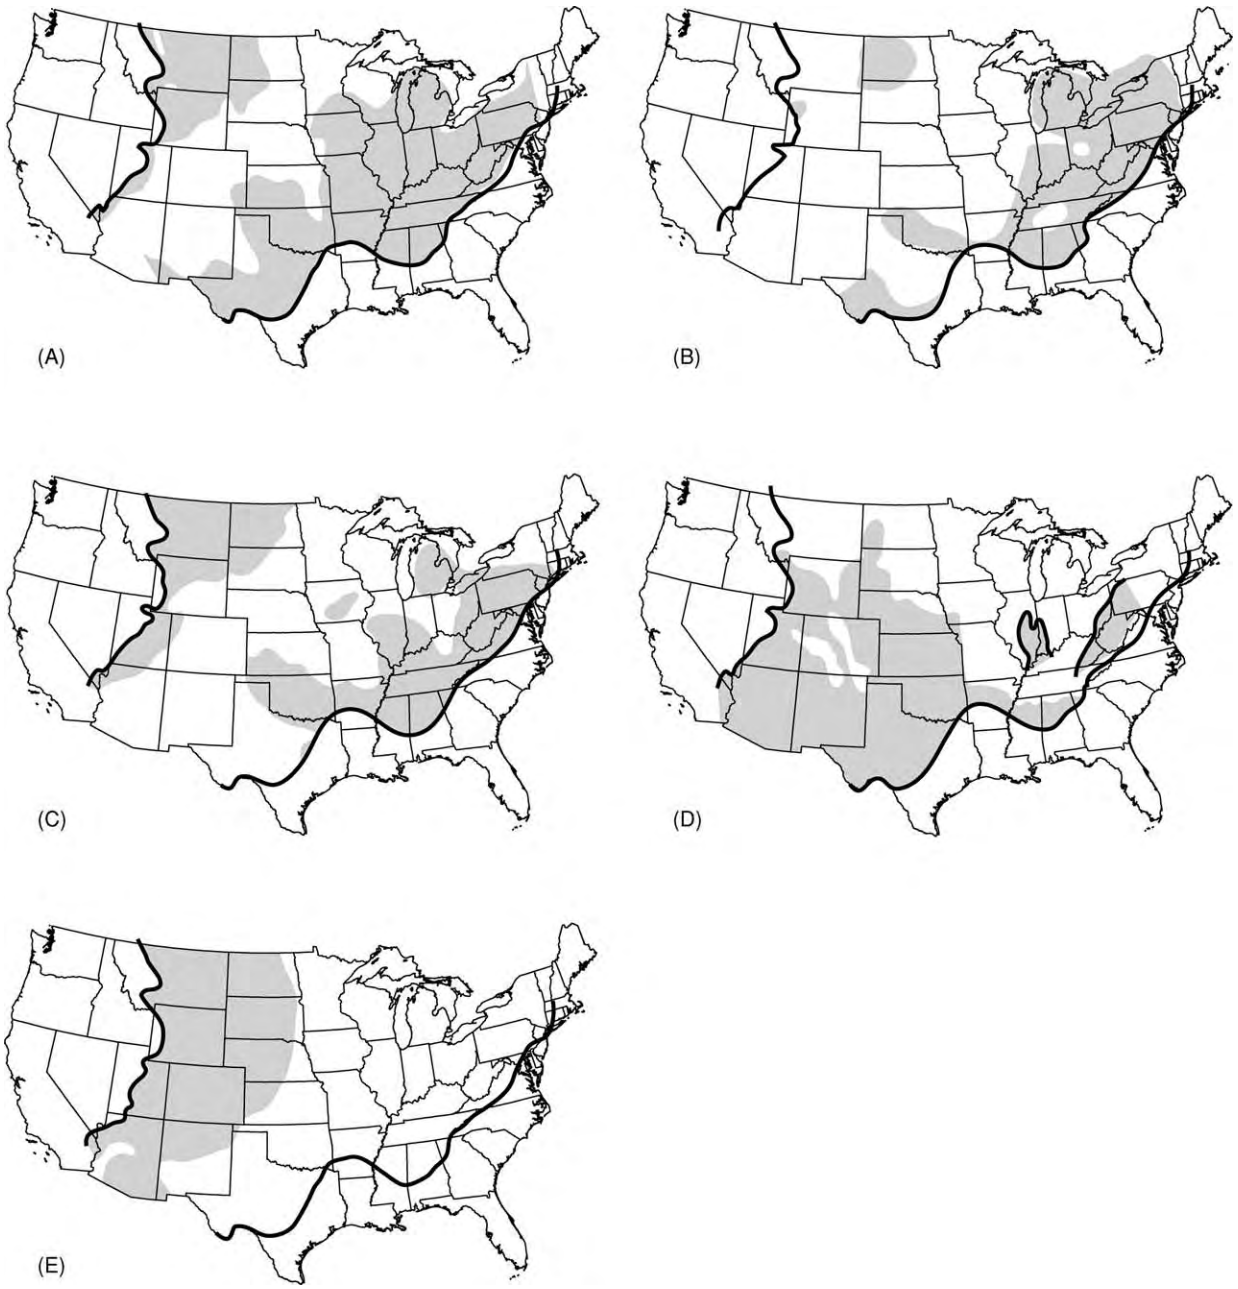

Figure 7 Location of sedimentary sequences preserved on North American craton by sequence. (Modified from Sloss (1988) GSA, The Geology of North America, v. D 2.) (A) Sauk sequence; (B) Tippecanoe sequence; (C) Kaskaskia sequence; (D) Absaroka sequence; and (E) Zuni sequence.

their way up from the depths, incorporated bits and pieces of mantle, continental crust, and Phanerozoic sediments.

The beginning of the last chapter of the story is concerned with the large continental glaciers that covered much of the north-eastern and east-central part of North America (*see* **Tertiary To Present:** Pleistocene and The Ice Age). Numerous advances and retreats of the glaciers are recorded in the remains they left behind – glacial debris (outwash and till; Figure 8A and B) and large erratics (out-of-place foreign boulders; Figure 8C) with thick deposits of loess (wind-blown glacial dust; Figure 8D). In places this forms a cloak over the area, the icing on the layer cake, so to speak.

The glaciers had disrupted the inplace drainage from the end of the Tertiary so that with their retreat, the drainage reoriented to its present

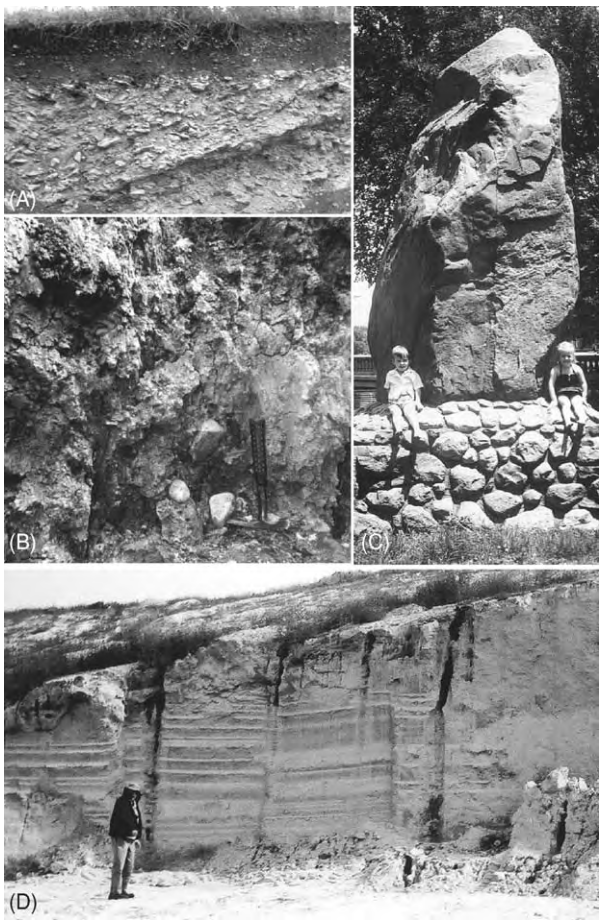

Figure 8 Glacial debris. (A) Glacial outwash deposit, which covers extensive areas of the Continental Interior; (B) glacial gumbo till deposited directly from the glacier; (C) large glacial erratic in Lawrence, Kansas; (D) thick loess deposit (glacial wind blown dust) in central Nebraska.

position. Drainage south of the southern extent of the glaciers was profoundly affected with overloads of water and material, and this latest episode of history is evidenced by the underfit streams, stream piracy, and extensive stream and river terrace development. The final adjustments are taking place today as the Continental Interior returns to 'normal'.

The Sediments

The succession of stratigraphic units on the craton could be and have been described as monotonous, but they are anything but boring. Special features of these unique sedimentary units are their; (i) lateral persistence; (ii) extreme thinness, the tremendous ratio of width to thickness; (iii) sharpness of boundaries; and (iv) cyclic nature.

The contained micro- and macro-fauna and flora (or lack thereof) in these sediments not only gives information on conditions under which the sediments formed, but provides information on relative age for correlation from one area to another, where the sediments are not continuous. Understanding life as it occurred in ancient times is based mainly on understanding the occurrence and distribution of similar forms today.

In addition to the usual sedimentary types, such as sandstone, siltstone, shale, limestone, dolomite, anhydrite, and gypsum, that occur in the Phanerozic sequence, there are four rock types that are formed under special circumstances: chalk, salt, black shale, and coal. Chalk is made up of tiny micro-organisms that accumulated in the open sea in warm water (**Figure 9A and B**). Major chalk deposits throughout the Earth are prominent in the Cretaceous (Zuni) and the Kansas chalk is famous for its marine vertebrate fauna. Salt is formed when and where marine waters are restricted and evaporate (**Figure 9C**). Salt is used here as an all-inclusive term for minerals precipated from the evaporation of sea-water. The Silurian (Tippecanoe) and Permian (Absaroka) are two of those times in Earth history when vast areas of salt were formed on the craton under these conditions.

The black shale accumulates under confined conditions at the bottom of the sea, where because of lack of water circulation and reducing conditions, all forms of carbonate and other soluble material are dissolved (**Figure 9D**). Radioactive material is concentrated in the black shales, making them distinctive subsurface marker beds on gamma-ray wireline logs and easy to correlate. On the North American craton, black shales are prevalent in the Late Devonian to Early Mississippian (Kaskaskia) and numerous thin but persistent ones in the Middle and Upper Pennsylvanian and Lower Permian (Absaroka). Lignite and coal form near sea-level and are thus a good palaeoenvironment indicator (**Figure 10A and B**). In the Interior Province, several basins contain bituminous coal, mostly Pennsylvanian in age, whereas in the Northern Great Plains it is mostly sub-bituminous coal or lignite, and Cretaceous or Tertiary in age. The plant material grew in the shallow water along the shore, dying in place, accumulated, and was buried, eventially forming peat. As the peat was buried, the material compacted to coal and in doing so created a handy indicator to determine the depth of burial. However, it never has been buried deep enough in the Continental Interior, or subjected to tectonic forces, to create the highest grade of coal, anthracite.

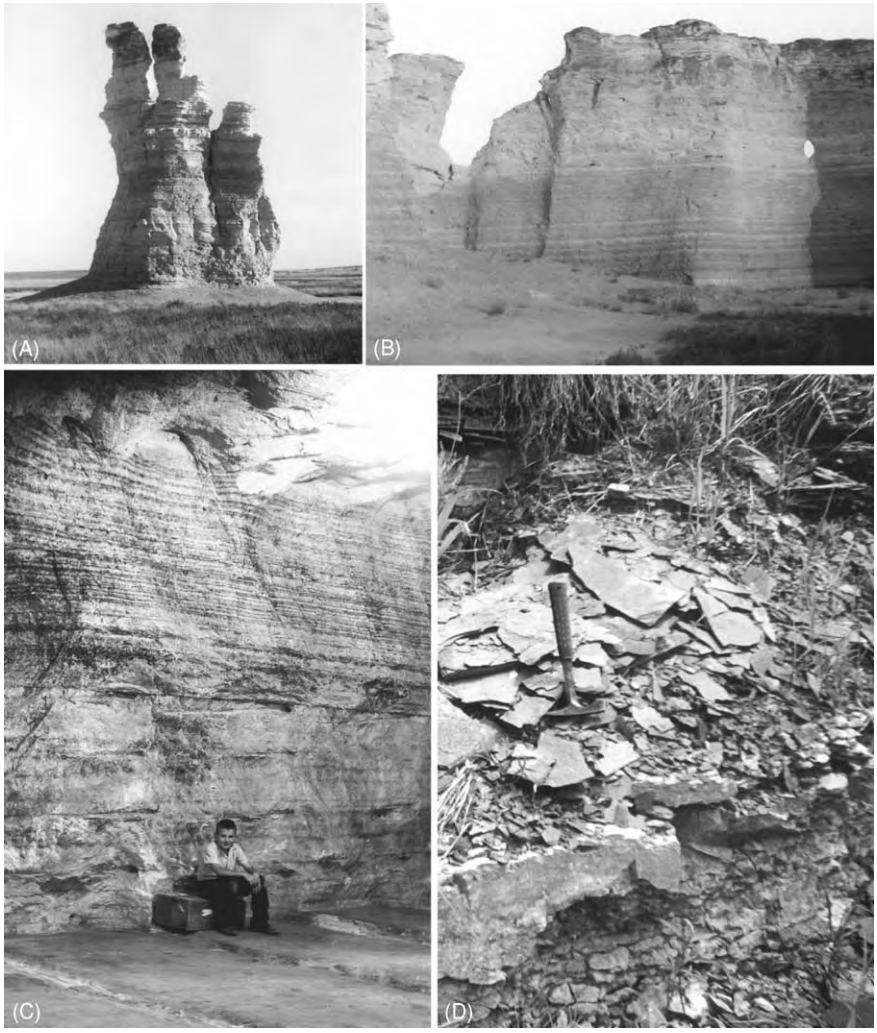

Figure 9 Examples of special rock types in the Continental Interior. (A) Cretaceous chalk in western Kansas; (B same exhibiting rhythmic layering of chalk and bentonite; (C) Permian salt in mine in central Kansas (note: rhythmic layering); and (D) Pennsylvanian thin bedded, fissile black shale.

Several other less widely distributed rock types are distinctive and informative: volcanic ash (Figure 10C) and its altered form bentonite, fossil soils (palaeosols), and extensive thin-layered chert beds (Figure 10D). Volcanic ash is recognised easily in the Tertiary and its altered form of bentonite in the Cretaceous.

The bentonites occur in distinctive thin bands over large areas and form instant time-lines. Multiple fossil soils are widespread in the Upper Permian and indicators of subareal exposure and climatic conditions at the time. In the Lower Permian, thin but persistent nodular chert beds occur and individual beds can be traced for many miles, indicating uniform conditions in the sea over a wide area. And lastly, the mantle of Pleistocene glacial material (either deposited from the glaciers or derived from their action) is an indicator of climatic conditions. These masses of thick, heavy ice deformed the crust and modified the landscape extensively.

Accumulation time of sediments can be estimated by applying known sediment accumulation rates of today to their thickness or using the relation of total sediment thickness to the known time period. Because of the limiting factors in both methods, the results are only an indication.

Erosion, usually by water and wind, and the rates at which it takes place, is of interest; generally the rates are higher in young terrains and less in the older ones, such as the Continental Interior. The obvious exception to the erosion rate, of course, is in those areas that are farmed and thus subject to the plough and other forms of tillage that break the surface and hasten the destruction of the land. Erosion rates generally are steady, but accelerated in times of crisis such

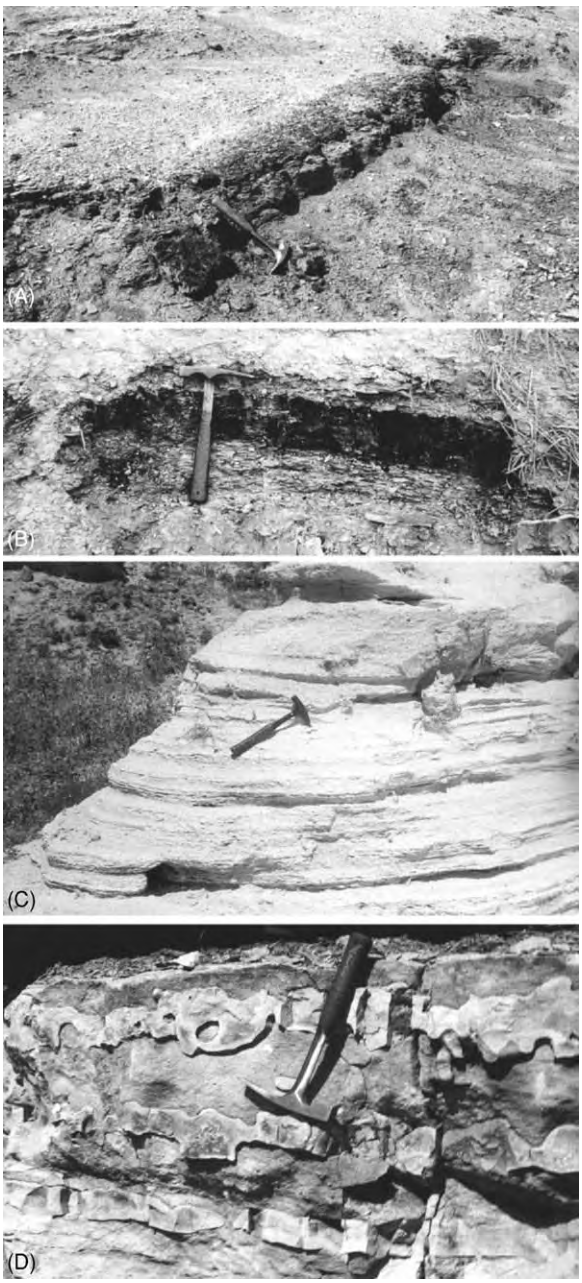

Figure 10 Other distinctive rock types that occur in the Continental Interior. (A) Lignite from Cretaceous of central Kansas; (B) thin bituminous coal (Upper Pennsylvanian); (C) Pliocene volcanic ash, a distinctive geochemical signature makes it an excellent marker bed for correlation; (D) layered chert in limestone in the Flint Hills of central Kansas.

as floods or devastating wind storms. More 'normal' rates generally prevail in between catastrophic events.

Rates of denudation can be determined by measuring the amount of material carried by streams and rivers in a unit of time. This usually is reported as so many centimetres reduction in the land surface per millennium. Because of the relatively high elevation of the North American Continent today, these rates are high and probably are not representative of the past. Another approach to denudation rates is to determine how much material was present and now evoded away and to divide that amount by the time interval. Neither approach is totally satisfactory, but both give a fair estimate.

The Sedimentary Sequence

With special conditions, unique rock sequences occur. The North American Craton is one place where these special sequences – rhythmites and cyclothems – are preserved. Rhythmites are alternations of two sediment types, such as the chalk and bentonite that developed in the Cretaceous (Zuni), or siltstone and the shales that are present in the Pennsylvanian (Absaroka). Cyclothems are repetitious sequences that occur repeatedly in the Permo-Pennsylvanian (Absaroka). The classic cyclothem records a single advance and retreat of the sea in an area, giving rise to a symmetrical rock cycle of non-marine to marine to non-marine sediments; however, the ideal seldom occurs. Because the transgressive part of the cycle usually is better represented (or better preserved) than the regressive part, most cycles are asymmetrical and many are incomplete or have components repeated.

Bundles of cyclothems have been termed megacyclothems and an example is given in Figure 11. Origin of cyclothems has been proposed as being the result of: (i) change of sea-level; (ii) tectonic movements; or (iii) climatic factors; the truth is that all three are probably responsible to some degree. In Kansas alone, in just the Middle and Upper Pennsylvanian (Absaroka) section, there are parts or all of about 40 cyclothems. Their formation probably was the result of changes in sea-level as a result of the waxing and waning of southern-hemisphere glaciers. Sediments were accommodated spatially by the craton gradually sinking in relation to sea-level, perhaps partially as a result of the weight of the added sediments and the glaciation was caused by changes in the climate.

Structural Development

The development of the structural elements on the craton to their present disposition has not been spectacular, but has been incremental and persistent. The movement is recorded, not only by the sediments, but by the gaps in the record – the unconformities. Much of the regional structural development on the craton has been by epeirogenesis; that is, up-and-down movement and tilting of the area in response to orogenic (tectonic) activity elsewhere. Four major unconformities indicate four major changes in the structural regimen – the end

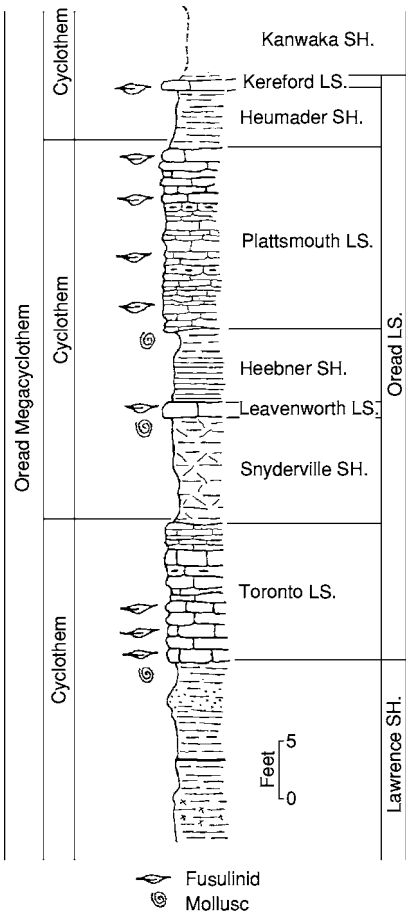

Figure 11 Example of Pennsylvanian megacyclothem from Kansas, showing individual cyclothems in the Oread Limestone Formation (Virgilian, Pennsylvanian). (Adapted from Merriam (1963) Kansas Geological Survey Bulletin 162.)

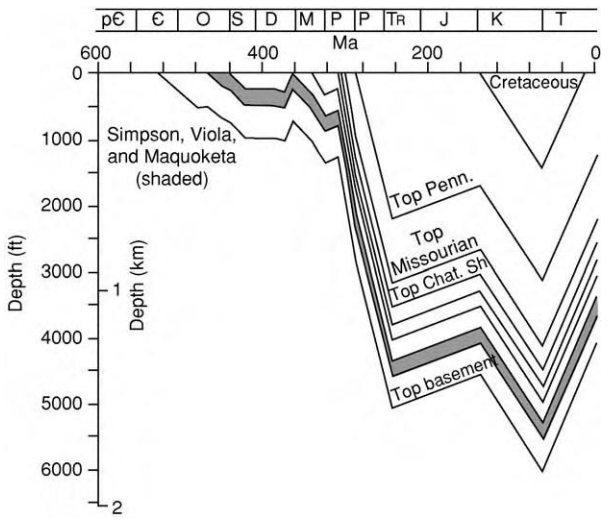

Figure 12 Burial history diagram of the Salina Basin (central Kansas; for location see Figure 13. Diagram shows amount of sediment deposited and amount removed giving depth of burial of sediments. (From Newell and Hatch (1997) Kansas Geological Survey Bulletin 240.) The diagram illustrates that the basin sub sided and received sediments from Late Cambrian to end of the Devonian when it was uplifted. Major subsidence commenced in the Mississippian, with minor uplift near end of the Mississippian and continued from then, with minor ups and downs until the present.

of the Precambrian, the Ouachita Orogeny (Mississippian), the Allegheny or Appalachian Orogeny (Late Palaeozoic), and the Laramide Orogeny (Cretaceous).

An important part of the story on the structural development of the Continental Interior is knowing how deep and when the sediments were buried. The ups and downs of the craton at any location is profiled by constructing a two-dimensional burial-history diagram (Figure 12). Another question is how much material was removed at an unconformity. There are numerous ways in which this can be done, but a combination of several approaches for any area is the most satisfactory (Table 1). This information then can be used together with the sediment distribution to understand the history.

Cratonic Structures

The sediments are preserved more completely in the basins than on the adjoining uplifts, as would be expected. The major basins, uplifts, and structural discontinuities in the Continental Interior are shown in Figure 13. A series of cross-sections of the Continental Interior are shown in Figure 14. These cross-sections give the best impression of the subsurface layer-cake nature and the relation of stratigraphic units to one another. Most impressive is the thinness of the sedimentary cover (when viewed in perspective (Figure 15); indeed, the sediments are but a facade over the Precambrian foundation. The structures shown in Figure 13 are those that formed near the end of the Mississippian and in the Early Pennsylvanian during the Alleghany/Appalachian orogenies and since have been slightly modified.

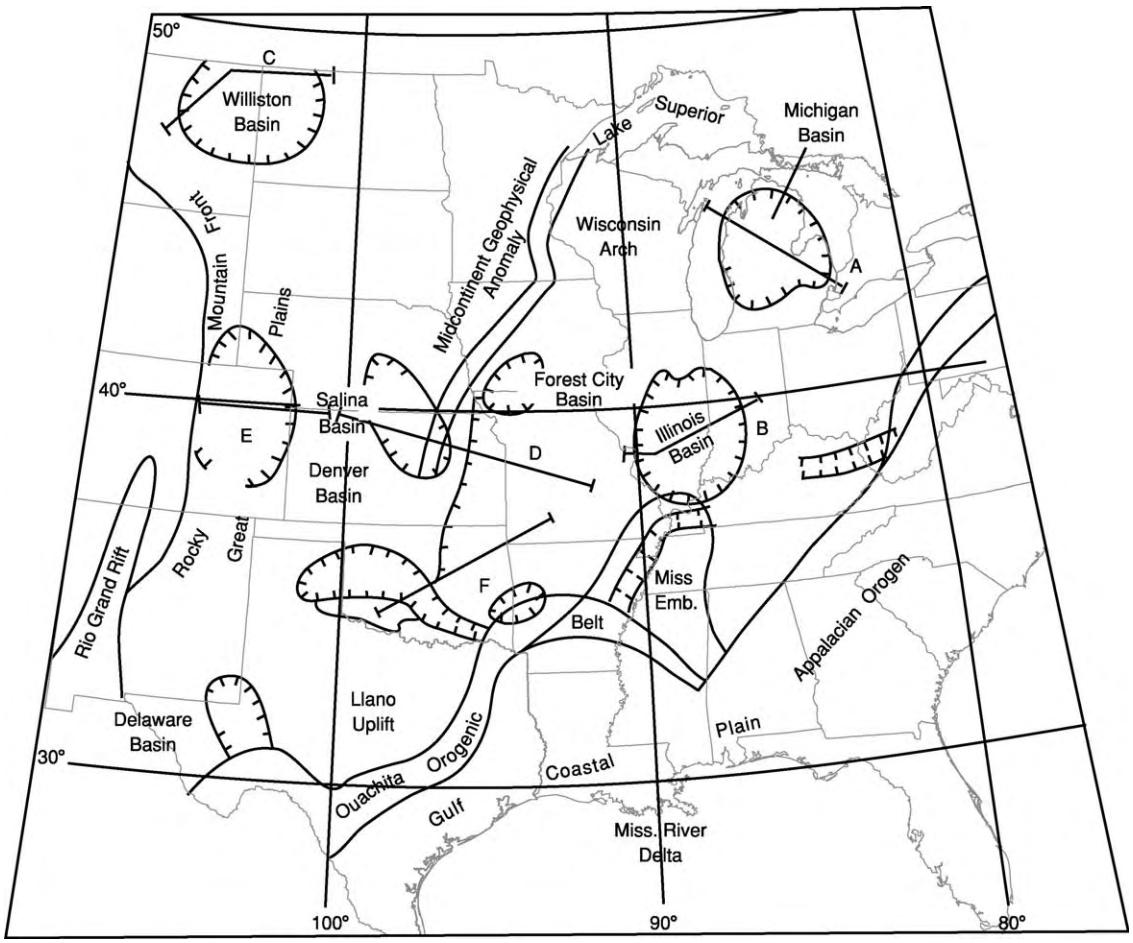

Figure 13 Location of major structural features in the Continental Interior. A, New York Alabama Lineament; B, Ouachita Foldbelt; C, Wichita Uplift; D, Anadarko Basin; E, Ardmore Basin; F, Aricoma Basin; G, Nemaha Uplift. (From Hinze and Braile (1988).)

There is no apparent spatial pattern of the basins; they seemingly formed wherever there was a weakness in the foundation. Through time, several of these regional structures were inverted, (that is, basins were uplifted to become positive areas, or vice versa), and some positive features foundered to form depressions.

The Precambrian basement also is the key to the location of the minor structures of the region. These secondary features show a preferential orientation: one set north-east–south-west and the other north-west–south-east, with a ancillary set north–south and east–west. These structures were formed by the vertical displacement of basement fault blocks in response to outside tectonic forces in which the overlying sediments were draped over the offset blocks by differential compaction of the unconsolidated, soft sediments. These anticlines (plains-type folds) are present in the sedimentary cover on cratons worldwide (Table 2; Figure 16). After initial formation of the structural regimen in Late Mississippian to Early Pennsylvanian time (Absaroka), continued movement of the basement blocks accentuated the folds. This incremental movement has continued from the Late Palaeozoic until today.

The incremental movement of the fault blocks is recorded in the Permo-Pennsylvanian (Absaroka) sedimentary section by thinning of beds over the structure and by convolute features known as seismites (Figure 17). The seismites, formed by dewatering of soft sediments, were triggered by palaeoearthquakes. By noting the geographic and stratigraphic occurrence of the seismites, it is possible to determine the relative intensity and size of the area affected by the palaeoquake. Earthquakes are the result of the adjustment of the basement to stress and are recorded on the craton today. In historic times, several large earthquakes occurred – the New Madrid quake (1811–1812) in Missouri and Manhattan quake (1867) in Kansas are two examples; fortunately there was little to damage at those early dates.

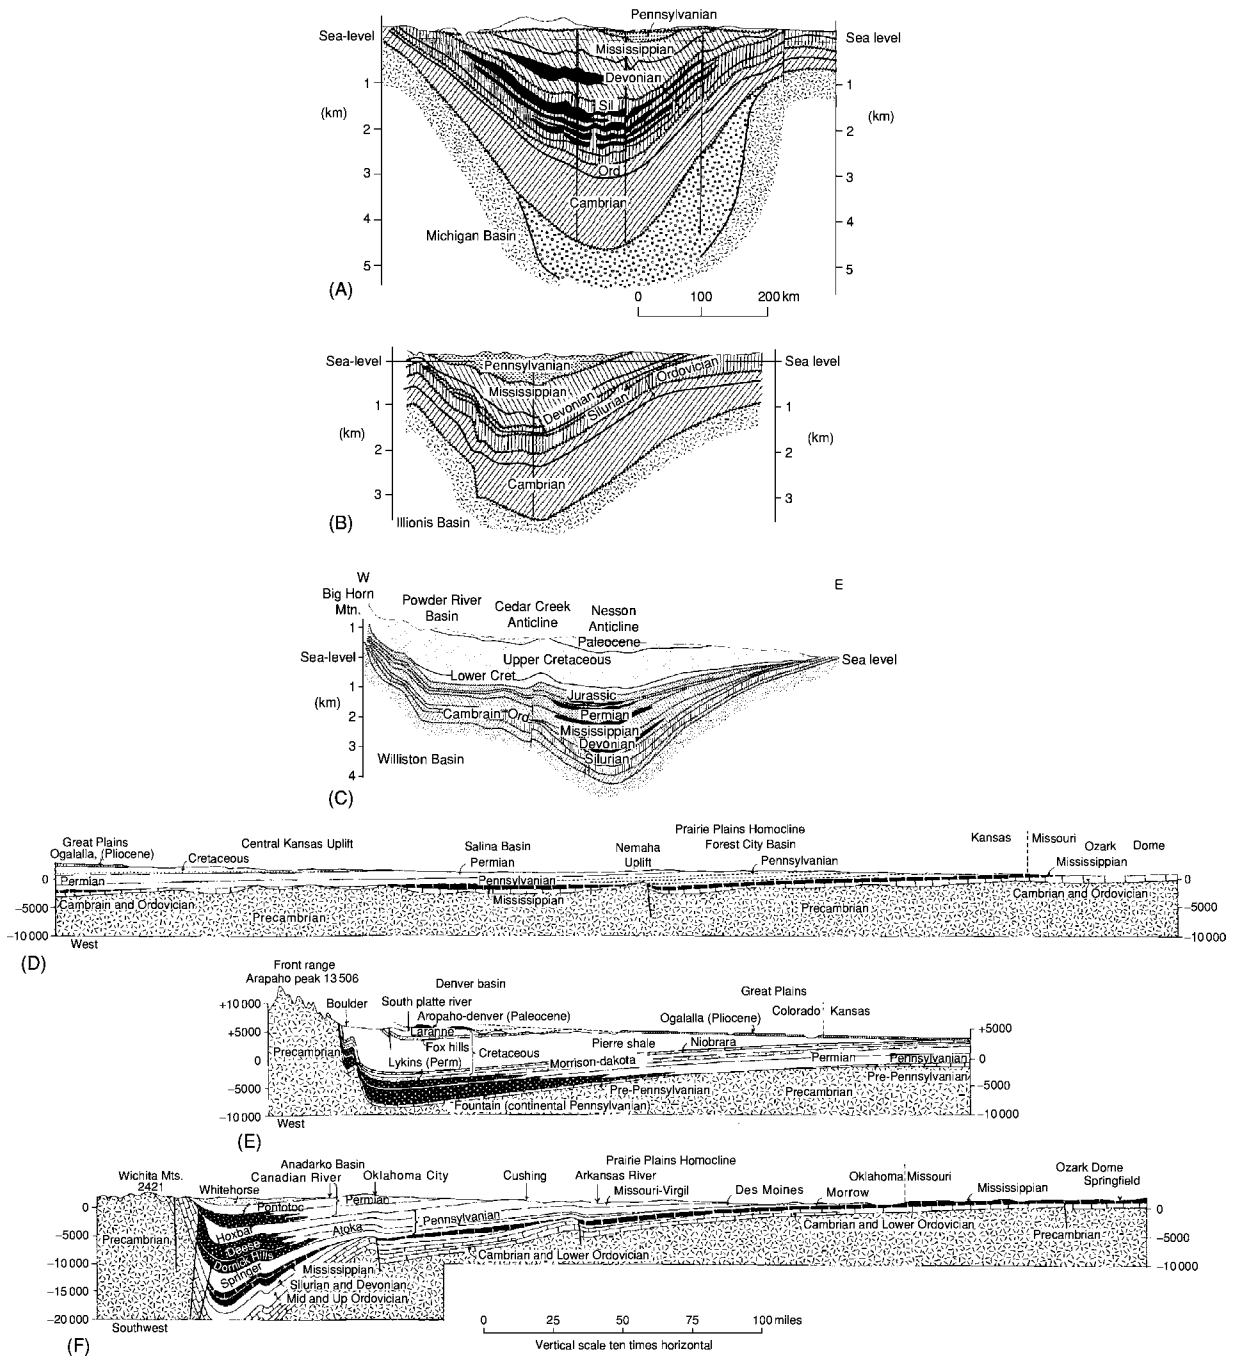

Figure 14 Cross sections of selected areas in the Continental Interior. A Michigan Basin; B Illinois Basin; C Williston Basin; D Ozark Dome west to Great Plains; E Great Plains through Denver Basin to Rocky Mountains; F Ozark Dome south west through the Anadarko Basin to Wichita Mountains. Denver and Anadarko basins are two of the deepest troughs in the Continental Interior. (A, B, and C from Bally (1989) Phanerozoic basins of North America, *in* The Geology of North America, v. A; E, F, and G from King (1951) The tectonics of middle North America: Princeton University Press.)

Mineral Resources

The Continental Interior has long been known as a rich source of metallic minerals, mostly produced from Precambrian rocks. Gold has been produced from the Precambrian at Lead, South Dakota and the Porcupine and Kirkland Lake districts in Ontario, Canada. The extensive Lake Superior (Michigan) copper deposits occur in Precambrian rocks and have been known for

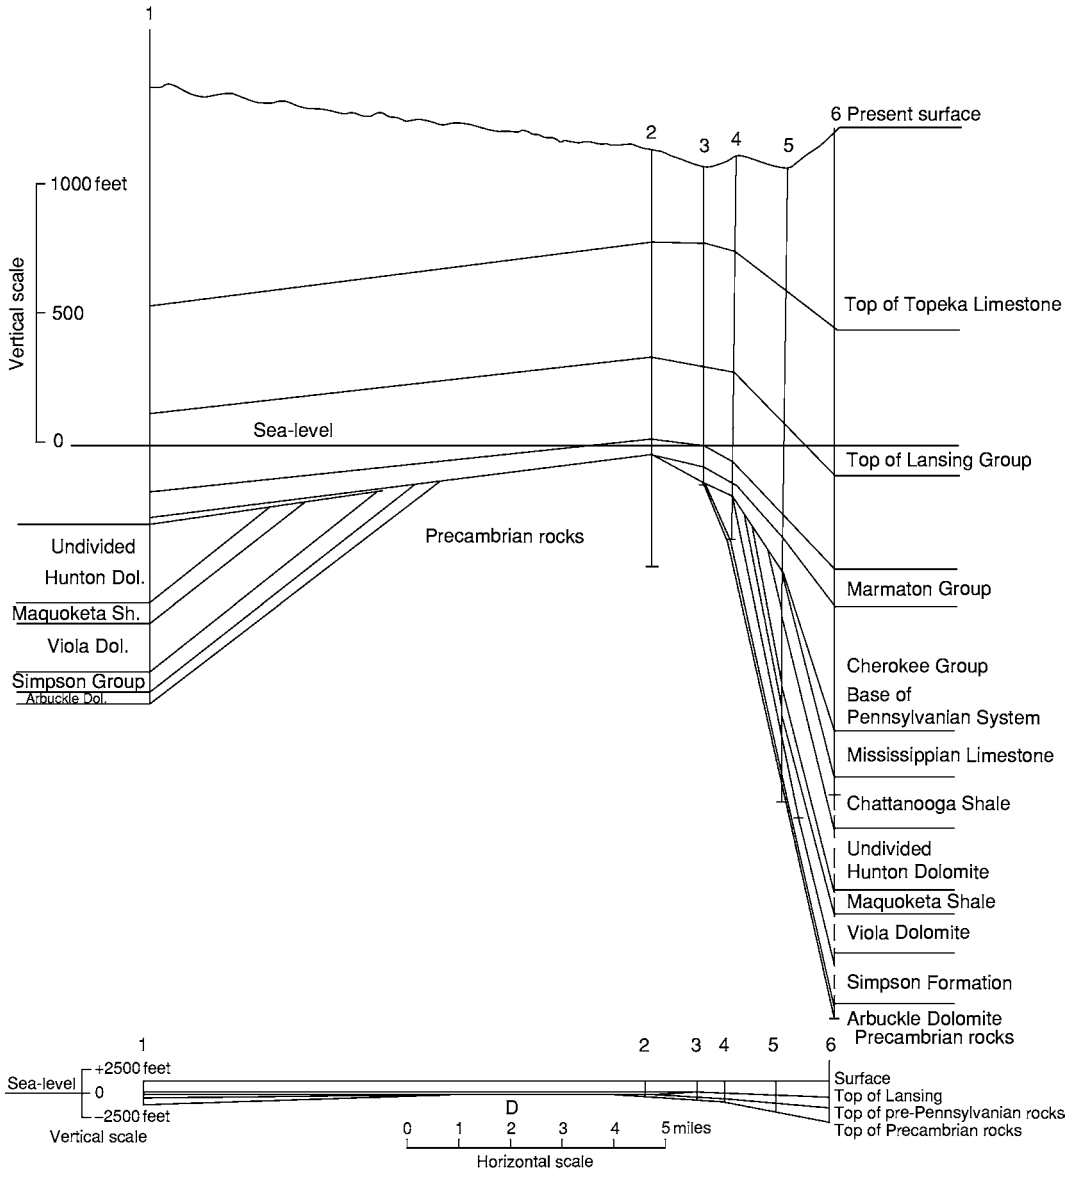

Figure 15 Cross section of the Nemaha Anticline, a major structural feature showing the result of exaggeration (upper) to at scale (lower). Exaggeration is used by geologists to show relationships better in flat lying stratigraphic units (from Lee, 1956, Kansas Geological Survey Bulletin 121).

Table 2 Feature of plains type folds. (Modified from Powers (1925) Geological Society of America Bulletin, v. 36.)

- Structural noses are dominant structure at shallow depth (ie in surface units)
- Most folds are small in areal extent and amount of structural closure
- Closure increases downward and structure becomes sharply defined
- Amount of closure is proportional to size in many structures

centuries and were utilized by the Indians. Copper was also produced at Ducktown, Tennessee from Cambrian metamophosed sediments. The occurrences of lead and zinc deposits in south-eastern Missouri were known from the eighteenth century. The Tri-State District centred on Joplin, Missouri, described as the greatest zinc district on Earth, occurs in Mississippian carbonates. The rich Precambrian iron-ore deposits of the Mesabi Range in Minnesota and in the adjacent states of Wisconsin, and Michigan have been utilised for a century. Sudbury, Ontario, Canada is a major world source of nickel that occurs in a Precambrian complex.

Extensive sub-bituminous and bituminous coal deposits occur in the Midcontinent area and is mined both underground and in strip pits where shallow. Petroleum seeps in Miami County, Kansas were used by the Indians for medicinal purposes, and pioneers

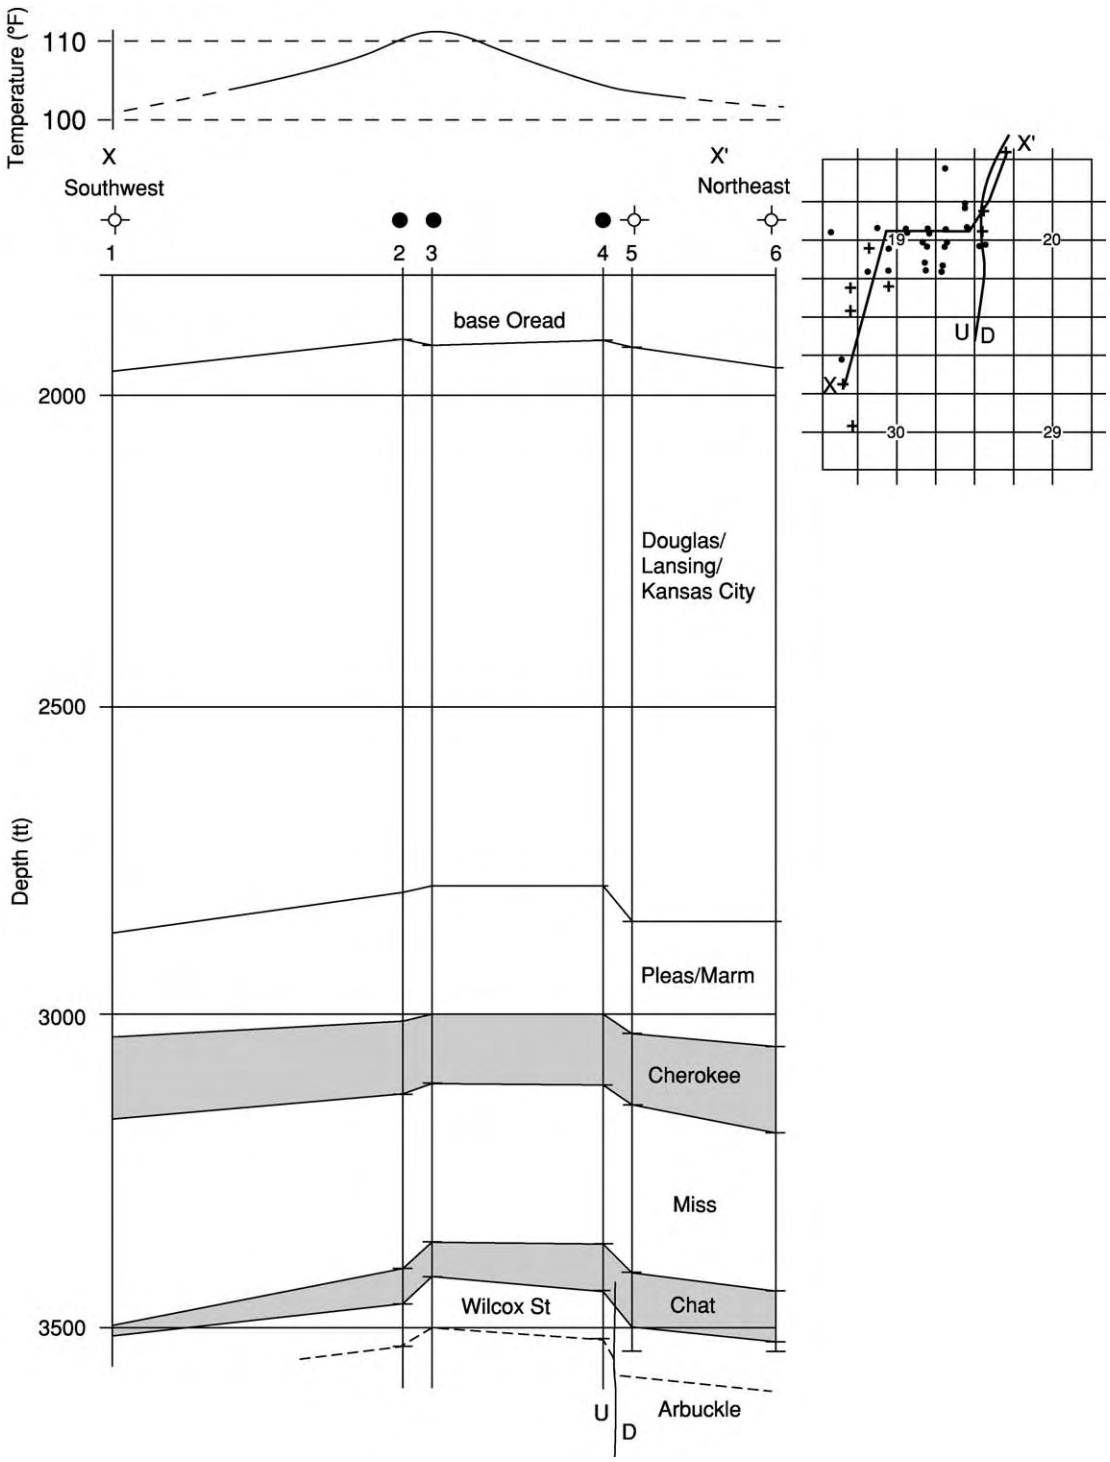

Figure 16 Cross section of typical 'plains type fold' (Slick Carson oil field, T32S, R3E, Cowley County, Kansas). Note the anticline closure increases with depth, faulted on east flank, and temperature high over crest of anticline; all characteristics of oil producing plains type folds.

on the Santa Fe and Oregon trails on their way west used it for lubricating their wagon wheels. Petroleum was discovered in a well drilled in 1860 near Paola, Kansas, opening the large Midcontinent Oil and Gas Province shortly after the Drake well was drilled in 1859 in Pennsylvania. Natural gas was exploited for town lighting, starting in about 1870.

Gold discoveries in the Black Hills of South Dakota and in the Rocky Mountains in Colorado spurred the gold rushes, with thousands of get-rich

gold seekers making their way across the plains to the 'promised land'. As the area was populated, building material and water were needed and many other resources besides metals were exploited, including gypsum, salt, fluorite, clay, lime, glass sand, sand and gravel, building and crushed stone, and fertilizer minerals.

Northern Cordillera

J W H Monger, Geological Survey of Canada, Vancouver, BC, Canada and Simon Fraser University Burnaby, BC, Canada

W J Nokleberg, United States Geological Survey, Menlo Park, CA, USA

Introduction

The northern Cordillera extends some 3500 km north-westward from latitudes 47–48° N in Washington–Montana, USA, through Canada, and westwards across Alaska to terminate physiographically, but not geologically, at the Bering and Chukchi Seas between Alaska and the Russian Far East. Its southern boundary is delineated by the southern limits of the Olympic Mountains and North Cascade Ranges in north-western Washington, the northern Columbia Plateau in central Washington, and a system of west–north-west-trending faults in northern Idaho and western Montana called the 'Lewis and Clark line'.

The northern Cordillera follows an ocean–continent boundary created by about 540 Ma, emerged as a mountain belt between 185 and 60 Ma, and is still growing. A noteworthy feature is that about three-quarters of its surface, and all of Alaska, is underlain

by an orogenic collage composed of allochthonous rocks accreted to the ancient continental margin of western North America.

Physiography

The northern Cordillera contains three major physiographical divisions, the Rocky Mountains System, the Intermontane Plateau System, and the Pacific Mountains System, each comprising subsidiary ranges or other physiographical features (Figure 1; Appendix A). It is flanked on the east by the Interior Plains System, and on the north by a continental shelf and slope less than 200 km wide that terminates in water depths of about 2000 m in the Arctic Ocean. The Rocky Mountains System contains many summits that exceed 2000 m in elevation, with Mount Robson near latitude 53° N the highest peak at 3955 m. Between latitudes 48° and 60° N, the great valley called the Rocky Mountains Trench divides the system longitudinally, but its continuation north of this, called the Tintina Trench, extends into the Intermontane Plateau System in east-central Alaska. The Intermontane Plateau System has lower relief than flanking systems, and is mostly between 1000 and 2000 m in height, but in Alaska includes extensive lowlands under 300 m. Summit elevations in the Pacific Mountains System are mostly between 2000 and 3000 m, except for the Alaska Range in southern Alaska and Saint Elias Mountains in south-western Yukon where, respectively, Mount McKinley (or Denali) at 6193 m and Mount Logan

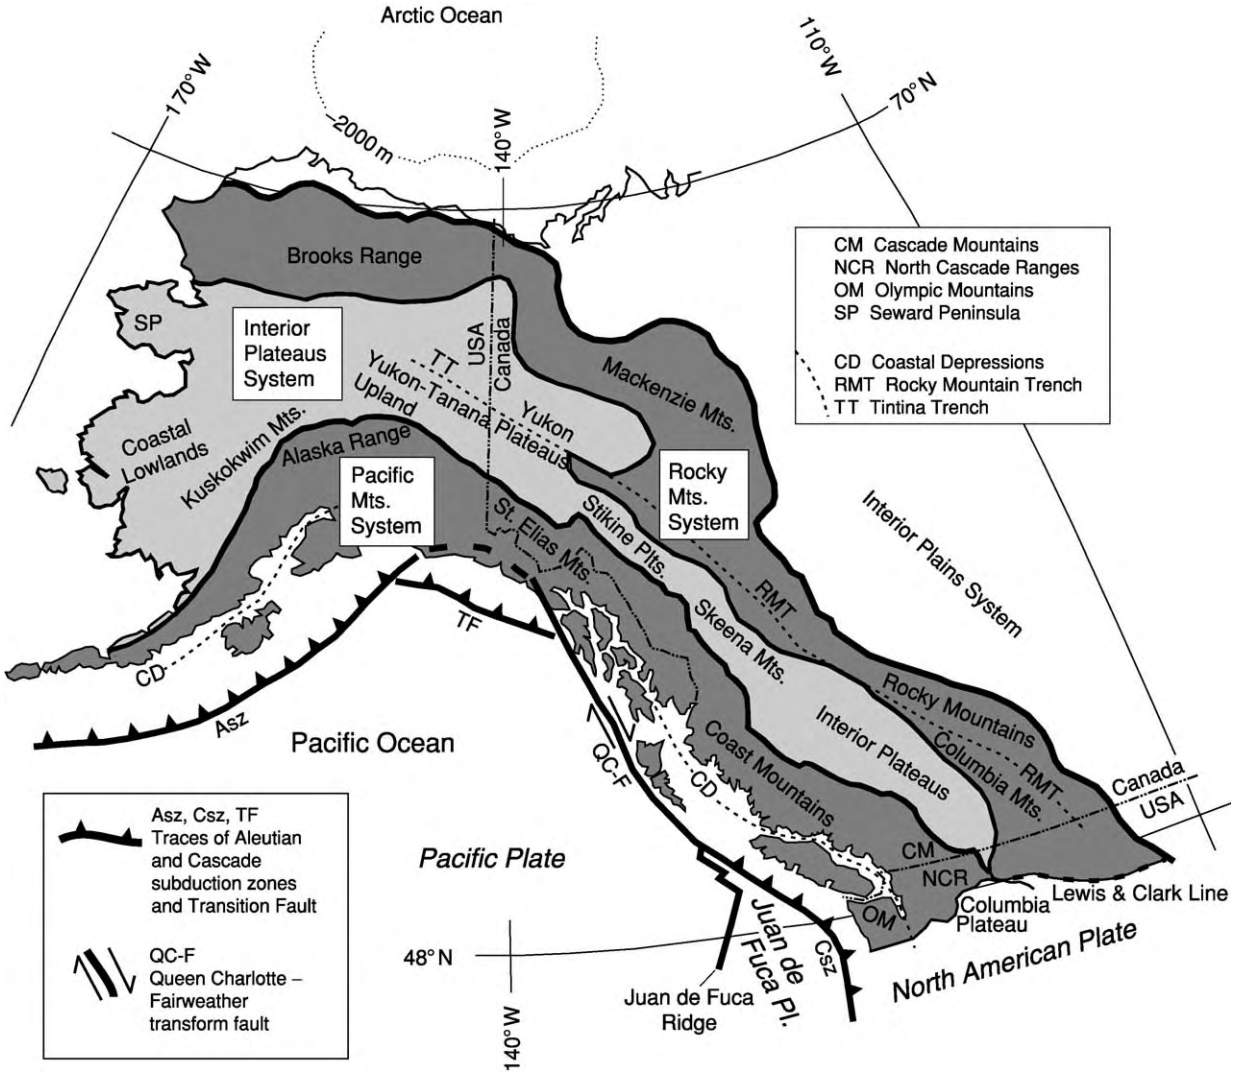

Figure 1 Major physiographical systems of the northern Cordillera, some subsidiary physiographical features, and plate boundaries.

at 6050 m are the highest peaks on the continent. The Pacific Mountains System contains a longitudinal but discontinuous coastal depression, oceanward of which are many islands and the Olympic Mountains in the south and Saint Elias Mountains in the north. The continental shelf and slope along the Pacific Ocean are about 200 km wide; the base of the continental slope is about 2000 m deep south of latitude 60° N, but westwards across the northern Gulf of Alaska its depth increases to 7000 m in the Aleutian Trench off the western Aleutian Islands. The Bering and Chukchi Seas are mostly less than 200 m deep, except for a 3000 m deep basin north of the western Aleutians.

The Cordilleran ice-sheet covered most of the region several times between 2 Ma and 12 Ka, was up to 2.5 km thick in places, and shaped local landforms. Parts of central Alaska, the eastward extension of this region into Yukon, and the Arctic coastal plain remained largely ice-free. Today, ice cover is restricted to mostly retreating glacier complexes mainly at higher elevations, but which descend to sea-level in parts of southern and south-eastern Alaska.

Neotectonics

The northern Cordillera occupies a 'soft' plate margin up to 1200 km wide landward of an offshore convergent–transform–convergent plate boundary (Figure 1). Earthquakes are concentrated near most plate boundaries, but are scattered across the entire region. South of latitude 51° N, the small, young (≤9 Ma) Juan de Fuca and Explorer oceanic plates converge with the North American Plate at rates of 2–4.6 cm year ^{1} along the currently aseismic, locked Cascadia subduction zone, 200–300 km landward of which is the active Cascade magmatic arc. Between latitudes 51° and 60° N, the plate boundary is the dextral transform Queen Charlotte–Fairweather Fault, west of which the enormous Pacific Plate moves northwards to converge with the North American Plate at rates ranging from 5.7 cm year ^{1} near the transform to 8 cm year ^{1} south of the western Aleutian Islands. The Pacific Plate descends beneath Alaska along the Aleutian subduction zone, and above it the Aleutian–Wrangell magmatic arc extends eastwards some 3800 km from the Komandorsky Islands near Kamchatka, along the Aleutian Island chain, and into the mountains of southern Alaska and south-westernmost Yukon. The North American Plate continues for some 2000 km west of the Bering Strait to terminate against the Eurasian Plate near longitude 140° E.

There is widespread evidence for neotectonic activity in the northern Cordillera in addition to earthquakes and volcanoes. Seismically imaged folds and thrust faults in Late Tertiary and Quaternary strata are in the accretionary wedges above the Cascadia and Aleutian subduction zones, and faults and folds occur in the Arctic shelf-slope region off northern Alaska and Canada. On-land surface evidence for latest Tertiary to Holocene deformation is sparse, possibly because erosion by ice eliminated the surface expression of many small-scale tectonic features. Segments of the Denali Fault in southern Alaska and south-western Yukon are active dextral strike-slip faults, as are other fault segments in central Alaska. Glaciated valleys crossing the Fairweather Fault in south-eastern Alaska are dextrally offset, and neotectonic faults occur on Vancouver Island in south-western British Columbia. In western Washington, east–west-trending Holocene folds and reverse faults in the coastal depression are related to north–south compression, as are structures involving Late Miocene lava flows in the Columbia Plateau, east of the Cascade arc.

On a larger scale, regional differential uplift of up to several kilometres in the last 5–10 million years in the Alaska Range, Saint Elias Mountains, Coast Mountains, and Olympic Mountains is documented by elevated Late Tertiary erosion surfaces, changes from wet to dry floras in regions now in rain-shadows inland of the coastal mountains, palaeodrainage patterns, and fission track studies. Differential regional uplift is not well documented elsewhere, but major reversals of drainage in upper reaches of the Fraser and Columbia Rivers in central and south-eastern British Columbia, respectively, possibly reflect Neogene differential uplift of parts of the Rocky Mountains System, in addition to documented blockage by temporary ice dams and landslides during waning stages of Cordilleran glaciation. The late differential uplift means that physiographical system boundaries only approximately coincide with major bedrock boundaries, many of which formed between the Early Jurassic and the Neogene.

Crustal Thickness

Seismic refraction and reflection profiles across the northern Cordillera show the crust to be nearly 50 km thick under the south-eastern Canadian Cordillera and parts of northern Alaska (Figure 2). Below the Intermontane Plateau System in Alaska and northern Canada, it is about 35 km thick, and under the southern Canadian Cordillera only 30 km thick. Above subducting lithosphere in southern Alaska and south-western Canada, the crust is apparently underplated by material detached from the lower plate and is over 50 km thick, whereas landward of the Queen Charlotte–Fairweather transform fault it is only about 25 km thick.

Bedrock Features

Two fundamentally different divisions of older rocks in the northern Cordillera are separated by a boundary that snakes back and forth across the physiographical boundary between the Rocky Mountains and Intermontane Plateau Systems. In most of the Rocky Mountains System, autochthonous or parautochthonous rocks were deposited on or near continental basement. Much of the remainder is an orogenic collage of allochthonous terranes, many of which show little geological or isotopic evidence of continental influence. Superimposed on the older rocks are features formed during the evolving Cordilleran mountain belt in Mesozoic and Tertiary time (Figures 3 and 4).

Autochthonous and Parautochthonous Rocks

Rocks of the ancient continental margin, and deposited on or near it, form five divisions based on age and the tectonic setting in which they formed.

1. The continental basement that extends under the eastern Cordillera from Montana–Idaho–eastern Washington to north-western Yukon is a Palaeoproterozoic orogenic collage composed of fragments of Archaean (4.0–2.6 Ga) continental crust embedded in metamorphosed remnants of

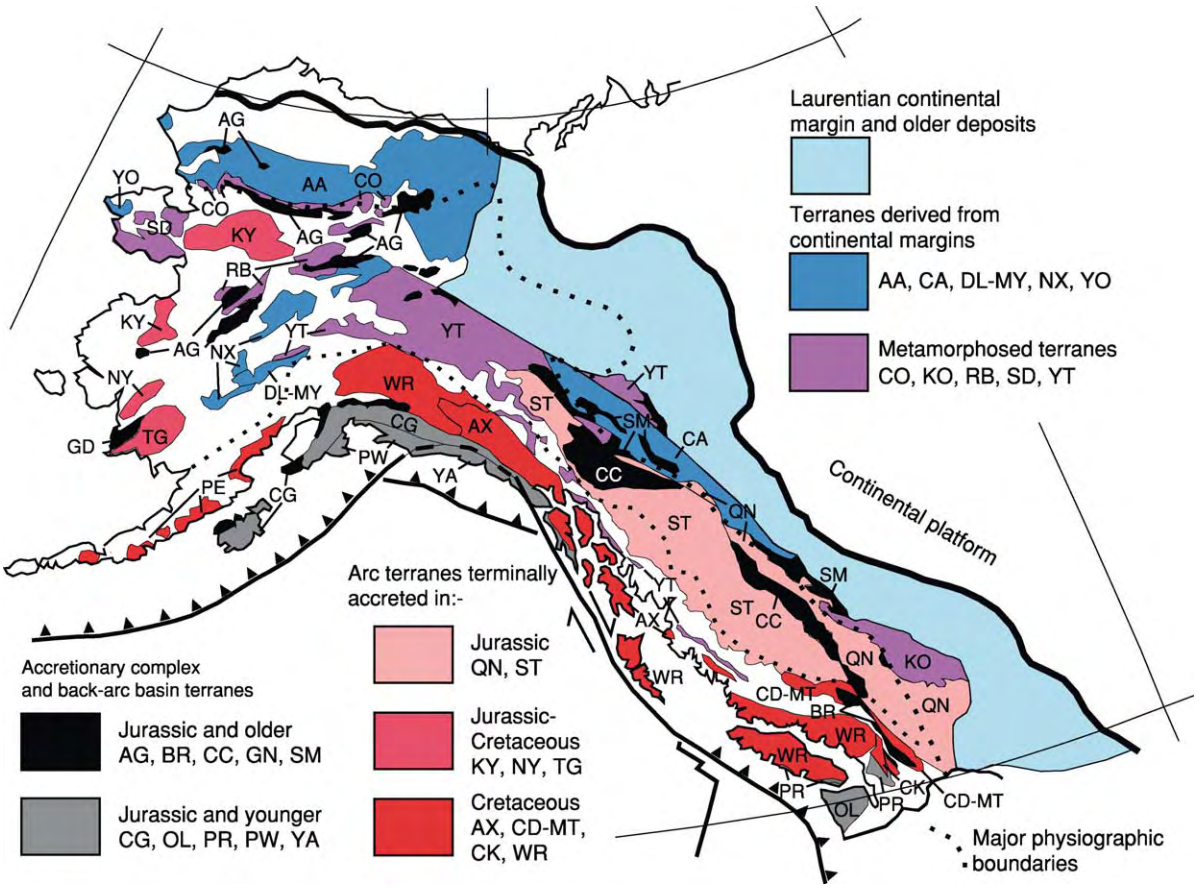

Figure 3 Distribution, origins, and times of accretion of terranes. Terrane names, abbreviated herein as AG, BR, etc., and brief terrane descriptions are in Appendix B.

Palaeoproterozoic (2.3–1.8 Ga) magmatic arcs and accretionary wedges. Although mostly buried, it is exposed locally in south-eastern British Columbia (Monashee Complex) and northern Idaho (Priest River Complex). The continental basement slopes beneath the eastern Rocky Mountains System as a layer about 35 km thick, but thins abruptly and appears to be no more than a few kilometres thick beneath the southern Intermontane Plateau System, and is absent below the Pacific Mountains System.

2. Palaeoproterozoic (1.8–1.7 Ga) basinal to platformal deposits (the Wernecke Supergroup) in northern Canada and east-central Alaska (Tindir Group) are rift-related and as much as 13 km thick. However, it is uncertain whether they formed in an intercontinental basin or during continental break-up. An angular unconformity between folded and slightly metamorphosed rocks of the Wernecke Supergroup and younger (1.4–1.0 Ga) Mesoproterozoic basinal to platformal deposits brackets the age of the Racklan Orogeny. Mesoproterozoic (1.5–1.4 Ga) strata (Belt-Purcell Supergroup) in Montana, Idaho, and adjoining parts of British Columbia and Alberta form a north-west-trending prism up to 20 km thick. The lower part consists of deep-water turbiditic quartzite, siltstone and argillite, and voluminous mafic sills; the upper part comprises shallow-water siliciclastics and stromatolitic carbonates deposited in intertidal and floodplain settings. The rocks apparently accumulated within and near an intracontinental rift basin.
3. Neoproterozoic (780–550 Ma) strata are the oldest rocks to occur more or less continuously along the entire northern Cordillera. Glaciogenic deposits (Sturtian?) at the base of the Windermere Supergroup contain mafic volcanic rocks with ages of 780–760 Ma. These date the initiation of rifting that led eventually to dispersal of components of the Neoproterozoic Rodinian supercontinent and creation of what became the margin of Laurentia. The overlying succession, up to 10 km thick, consists of shale with intercalated quartz-and-feldspar 'grit' turbidites, and grades upwards into slope deposits, carbonate, and evaporite shelf deposits.

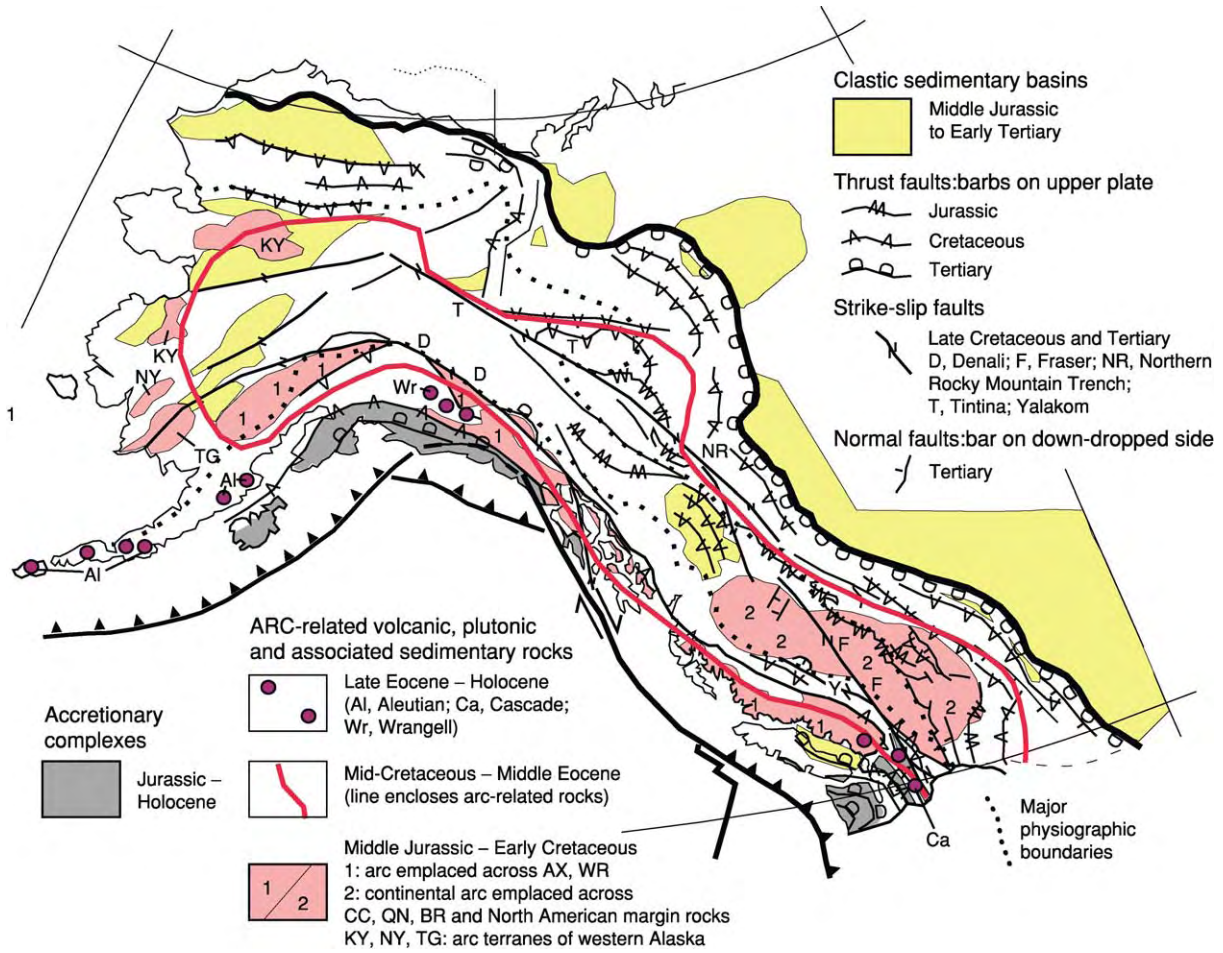

Figure 4 Features accompanying Cordilleran orogenesis: magmatic arcs and associated accretionary complexes; basins resulting from contraction, crustal thickening, uplift, and erosion; and syn and post accretionary structures. Terrane names, abbreviated herein as AX, WR etc; are in Appendix B.

Younger glaciogenic sediments (Varanger equivalent?) occur locally in the upper Windermere. A second major rifting episode at the top of the succession is recorded by an angular unconformity beneath Cambrian rocks and by coarse siliciclastic deposits and associated magmatic rocks dated at 550–600 Ma. Rifting culminated in complete supercontinental separation by about 540 Ma at latitudes 48–55° N, but took place earlier further north.

4. Early Cambrian to Late Jurassic (540–150 Ma) miogeoclinal strata were deposited along the newly formed continental margin of Laurentia. In the south, the continental shelf appears to have been relatively narrow and contains abundant shallow-water carbonates, but in the north it is broader and deeper water sediments are more abundant, characteristics that have been ascribed to asymmetric rifting. Cambrian to Late Devonian carbonates with locally interbedded shales exhibit lateral facies changes from incomplete platform successions about 2 km thick below the plains and in the eastern mountains, to shallow-water accumulations up to 10 km thick that were deposited on the former continental shelf. Beyond the shelf, the strata are replaced by calcareous shale and shale, and further west by deep-water carbonaceous shale with local intercalated mafic volcanic rocks and coarse-grained siliciclastic deposits. Devonian–Mississippian and Permian–Triassic siliciclastic rocks, widespread along the Laurentian continental margin from northern Alaska to north-eastern Washington, have distinctive detrital zircon and geochemical signatures indicating their derivation from northern source areas. The predominance of latest Palaeozoic and Early Mesozoic siltstone and shale over carbonate may reflect relocation of this margin to higher latitudes as a result of the northward drift and rotation of Laurentia.
5. Latest Jurassic to Palaeogene (150–40 Ma) clastic deposits were eroded from older rocks that

were uplifted and exposed above sea-level during folding and thrusting towards, and over, the edge of the continental platform, and accumulated in foreland basins along the margins of the advancing fold and thrust belt. The sediments, up to 4 km thick, consist of deltaic and alluvial sandstone, shale, conglomerate, and coal, as well as interfingering marine sediments deposited during three transgressive–regressive cycles of latest Jurassic and Early Cretaceous, mid-Cretaceous, and Late Cretaceous and Palaeogene ages.

Rocks of the Orogenic Collage

Major components of the orogenic collage have been called terranes. These are fault-bounded regions of upper crustal rocks, detached from their lower crust and mantle lithospheres, and with different geological histories from one another. Many terranes contain palaeomagnetic, palaeobiogeographical, and/or detrital zircon signatures very different from those of neighbouring terranes and from the north-western (in present co-ordinates) Laurentian margin. Most terranes in the Pacific Mountains and Intermontane Plateau Systems south of latitude 60° N are remnants of arcs and accretionary complexes whose generally low Sr_i and positive ε_{Nd} values indicate the mantle origins of the magmatic rocks within them. Others, mainly in the western Rocky Mountains System and Intermontane Plateau System north of latitude 60° N, are displaced former continental margin deposits (**Figure 3**; Appendix B). Evidence of terrane provenance and amounts of displacement can be gathered by comparing these signatures with those in coeval rocks of the ancient continental margin, which has been oriented approximately longitudinally since the Late Palaeozoic, and thereby provides latitudinal control.

Continental margin terranes mostly formed along the Laurentian margin. The Arctic Alaska Terrane in the northernmost Cordillera consists of Neoproterozoic to Jurassic continental margin strata. The terrane has affinities with parts of the Innuitian Orogen of Arctic Canada in that it contains rocks deformed, metamorphosed, and intruded during the Devonian Ellesmerian Orogeny. However, there is disagreement about whether or not it underwent large amounts of counterclockwise rotation or translation relative to the rest of North America during the Early Cretaceous rifting and seafloor spreading that created adjacent parts of the Arctic Ocean basin. The Coldfoot, Kootenay, Seward, and Yukon–Tanana terranes contain metamorphosed Neoproterozoic and Palaeozoic strata formed in distal continental margin settings, and some contain Middle Devonian to Early Carboniferous arc magmatic rocks and underwent latest Palaeozoic metamorphism. Possible exceptions to a Laurentian provenance are the Dillinger, Mystic, and Nixon Fork terranes in Intermontane Alaska, whose Early and Middle Palaeozoic stratigraphy and faunas are similar to those of the Siberian Craton, and possibly parts of the Kootenay Terrane, for which a peri-Gondwanan provenance has been suggested.

A key question, whose answer constrains the potential amount of displacement of magmatic arc terranes relative to the former continental margin, is whether subduction was beneath the continent or away from it. Mid-Mesozoic and younger magmatic arcs evidently faced away from the continent, because contemporary accretionary complexes are located oceanward of them, with the exception of the Koyukuk–Nyak–Togiak Arc terranes in western Alaska, which are outboard of the oceanic Angayucham terrane. The facing directions of Early Mesozoic arc rocks in the Quesnel Terrane and of the Middle Jurassic arc in the Stikine Terrane were also away from the continent, but those of Early Mesozoic and older arcs of the Stikine, Alexander, and Wrangellia terranes are unknown. It has been suggested that the facing direction of the Late Palaeozoic arc in the Quesnel Terrane in southern British Columbia was away from the continent, but, conversely, that of a Late Palaeozoic arc in the Yukon–Tanana Terrane, where Carboniferous and Permian subduction evidently involved the Slide Mountain Terrane, is thought to have been towards it. Middle and Late Devonian arc rocks extend into continental margin deposits in the southeastern Canadian Cordillera, suggesting that at that time subduction was beneath the continent.

Terranes mainly in the Intermontane Plateau System south of latitude 60° N have counterparts as far south as central California and north-western Nevada. Permian to earliest Jurassic faunas in the Quesnel, Slide Mountain, and Stikine terranes differ from those in rocks deposited on the ancient continental margin in Canada, but are comparable to coeval faunas in the western conterminous USA and Mexico. Middle Permian to Middle Triassic faunas in the accretionary complex called the Cache Creek Terrane, located between the Stikine and Quesnel terranes, are similar to faunas found in eastern Asia and in rocks of Permian Tethys.

The Wrangellia and Alexander terranes in the Pacific Mountains System of Canada and Alaska contain Palaeozoic faunas most similar to those in the Canadian Arctic and Siberia. Their Early Mesozoic faunas are more comparable to those further south in the western Cordillera, although Wrangellia also contains an Early Jurassic ammonite of a characteristic Russian species unknown elsewhere from North America. The Alexander Terrane features a

distinctive record of Neoproterozoic and Early Palaeozoic arc magmatism and orogeny; suggestions have been made for its origin in regions as far apart today as eastern Australia and the Barents Sea, with the latter currently favoured.

Northern Cordilleran Mountain Building

The final accretion of terranes to the former continental margin started in the Early Jurassic and was associated with the subduction of oceanic lithosphere beneath the western North American Plate, accompanying arc magmatism, and the collapse of back-arc basins. By the Late Cretaceous, almost the entire region was above sea-level.

For much of its length, the northern Cordillera features two tracts of Mesozoic and Palaeogene high-grade metamorphic rocks that are loci of the greatest amounts of burial, crustal thickening, differential uplift, and erosion and/or tectonic exhumation. The metamorphic rocks are located in internal parts of the Rocky Mountains and Pacific Mountains Systems and are flanked on both sides by far less metamorphosed rocks in much of the remainder of the Cordillera (Appendix A). Some metamorphic rocks in Intermontane Alaska and Yukon (in the Ruby, Seward, and Yukon–Tanana terranes) are older. Starting in the latest Early Jurassic ($\leq$185 Ma), terranes (Cache Creek, Quesnel, Stikine, and Slide Mountain) in the Intermontane Plateau System in Canada were thrust towards the continent and deeply buried former continental margin rocks that are exposed today in internal parts of the Rocky Mountains System. Metamorphism along the southern Arctic Alaska Terrane and in parts of Intermontane Alaska similarly appears to be related to Middle Jurassic–Early Cretaceous thrusting of oceanic rocks and arc terranes (Angayucham, Koyukuk, Nyac, and Togiak) on to Arctic Alaska. Beginning in the mid-Cretaceous ($\sim$95 Ma), the terranes (Alexander, Wrangellia) near the present coast tectonically overlapped the previously accreted terranes, mainly preserved in the Intermontane Plateau System, along a boundary located in the internal part of the Pacific Mountains System.

Compressional structures in the remainder of the northern Cordillera can be directly related to those in the two tracts of high-grade metamorphic rocks (Figure 4). External parts of the Rocky Mountains System contain Cretaceous and Paleocene thrust faults that carried miogeoclinal and older deposits for distances of up to 200 km over the continental platform. In the Pacific Mountains System, Late Cretaceous to Holocene folds and thrust faults mostly verge oceanward. In the Intermontane Plateau System in Canada, oceanward-verging folds and thrust faults are Jurassic, whereas those directed towards the continental interior are mainly Cretaceous. Convergent deformation is contemporaneous with uplift, erosion, and deposition in marine to non-marine basins that are both internal and external to the Cordillera (Figure 4).

In western Alaska, Cretaceous and Palaeogene convergence between the North American and Eurasian Plates may have driven the 40–60° counterclockwise rotation of south-western Alaska. Rotation, combined with dextral displacement on major faults in Intermontane Alaska, created the curvilinear grain of the Alaskan Cordillera and its expanded western termination.

Late Cretaceous, Tertiary, and Holocene dextral strike-slip faults lace the northern Cordillera and apparently reflect oblique subduction and partial coupling of the western North American Plate margin to the northward-moving Pacific Plate and to its precursor, the Kula Plate, which had been entirely subducted by $\sim$37 Ma (Figure 4). The total amount of displacement on these faults, as determined from geological features offset across them, approaches 1000 km. In the north, there are displacement amounts of 425 km on the Tintina Fault and up to 400 km on the Denali Fault, and, in the south, about 300 km on combined Fraser and Yalakom Faults. A major unresolved discrepancy exists between the above numbers and those arising from palaeomagnetic studies on Late Cretaceous rocks ($\leq$85 Ma), which suggest dextral displacements of as much as 3500 km for parts of the western Cordillera.

In addition to the above, a sparse record of Early Cretaceous sinistral, Early to Middle Jurassic dextral, and Triassic–Jurassic sinistral strike-slip faulting was possibly responsible for the fragmentation, displacement, and duplication of arc terranes in the collage prior to their final accretion and further disruption by dextral faulting. In the Pacific Mountains System, a Middle Jurassic–Early Cretaceous island arc founded on Wrangellia and Alexander terranes was apparently displaced southward in Early Cretaceous time. There is about 800 km of overlap between it and the northern end of the contemporary continental arc in the southern Intermontane Plateau and internal Rocky Mountains Systems (Figure 4). In addition, Early Mesozoic oroclinal bending, or left-lateral strike-slip faulting, has been invoked to account for apparent duplication of a Quesnel–Stikine Arc and enclosure of the associated Cache Creek Accretionary Complex (Figure 3).

Palaeogene (58–40 Ma) normal faults are widespread south of latitude 55° N in the Intermontane System and in parts of the Pacific and Rocky Mountains Systems. Many faults are oriented north–north-easterly or north-easterly, at angles to the prevailing

general grain of this part of the Cordillera, and some clearly are associated with movement on dextral strike-slip faults. Normal faults bound graben and half-graben structures containing coeval clastic and volcanic rocks, and many, especially in south-eastern British Columbia and adjoining parts of Idaho and Montana, contributed to the tectonic exhumation of formerly deeply buried rocks in metamorphic core complexes, in some of which Palaeoproterozoic continental basement is exposed.

Economic Deposits

Hydrocarbon deposits occur mainly in the Rocky Mountains System and include oil and gas originating from Palaeozoic and Early Mesozoic strata, and coal in foreland basins. Coal was formerly exploited in Late Mesozoic and Early Tertiary basins in the western Cordillera, and oil and gas are known in rocks of the Pacific continental shelf.

Metallic mineral deposits occur widely. Interior parts of the Rocky Mountains System contain widespread lead, zinc, and silver deposits, two of which, the former Sullivan Mine in south-eastern British Columbia and the active Red Dog mine in north-western Alaska, are some of the largest known. The Intermontane Plateau and Pacific Mountains Systems contain several large copper and molybdenum deposits, with associated golds in porphyry systems in arc-related plutons. Placer gold deposits were of historical importance, but currently are less so.

Evolution of the Northern Cordillera

The origins of the northern Cordillera extend back some 770 Ma to rifting events that marked initial stages in the break-up and dispersal of components of the Rodinian supercontinent. By Early Cambrian time (~540 Ma), rifting had culminated in the seafloor spreading that opened the distant ancestor of the Pacific Ocean basin and created the Laurentian continent–ocean boundary that now is embedded in the Rocky Mountains System.

The intraplate continent–ocean boundary persisted until the Middle Devonian (~390 Ma), when it was succeeded by a convergent plate boundary that initially generated arc magmatic rocks within distal continental margin strata in a belt that extends from California to the Canadian Arctic. Arc magmatism has continued until the present, but has varied greatly in character and volume. From the Early Carboniferous until the Early Mesozoic (355–185 Ma), the period spanning amalgamation and eventual break-up of the supercontinent called Pangaea, the convergent plate boundary lay well offshore and featured island arc chains (Quesnel, Stikine) separated from the continental margin by back-arc basins (Slide Mountain). The region offshore western Pangaea probably was similar to the present western Pacific Ocean basin.

The accretion of arc, back-arc basin, and accretionary prism rocks and former continental margin fragments to the old continental margin started in the Jurassic at about 185 Ma. The accretion records the initiation of Cordilleran mountain building and coincided with the break-up of Pangaea and the advance of the North American continent towards the trench on its western margin. It resulted in the relocation of the continental margin some 500 km oceanward of its original position by the Late Cretaceous (~90 Ma), when the Cordillera probably resembled parts of the modern Andes.

During and following accretion, the collage and parts of the former continental margin were sliced and shuffled by strike-slip faults associated with oblique plate convergence, stretched and dismembered by extension and, in Alaska, apparently rotated counterclockwise. Most of the major physiographical features of at least the Pacific Mountains System, and probably much of the remainder of the northern Cordillera, probably emerged in the later Neogene ($\leq$12 Ma).

Appendix A: Northern Cordilleran Physiographical Systems and Underlying Bedrock Geology

The names Rocky Mountains, Intermontane Plateau, and Pacific Mountains Systems, used for the major physiographical divisions in Alaska, are approximately, but not completely, equivalent to the Eastern, Interior, and Western Systems used in British Columbia.

Features east and north of the Northern Cordillera: Interior Plains System, Arctic Coastal Plain, and Arctic Ocean

Rocky Mountains System
External part

Some major physiographical units: Montana and Canadian Rocky Mountains, Mackenzie Mountains, northern Brooks Range.

Bedrock: (1) Archaean and Palaeoproterozoic continental basement; (2) Mesoproterozoic (locally Palaeoproterozoic) clastic, carbonate, and minor magmatic rock associated with rift-related basins; (3) Neoproterozoic clastic, minor carbonate, and mafic magmatic rocks formed during rifting of the Rodinian supercontinent; (4) Cambrian to Jurassic carbonate and shale deposited on platform, shelf, and slope of Laurentian continental margin; and

(5) latest Jurassic to Palaeogene marine to non-marine clastics deposited in foreland basins concomitantly with folding and thrusting towards and over the continental platform.

Rocky Mountains and (in part) Tintina Trenches
Internal part

Some major physiographical units: Columbia, Cassiar, and southern Brooks Range.

Bedrock: (1) local Palaeoproterozoic continental basement; (2) Neoproterozoic rift-related clastic and volcanic rocks; (3) Palaeozoic, mainly deep-water, clastic rock, rift- and arc-related volcanic and plutonic rocks; (4) local Late Palaeozoic to Early Jurassic magmatic and sedimentary rocks formed in island arcs and marginal basins; (5) Middle Jurassic to Paleocene plutonic rocks; and (6) local Palaeogene magmatic and sedimentary rocks; rocks typically metamorphosed up to high grades and complexly deformed (mainly) during Middle Jurassic to earliest Tertiary compression, and also (in the south) by Palaeogene extension and (in the north) dextral strike-slip faulting.

Intermontane Plateau System

Some major physiographical units: northernmost Columbia Plateau, Interior Plateaus, Skeena Mountains, Yukon Plateaus, Yukon–Tanana Upland, Kuskowim Mountains, Coastal Lowlands, Seward Peninsula.

Bedrock: (1) variably metamorphosed Neoproterozoic and Palaeozoic continental margin deposits in Alaska and Yukon; elsewhere (2) Devonian to Early Jurassic sedimentary and magmatic rocks formed in island arcs, accretionary complexes, and back-arc basins; (3a) Middle Jurassic to Palaeogene continental magmatic arc rocks, and (3b) marine and non-marine clastic deposits eroded from tectonically uplifted regions; (4) local Neogene flood basalt; rocks deformed by compression mainly in the Mesozoic and extension–transtension in the Early Tertiary.

Pacific Mountains System
Internal part

Some major physiographical units: North Cascade Ranges (in Washington) and Cascade Mountains (in British Columbia), Coast Mountains, northern Alaska Range.

Bedrock: (1) dominant (~80%) Middle Jurassic to Palaeogene plutonic rocks (called the Coast Plutonic Complex); (2) Palaeozoic to Holocene volcanic and sedimentary rocks formed mainly in magmatic arcs, but locally in accretionary complexes; most rocks metamorphosed up to high grades and complexly deformed mainly in mid-Cretaceous to Palaeogene time.

Coastal depressions
External part

Some major physiographical units: Olympic Mountains, Insular Mountains, Saint Elias Mountains, Alaska Ranges, Aleutian Range, Aleutian Islands, continental shelf and slope.

Bedrock: (1) latest Proterozoic to mid-Cretaceous volcanic and sedimentary rock formed mainly in island arc and (in Triassic) oceanic plateau settings; (2) mid-Cretaceous and younger clastics eroded mainly from Coast and Cascade Mountains region; (3) Early Palaeozoic to Palaeogene plutons; (4) Early Jurassic to Holocene clastic-rich accretionary complexes in part underlying continental shelf and slope; most rocks folded and thrust oceanwards in Cretaceous to Holocene time.

Features west and south of the Northern Cordillera: Pacific Ocean here underlain by Juan de Fuca and Pacific oceanic plates

Appendix B: Summary Descriptions of Northern Cordilleran Terranes

The abbreviations in parentheses are used in Figure 3; most palaeogeographical references are made with respect to the North American continental interior.

Continental Margin Terranes

Displaced Neoproterozoic, Palaeozoic, and, locally, Early Mesozoic sedimentary rocks.

Arctic Alaska (AA): former North American continental margin deposits, locally with Devonian plutons, possibly rifted away by counterclockwise rotation of ~70° from its former position near the Canadian Arctic Islands in Early Cretaceous time (≤130 Ma).

Cassiar (CA): former North American continental margin deposits, sliced off and translated northwards by 425–2000 km on right-lateral strike-slip faults.

Coldfoot (CO), Kootenay (KO), Ruby (RB), Seward (SD), and Yukon-Tanana (YT): derived mainly from Neoproterozoic and Early Palaeozoic rift and lower slope deposits, and Middle Devonian to Early Carboniferous continental margin arcs; metamorphosed

and multiply deformed in Palaeozoic (?), Mesozoic, and Palaeogene times.

Dillinger (DL), Mystic (MY), and Nixon Fork (NX): small terranes in Intermontane Alaska whose stratigraphy and Early and Middle Palaeozoic faunas resemble those of the Siberian (or North Asian) craton margin.

Accreted Terranes

Arc terranes terminally accreted in the Jurassic

Quesnel (QN) and Stikine (ST): Devonian to Permian clastic rock and carbonate, arc-related volcanic, and plutonic rocks; local Palaeozoic ultramafic rocks, basalt, chert, pelite, and carbonate formed in marginal basins or ocean floor (=SM?); overlying Late Triassic and Early Jurassic arc-related magmatic and clastic rock and minor carbonate. Permian, Triassic, and Early Jurassic faunas most similar to those further south in the western conterminous USA and north-western Mexico; contrarily, palaeomagnetic data suggest little or no northward displacements. ST apparently duplicated QN in the Early Mesozoic by oroclinal bending or left-lateral strike-slip faulting and enclosed the associated accretionary complex (CC).

Arc terranes terminally accreted in the Cretaceous

Alexander Terrane (AX): latest Proterozoic and Early Palaeozoic magmatic arc and associated clastic rock and carbonate, and Late Palaeozoic and Early Mesozoic rift-related clastic and volcanic rock and carbonate. AX and WR apparently linked by Carboniferous plutons and overlapped by Middle Jurassic–Early Cretaceous arc rocks. Palaeomagnetic data suggest an Early Palaeozoic palaeogeographical location either near eastern Australia or the Barents Sea; Silurian and Devonian faunas favour the latter location; Triassic palaeolatitudes of AX comparable with those of Alaskan WR.

Cadwallader (CD) and Methow (MT): Upper Triassic magmatic arc rocks and associated sedimentary rock overlying Permian ocean floor rocks; unconformably overlain by Early Jurassic to Early Cretaceous marine arc-derived clastic and local volcanic rocks; overlying Late Cretaceous continental arc volcanics carry palaeomagnetic signatures indicating $\sim 35^\circ$ of northward displacement.

Chilliwack (CK): Devonian to Early Jurassic arc-related volcanic and clastic rocks and carbonate; in general, stratigraphy and faunas resemble ST and QN; possibly a fragment of ST, sliced off and translated southwards by sinistral strike-slip faults in the Early Cretaceous.

Koyukuk (KY), Nyac (NY), and Togiak (TG): Late Jurassic–Early Cretaceous arc rocks in western Alaska associated with the subduction of AG and GN oceanic terranes.

Wrangellia (WR): Devonian to Middle Jurassic magmatic arc rocks, with associated clastic rock and carbonate, and conspicuous Upper Triassic plume-related (?) tholeiitic basalt overlain by carbonate; Permian faunas comparable with some in Canadian Arctic and Urals; Early Jurassic faunas comparable with those elsewhere in the western Cordillera; palaeomagnetic data from Triassic strata on Vancouver Island indicate little or no latitudinal displacement, whereas those from southern Alaska indicate about 20° northward translation; interpreted as due to Tertiary separation of the two regions; WR linked to AX by Middle Jurassic and possibly Carboniferous.

Accretionary complex and back-arc basin terranes; ordered from continental interior to ocean Unless noted otherwise, all are characteristically highly disrupted and most contain melanges; pillow basalts, local alpine-type ultramafic rocks, and rare blueschists, in places associated with eclogite. Pre-Late Jurassic accretionary complexes in the Cordillera typically contain abundant radiolarian chert, whereas younger ones contain abundant clastic rocks including sandstone.

Angayucham (AG), Goodnews (GN), and Slide Mountain (SM): remnants of oceanic and marginal basins. SM is Carbonifereous to Triassic; AG and GN range in age from Devonian to Late Jurassic and appear to be accretionary complexes related to KY, NY, and TG arc terranes in western Alaska; SM in Yukon is associated with a Late Palaeozoic arc in YT and contains blueschist; further south, SM appears to be a back-arc basin, lacking melanges, eclogites, and blueschists, and separating QN from the former continental margin. The late Palaeozoic palaeomagnetic record of SM suggests northward displacement of $\sim 20^\circ$ with respect to the craton, in accord with displacements indicated by its Middle Permian fauna, which is similar to that in the south-western USA and north-western Mexico.

Cache Creek (CC) and Bridge River (BR): CC is Early Carboniferous to Early Jurassic and contains distinctive large masses of Late Carboniferous to Late Triassic shallow-water carbonate that probably formed as atolls capping seamounts, as do several similar complexes of this age in the circum-Pacific region. Middle Permian to Middle Triassic faunas

are similar to those in eastern Asia and the region occupied by Permian Tethys. CC contains Triassic blueschist and is interpreted as the accretionary complex accompanying QN and ST magmatic arcs. BR is similar to CC, but is of Early Carboniferous to Late Jurassic age, lacks distinctive large carbonate bodies, and was finally accreted in the Cretaceous.

Chugach (CG) and Pacific Rim (PR): CG is a long-lived Mesozoic accretionary complex. The inboard part of CG is a chert-rich assemblage that, in one locality, contains a limestone block with Permian Tethyan fauna and Early Jurassic blueschist; it is the accretionary complex associated with an Early Mesozoic arc on WR. The outboard part of CG is a Late Jurassic and Cretaceous clastic-rich assemblage with local Cretaceous blueschist; PR is similar but local; it is the accretionary complex accompanying the Middle Jurassic–Early Cretaceous arc founded on WR and AX.

Olympic (OL) and Prince of Wales (PW): Eocene to Oligocene; OL contains the youngest Cordilleran accretionary complex exposed on land; PW lies outboard of CG.

Yakutat (YA): Late Mesozoic accretionary complex overlain by Tertiary marine and continental clastic rocks; probably displaced northwards along the continental margin on the Queen Charlotte–Fairweather transform fault.

Southern Cordillera

A W Snoke, University of Wyoming, Laramie, WY, USA

Introduction

The Spanish term 'cordillera' refers to a series of parallel ranges or chains of mountains. The word was first applied in the western hemisphere to the mountain ranges of western South America, i.e., Las Cordilleras de los Andes. In the western United States, the Rocky Mountains and Coast Ranges and mountains between are collectively called the Cordillera. In Mexico, the cordillera includes the Sierra Madre Occidental, Del Sur, and Oriental systems, as well as the Sonoran Basin and Range Province and the Baja California peninsula (Figure 1). The focus in this article is on the southern half of the western North American Cordillera, including the mountain belt from ~47° N to ~16° N, an area that extends >4500 km. Thus this region is referred to as the 'Southern Cordillera'.

Diverse physiographic provinces are included in the Southern Cordillera. Where crossed by the Fortieth Parallel, it includes, from east to west, the Rocky Mountains, the Basin and Range Province, the Sierra Nevada, the Great Valley, and the Coast Ranges (Figure 1). Farther south, the Colorado Plateau is a prominent physiographic province between the Rocky Mountains and the Basin and Range Province, whereas in the north-western United States the Cenozoic volcanic provinces (Snake River Plain, Columbia Plateau, and Cascade Range) are prominent. An important topographic feature in the Southern Cordillera is the tract of high elevation that constitutes the Rocky Mountains and adjacent Colorado Plateau and Great Plains. Most of the 14 000-foot or greater mountain peaks in the conterminous United States are within the Southern Rocky Mountains, with the exception of Mt Whitney (14 494 ft; ~4421 m) in the Sierra Nevada and Mt Shasta (14 162 ft; ~4319 m) and Mt Rainier (14 410 ft; ~4395 m) in the Cascade Range.

Crustal thickness in the Southern Cordillera is strikingly variable. The Colorado Rocky Mountains and Sierra Nevada both exceed 50 km in thickness. The thinnest continental crust is in the north-western and north-eastern parts of the Basin and Range Province (~25–20 km) and around the northern part of the Gulf of California (Salton Trough), where the crust of south-eastern California and south-western Arizona has been rifted.

The fundamental nature of the Southern Cordillera is a Mesozoic and Cenozoic history as a convergent margin. The subduction of oceanic lithosphere along the Pacific margin and partial subduction of continental lithosphere in the interior of the orogen led to the development of accretionary complexes, magmatic belts, a mobile igneous and metamorphic core zone, and a foreland belt of thin- and thick-skinned contractional deformation. In contrast, the Late Cenozoic history of this circum-Pacific orogen is characterized by partitioning of deformation and magmatism into discrete magmatotectonic zones related to ongoing subduction of oceanic lithosphere, evolution of the San Andreas transform-fault system, north-westward migration of the Mendocino triple junction, and intraplate continental lithosphere extension.

Precambrian Framework

The nucleus of North America is the Precambrian craton, commonly referred to as 'Laurentia'. This Precambrian craton consists of seven Archaean microcontinents welded together along Palaeoproterozoic collisional orogenic belts. The Archaean Wyoming province is exposed in basement-involved, Laramide (Late Cretaceous and Early Palaeogene) uplifts of the Rocky Mountain foreland. The Wyoming province is bordered by Proterozoic orogenic belts on its northern, eastern, and southern margins, whereas its western margin, which extends into north-eastern Nevada and under the Snake River Plain, is a rifted margin formed during Neoproterozoic and Early Cambrian breakup of the Late Mesoproterozoic supercontinent 'Rodinia'. Along the southern margin of the Wyoming province, a Palaeoproterozoic geosuture (Cheyenne belt) is well exposed in the Medicine Bow Mountains of south-eastern Wyoming, and is interpreted as a Palaeoproterozoic collisional zone between a rifted continental margin (Archaean Wyoming province and overlying Palaeoproterozoic rocks) and a Palaeoproterozoic oceanic supra-subduction complex. This collisional orogenic event, the Medicine Bow Orogeny, developed during the interval 1.78–1.74 billion years ago (Ga). It was apparently the harbinger of a series of Palaeoproterozoic accretion events, which continued until ~1.65 Ga. This long history of lateral accretion of

Figure 1 Major physiographic provinces of the United States and Mexican Cordillera. Base map © 1992, Raven Maps & Images.

chiefly juvenile Palaeoproterozoic crust yielded a zone of accretion at least 1200 km wide, now extensively exposed in parts of Colorado, New Mexico, and Arizona. In the south-western United States, these accretion events have been traditionally referred to as the Yavapai and Mazatzal orogenies.

By ~1.6 Ga, a supercontinent (i.e., 'Nuna', after P F Hoffman) had been assembled that included Laurentia and other ancient elements that are now part of the Greenland and Baltic shields. This supercontinent experienced multiple magmatic and tectonic events in the next 500 million years. In the first event, a broad belt of Mesoproterozoic magmatism and associated tectonism developed across much of the supercontinent. In the Rocky Mountains, this magmatism is well represented by ~1.4-billion-year-old plutonic complexes that are widespread south of the Cheyenne Belt. Plutons of similar age are common in the Basin and Range Province of Arizona, in the Mojave Desert of south-eastern California, and in the subsurface of West Texas and eastern New Mexico. Near the end of the Mesoproterozoic, the North American Craton experienced both rifting (manifested by the Mid-Continent Rift System) and severe contraction, a product of the collisional Grenville Orogeny (~1.1–0.9 Ga). That orogeny culminated in assembly of the Late Mesoproterozoic supercontinent Rodinia, the reconstruction of which remains controversial.

Breakup of Rodinia, and Neoproterozoic to Mid-Palaeozoic Sedimentation

The breakup of Rodinia was followed by development of a thick wedge of Neoproterozoic through mid-Palaeozoic continental terrace deposits along the Cordilleran and Appalachian margins. In what is now the Canadian Cordillera, rifting began ~750 Ma and evolved into a Neoproterozoic passive margin where the Windermere Supergroup was deposited. In the Southern Cordillera, initial rifting was incomplete, and only during a second rifting event was the rift-to-drift transition achieved. Tectonic subsidence studies indicate that the drift phase in the US Cordillera did not occur until the latest Neoproterozoic or earliest Cambrian (~600–555 Ma). Nevertheless, Neoproterozoic clastic deposits, including glacial diamictite, can be traced from the Mackenzie Mountains in the Canadian Cordillera to the Death Valley region in southern California. The Neoproterozoic rocks in the Southern Cordillera are considered rift deposits that accumulated in isolated basins, but by the Early Cambrian, a continuous, Atlantic-type, passive margin existed virtually the length of the western North American Cordillera.

The Neoproterozoic deposits were the initial stratigraphic units of an enormous wedge of chiefly clastic and carbonate rocks that accumulated along the rifted, western margin of the Southern Cordillera through Late Devonian time. This wedge of continental margin deposits is often referred to as the 'Cordilleran Miogeocline', and it reached ~10 000 m in total thickness. The miogeocline is separated from a partially equivalent, but considerably thinner, cratonic sequence by the 'Wasatch Line', interpreted as a hinge line in the depositional framework of Southern Cordillera. This fundamental boundary is also interpreted as the eastern limit of Neoproterozoic, syndepositional faulting related to initial rifting of Rodinia in the Southern Cordillera. The Phanerozoic cratonic sedimentary sequence is characterized by disconformities and in some cases complete periods are unrepresented (e.g., the Silurian over most of Wyoming). Subsequently, the Wasatch Line represents an important boundary during Pennsylvanian–Permian basin development (e.g., Oquirrh Basin), coincides with a regional ramp during foreland fold-and-thrust belt development, and is the approximate eastern margin of the Cenozoic Basin and Range extensional province. Furthermore, a segment of the Intermountain seismic belt follows the Wasatch Line.

Another fundamental boundary in the Southern Cordillera is the $Sr_i = 0.706$ line, a boundary based on the initial $^{87}Sr/^{86}Sr$ ratio in Mesozoic and Cenozoic igneous rocks. This isotopic boundary has commonly been interpreted as the western extent of Precambrian basement rocks (Figure 2) and therefore also roughly correlates with the western extent of miogeoclinal sedimentary rocks.

Palaeozoic Orogenies

Passive margin sedimentation ended in Late Devonian time when Cambrian through Devonian oceanic rocks of the Roberts Mountains allochthon were thrust onto the continental shelf during the Antler Orogeny, best documented in north–central Nevada. Slope-and-rise sedimentary rocks and seafloor mafic volcanic rocks were thrust upon coeval, shallow-water shelf strata along a regional thrust fault (Roberts Mountains Thrust). Detailed palaeontological and stratigraphic studies have shown that the Roberts Mountains allochthon consists of fault-bounded packets of oceanic-facies rocks imbricated into a tectonic wedge. A great clastic wedge (Antler Flysch) was shed eastward from the resulting highlands into a broad foredeep that included much of eastern Nevada and extended into Utah. Upper Pennsylvanian and Permian limestone and clastic rocks unconformably overlie the Roberts Mountains

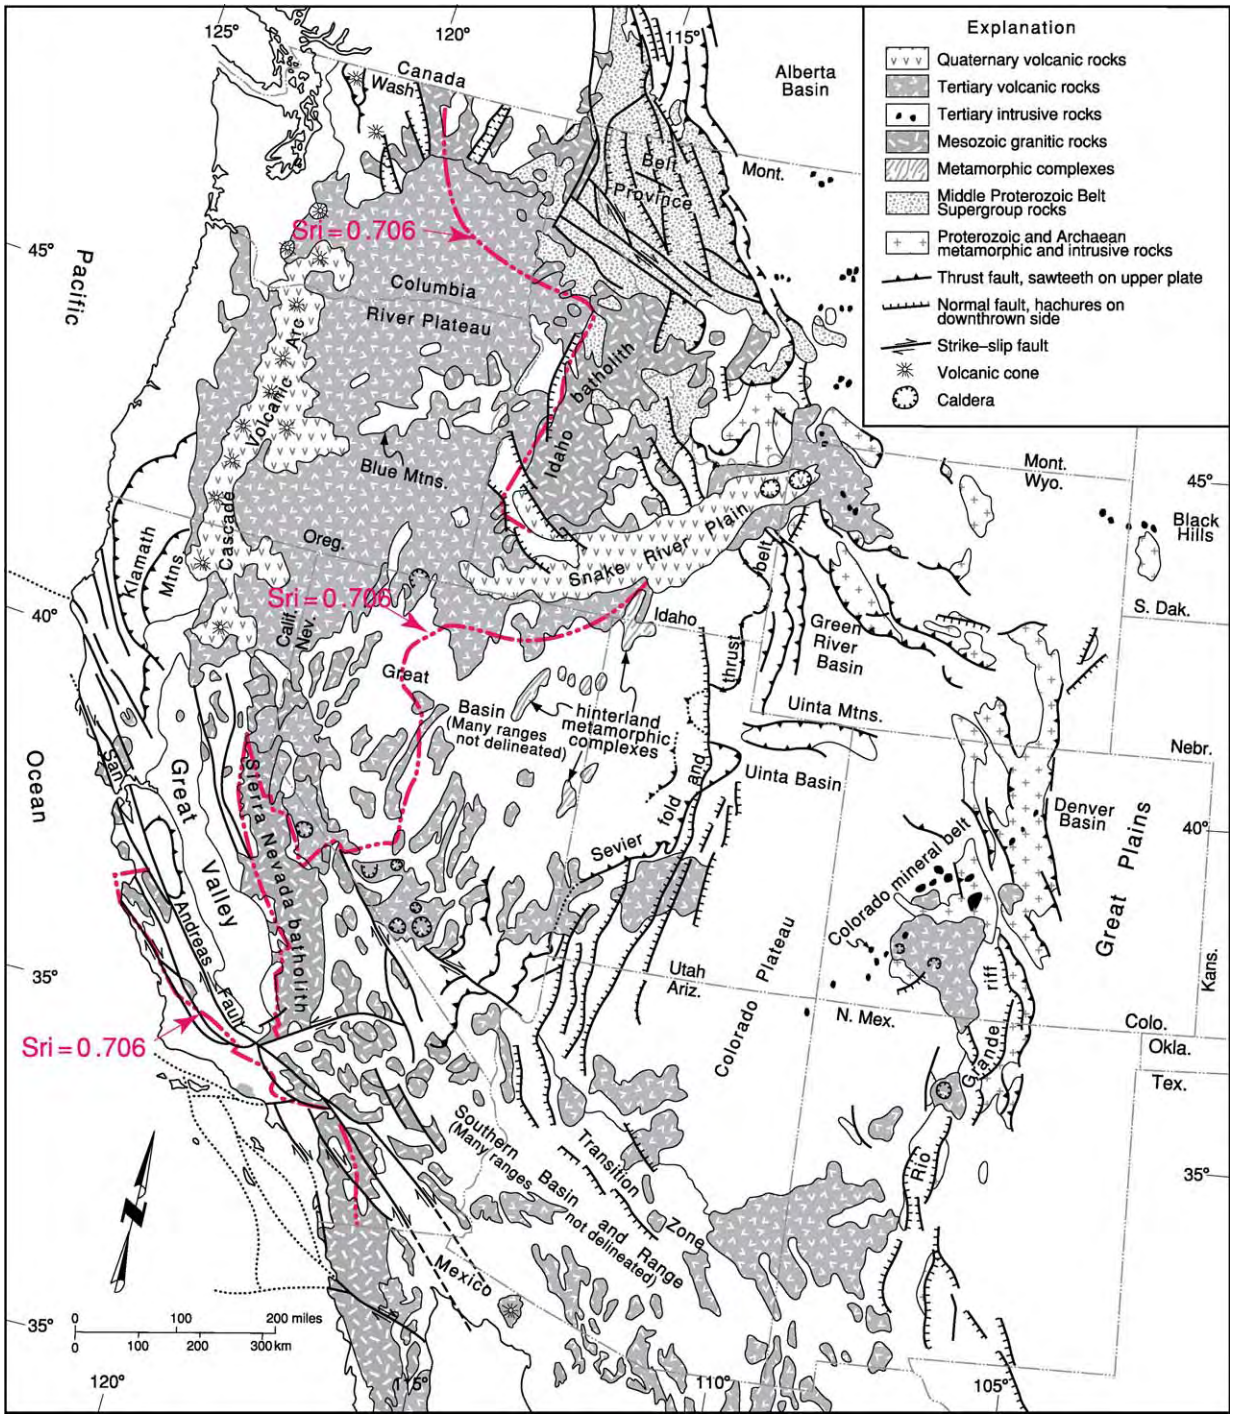

Figure 2 A tectonic map of the United States Cordillera, showing selected geological/tectonic features.

allochthon. Similar relationships occur to the north-east in the Pioneer Mountains of central Idaho and to the south-west in roof pendants in the Sierra Nevada batholith. Various plate tectonic models have been suggested for the Antler Orogeny and considerable debate has focused on the Antler Magmatic Arc that plays a role in virtually all of them. Some have argued that the Antler Arc subsided after collision with the western North American continental margin and was subsequently buried by younger rocks of later orogenic cycles. Others have stated that Devonian oceanic-arc rocks in the eastern Klamath Mountains and northern Sierra Nevada are the magmatic arc elements involved in the Antler Orogeny; however,

there is debate about the facing direction of the arc. One hypothesis is that the arc faced and migrated south-eastward during progressive rollback of the subducted slab. Still another model suggests that the arc faced westward, and the emplacement of the Roberts Mountain allochthon was related to the collapse of a back-arc basin.

Near the Permian–Triassic transition, a tectonic event similar to the Late Devonian Antler Orogeny occurred in the Southern Cordillera. The field relationships for this event are known best in north-western Nevada. The deep-water chert–argillite-limestone–greenstone of the Havallah sequence was thrust eastward onto autochthonous, shallow-water Upper Palaeozoic strata along the Golconda Thrust. This Golconda allochthon is composed of numerous fault-bounded slices of rock, such as the Roberts Mountains allochthon. This contractional orogeny is referred to as the 'Sonoma Orogeny', and again there is debate over the facing direction of the oceanic arc involved in this orogenic event. One school of thought interprets the tectonic setting for the Sonoma Orogeny as an oceanic arc–continental margin collision involving incipient subduction of continental crust beneath an east-facing oceanic arc (i.e., subduction directed westward). Others view the Sonoma Orogeny as another example of the collapse of a back-arc basin developed behind a west-facing oceanic arc (i.e., subduction directed eastward), remnants of which are preserved in the northern Sierra Nevada and eastern Klamath Mountains. An anomaly of the Sonoma Orogeny, unexplained by any model, is the fact that it did not create an extensive foreland basin.

Far to the east of the Antler and Sonoma orogenies, and approximately between them in time of origin, are structural and sedimentological effects related to the amagmatic, Pennsylvanian–Permian, intraplate Ancestral Rocky Mountains Orogeny. Manifestations of the Late Palaeozoic Ancestral Rockies are best demonstrated in the present-day Colorado Rocky Mountains and environs, but structural and sedimentological effects related to the Ancestral Rockies Orogeny can be traced from southern Oklahoma to northern Nevada. The uplifts supplied salmon pink to red arkosic sandstones, which grade into marine strata; these deposits are important components of the Late Palaeozoic stratigraphic section of the central Rocky Mountain region. The Ancestral Rockies Orogeny is commonly interpreted as an intraplate orogeny related to the Late Palaeozoic collision of the South American–African plates of Gondwana with the southern margin of Laurentia during the development of the supercontinent Pangaea. Orogenic effects of this continent–continent collision are manifested in the Marathon–Ouachita Orogeny in the south–central United States and are part of an extensive Late Palaeozoic orogenic system that can be traced from West Texas to central Europe.

Truncation of the Cordilleran Miogeocline and Pre-Cenozoic Strike–Slip Faulting along the South-western Margin of the Cordillera

In a 1969 synthesis of the plate tectonic evolution of California and environs, Warren Hamilton noted the apparent truncation of the south-west-striking Cordilleran miogeocline in southern California and north-western Mexico. Although Hamilton favoured Late Palaeozoic to Triassic truncation, subsequent studies have demonstrated that in Early to Middle Pennsylvanian time, the depositional framework in the Death Valley region experienced a fundamental change in orientation from north-east/south-west to north-west/south-east. This important change in orientation of Late Palaeozoic depositional facies in south-eastern California is interpreted as the result of a sinistral transform fault zone that was initiated during the Early or Middle Pennsylvanian and continued to be active into the Early Mesozoic. In Late Triassic time (Norian), this north-west/south-east strike was maintained during the initiation of the Cordilleran continental-margin magmatic arc that can be traced from southern Arizona into the eastern Sierra Nevada. Late Palaeozoic magmatism is recognized in eastern Mexico where it invades Gondwanan crust; whereas scarce Late Permian plutonic rocks occur in the western Mojave Desert and environs. How these igneous rocks relate to the development of the continental-margin magmatic arc is uncertain, but the occurrences in the Mojave Desert area suggest magmatism shortly after the establishment of a newly formed continental margin bounded by a transform-fault system.

Another widely cited tectonic hypothesis concerning major strike–slip displacement along the south-western margin of the Southern Cordillera postulates a major Late Jurassic, sinistral, transform-fault boundary designated the 'Mojave–Sonora Megashear'. This regional fault zone has been considered to be significant in the translation of part of northern Mexico (e.g., 'Caborca block') into its present position in the Southern Cordillera after the initial rifting and breakup of Pangaea and during the development of the Gulf of Mexico. However, the recognition that Palaeozoic depositional and structural trends were initially truncated in the Southern Cordillera in Late Palaeozoic time has dramatically reduced the potential significance of the Mojave–Sonora Megashear in reshaping the south-western

margin of the Southern Cordillera. Furthermore, detailed field studies in southern California have failed to locate the trace of the Mojave–Sonora Megashear in that region, although Late Jurassic (?) faults possibly related to it have been identified in Sonora, Mexico.

Possibly significant Early Cretaceous, dextral strike–slip faulting has been suggested in the wall rocks of the Sierra Nevada batholith; and younger, right-slip, crystal-plastic shear zones are known from the Sierra Nevada batholith. In one speculative model, a large-scale, Early Cretaceous dextral strike–slip fault system is hypothesized to have extended from the Mojave Desert region to the western margin of the Idaho batholith, suggesting significant northward translation of a large tract of the accreted terranes of the Western Cordillera. The region inferred to have been displaced northward following its accretion to western North America includes the Blue Mountains (north-eastern Oregon), Klamath Mountains (south-western Oregon and north-western California), and northern Sierra Nevada (Figure 1).

Early Mesozoic Continental to Oceanic Magmatic Arc

The Middle Pennsylvanian–Middle Early Triassic oblique truncation of the continental margin of the Southern Cordillera was subsequently overprinted by the development of a north-west/south-east-trending magmatic arc. It can be traced from southern Arizona, where it is built on continental (sialic) crust, to the eastern Klamath Mountains, where it is built on oceanic (ultramafic to mafic) crust. The transition from continental to oceanic arc is inferred to occur at about 39° N latitude in the Sierra Nevada. This Early Mesozoic magmatic arc is thought to have been west-facing with an eastward-dipping subduction zone. Late Triassic (~220 Ma) blueschist-facies metamorphic rocks in the northern Sierra Nevada, Klamath Mountains, and near Mitchell, Oregon (inlier of the Blue Mountains Province) are interpreted as the innermost subducted rocks of an accretionary complex that developed seaward of the magmatic arc. Its development initiated a long-lived convergent plate boundary zone along the Southern Cordillera. This west-facing magmatic arc served as the 'backstop' for the accretion of numerous tectonostratigraphic terranes that were added to the western North American continental margin from mid-Jurassic through Early Tertiary time.

Accreted Terranes

The 'terrane concept' was conceived and initially applied by W Porter Irwin (United States Geological Survey) to explain complex geologic relationships in the south-eastern Klamath Mountains of California. Subsequently, the concept has been utilized throughout the western North American Cordillera as well as in other orogens (e.g., the Appalachians and the Caribbean region). A tectonostratigraphic (or lithotectonic) terrane is an allochthonous, fault-bounded assemblage of rocks with a different geological history than that of adjacent rock units. Tectonostratigraphic terranes can consist of continental-margin features such as a displaced continental margin or part of an original fringing island arc and/or its subduction complex. Oceanic features such as plateaus, seamounts, or even back-arc basins may occur as discrete terranes in accretionary orogens. The tectonostratigraphic terranes in the western North American Cordillera are tectonic slices of such crustal elements and are not lithospheric or even crustal sections. The juxtaposition and amalgamation of such slices produced the Cordilleran 'collage' of terranes that characterizes the western part of the orogen.

In the Southern Cordillera, Phanerozoic tectonostratigraphic terranes are the basic 'building-blocks' of continental accretion west of the $Sr_i = 0.706$ line (i.e., the inferred western margin of Laurentia in the Southern Cordillera). Beginning in the late 1970s and extending to the present, many geological studies have focused on determining the affinity of various tectonostratigraphic terranes that are part of the Cordilleran Orogen. Clearly some of these terranes are 'pericratonic', having originated near the western margin of Laurentia, whereas other terranes are truly 'exotic' to the Cordillera. These far-traveled terranes represent major additions to western North America.

Ophiolites, sometimes dismembered, are an important component of some of the accreted, tectonostratigraphic terranes of the Southern Cordillera. In the Klamath Mountains of north-western California and south-western Oregon, well-preserved ophiolitic sequences range in age from Early Palaeozoic through Late Jurassic. The oldest are in the eastern parts of the Klamath Mountains and younger sequences are to the west. Some examples are the Trinity Subterrane, North Fork, Rattlesnake Creek, and Western Klamath terranes. The Josephine Ophiolite of the Smith River Subterrane (part of the Western Klamath Terrane) is the best-studied ophiolite sequence in western North America. To the north-east in the Blue Mountains of north-east Oregon, the Baker Terrane includes important ophiolitic sequences. In east–central California, ophiolitic sequences commonly occur as tectonic slices along the Foothills fault system of the western Sierra Nevada metamorphic belt. Many,

if not all, of these Cordilleran ophiolites developed in supra-subduction-zone settings, which indicate origins by rifting and spreading within oceanic arcs. This intra-arc extension may have been a result of oblique subduction and broad-scale transtension within the arc, similar to the present rifting and spreading in the Andaman Sea north of Sumatra. In contrast, the rifting and spreading may have been more orthogonal, such as the ongoing propagating rift and spreading centre related to the opening of the Lau Basin behind the Tofua (Tonga) Arc in the south-western Pacific. This supra-subduction interpretation of Cordilleran ophiolites implies proximity to, and temporal overlap with, oceanic-arc deposits, and has been demonstrated throughout the Cordillera by detailed geological mapping coupled with geochemical and geochronological studies. A particularly well-documented example of this relationship is the deposition of the Upper Jurassic Rogue and Galice formations and development of the Late Jurassic Josephine Ophiolite—all within the western Klamath Terrane. The Galice Formation, consisting of slaty metashales and metagreywackes with subordinate metaconglomerate and metavolcanic rocks, lies depositionally on both the Rogue Formation and Josephine Ophiolite. This situation suggests a close proximity in space and time between an oceanic arc (Rogue Formation), its adjacent sedimentary apron (Galice Formation), and the development of a complete ophiolite sequence (i.e., Josephine Ophiolite).

Another type of tectonostratigraphic terrane common in the western North American Cordillera is the accretionary complex terrane. Some of these terranes include ophiolitic components (e.g., the Baker Terrane in north-eastern Oregon), but most are either chert rich or clastic rich and are characterized by tectonic melange, broken formation, and/or olistostromal deposits. Fossiliferous rocks in some accretionary complex terranes provide some of the most reliable palaeogeographic data obtainable from tectonostratigraphic terranes. In the Cordillera, limestone blocks (of tectonic or olistostromal origin) yield fossils long recognized as 'exotic' to the western North American Cordillera. For example, Permian Tethyan fossils have been discovered in the Klamath and Blue Mountain provinces (North Fork, Rattlesnake Creek, and Baker terranes) and are especially characteristic of the Cache Creek Terrane of British Columbia, Canada. The significance of the Tethyan fauna in the Cordillera is still debated by palaeontologists. However, the association of these exotic limestones with blueschist-facies blocks strongly suggests that these terranes represent accretionary complexes that incorporated various rock types during the subduction of Pacific Ocean crust along the margin of western North America. The polarity of the original magmatic arcs related to these accretionary complexes is commonly controversial. Some accretionary complexes in the Southern Cordillera may be composites produced by collision of oppositely facing arcs. A possible example is the Baker Terrane (north-east Oregon) that apparently developed during Late Palaeozoic through Early Mesozoic time between the partly coeval Olds Ferry and Wallowa arcs. Such a situation is analogous to the arc–arc collision presently ongoing in the Molucca Sea between the oppositely facing Sangihe and Halmahera island-arc systems.

The largest accreted tectonostratigraphic terrane in the Southern Cordillera is the Guerrero Superterrane of western Mexico; its full geographic extent is still poorly known. The Guerrero Superterrane includes various volcanogenic terranes ranging in age from Late Jurassic to Early Cretaceous. They yield geochemical and isotopic data that suggest an intraoceanic arc setting. However, presence of a possible basement unit (the Arteage Complex with negative initial ε_{Nd} values) unconformably(?) overlain by the volcanogenic units suggests a composite history for the superterrane. In contrast, some tectonicists view the Arteage Complex as an underthrusted subduction complex overridden by the Guerrero Superterrane Arc. In many recent tectonic models, the Guerrero Superterrane is interpreted as an exotic, east-facing, intraoceanic arc accreted to mainland Mexico in mid-Cretaceous time. After collision with the Mexican continental margin, a polarity reversal occurred, with the development of a west-facing, continental-margin magmatic arc. In effect, it is the southern continuation of the Cretaceous arc of the Peninsular Ranges of southern California and northern Baja California. Some workers have argued that the Guerrero Superterrane arc is only part of an enormous, east-facing intraoceanic arc that included the Great Arc of the Caribbean. The latter is considered to be the source of the numerous allochthonous, arc-related terranes that rim the circum-Caribbean region from Cuba to Tobago and along the northern margin of South America.

Jurassic Magmatic and Tectonic Events

The Jurassic history of the western North American Cordillera is particularly complex and includes various events along the continental margin as well as orogenic effects within the interior of the continent. How these Jurassic orogenic processes interrelate is a major unresolved problem in Cordilleran tectonics. A classic Late Jurassic orogeny of the continental

margin is the Nevadan Orogeny originally defined by Eliot Blackwelder in 1914. Recent studies have suggested that the age of this orogeny can be tightly bracketed in the Klamath Mountains, at ~150 Ma. However, in light of the plate tectonic paradigm, coupled with recognition that terrane accretion is commonly progressive along a continental margin, the regional significance of a tightly defined orogenic event has been questioned. The classic definition of the Nevadan Orogeny is based on rock relationships in the western Sierra Nevada of California and the Klamath Mountains of Oregon, in comparison to the California Coast Ranges. These include folds and associated cleavage in Kimmeridgian–Oxfordian (Upper Jurassic) metasedimentary rocks of the Mariposa and Galice formations and the nearby association of relatively undeformed Tithonian (uppermost Jurassic stage) sedimentary rocks of the Knoxville Formation in the Coast Ranges. This classic definition was reinforced with the recognition that Early Cretaceous granitic plutons cut these structural features in the Sierra Nevada.

The plate tectonic setting of the Late Jurassic Nevadan Orogeny is especially controversial with respect to the inferred geological evolution of the western Sierra Nevada as compared to that of the Klamath Mountains. Many tectonicists have favoured a collision between a west-facing Early Mesozoic arc (i.e., an eastern arc) and an exotic, east-facing oceanic arc (i.e., a western arc) to explain the geological relations manifested in the western Sierra Nevada metamorphic belt. The accreted western arc would be separated from the eastern arc by a composite accretionary complex, in part manifested by the Palaeozoic and Triassic Calaveras Complex east of the Sonora fault. In the Klamath Mountains, structural relationships involving west-directed regional thrusting preclude the accretion of an exotic east-facing oceanic arc. In this light, the most widely accepted tectonic model for the Nevadan Orogeny in the Klamath Mountains is the collapse of a back-Arc basin behind a west-facing oceanic arc (Rogue–Chetco Arc). In this model, collapse could be related to increased coupling across the subduction system (i.e., the arc became contractional after an earlier extensional history). Resolution of these two contrasting tectonic scenarios has not been completely achieved, although some favour a polarity reversal of the western arc from east facing in the western Sierra Nevada to west facing in the Klamath Mountains. Such polarity reversals do occur along the strike of modern intra-oceanic arcs. However, this compromise requires drastically different tectonic settings for the deposition of the Galice and Mariposa formations, which have been recognized as probable stratigraphic and temporal equivalent units for over 100 years.

Cretaceous Palaeogeographic Belts and Transition to an Andean-Type Continental Margin

Late Cretaceous palaeogeography of western North America was dominated by three tectonic belts that extended virtually the length of the Cordillera: (1) an Andean-type volcanic–plutonic magmatic arc on the west (i.e., Cordilleran Magmatic Arc), (2) a thin-skinned fold-and-thrust belt on the east (initiated in mid-Cretaceous time), and (3) a hinterland (zone of metamorphism, magmatism, and deformation) (Figure 3). Another extensive feature of western North America during the Cretaceous was the Western Interior Basin. At its maximum development, the Western Interior Basin extended from the Arctic Ocean to the Gulf of Mexico.

Magmatism related to the development of the Cordilleran Magmatic Arc began in the Middle Triassic, but was only developed in the continental crust of Mexico, Arizona, and south-eastern California. From east–central California north, Late Triassic through Middle Jurassic magmatism is recorded in

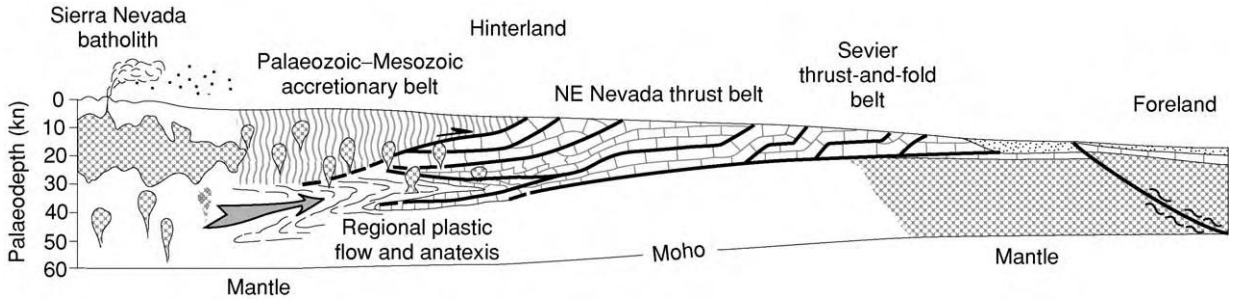

Figure 3 Schematic Late Cretaceous cross section of the western United States Cordillera, showing the relationship between the Sevier fold and thrust belt and fractured Rocky Mountain foreland on the east, metamorphic and igneous rocks of the hinterland, and Sierra Nevada batholith on the west. Reproduced (but modified) with permission from Miller EL and Gans PB (1989) Cretaceous crustal structure and metamorphism in the hinterland of the Sevier thrust belt, western U.S. Cordillera. *Geology* 17: 59 62.

tectonostratigraphic terranes not yet completely attached to the continental margin. During the Middle and Late Jurassic, magmatism spread eastward to include areas well within Laurentian crust (e.g., the Ruby Mountains of north-eastern Nevada). Also, during this time the Sundance Sea occupied an incipient foredeep in the Western Interior Basin and important terrane accretion took place in the western Sierra Nevada, Klamath Mountains, and Blue Mountains.

The geological history of the Southern Cordillera during the early part of the Cretaceous Period (i.e., Neocomian) is poorly understood. Exposures of Neocomian magmatic and sedimentary rocks are rare in the western North American Cordillera. The time interval ~140–125 Ma is commonly referred to as 'the Early Cretaceous magmatic lull'. Global sea-level was low during this time, and in the Rocky Mountain region and environs a regional unconformity exists between the chiefly fluvial deposits of the Upper Jurassic Morrison Formation and overlying mid-Cretaceous strata of the Western Interior Basin. In contrast, widespread Late Cretaceous magmatism in the Sierra Nevada and shortening in the foreland fold-and-thrust belt (i.e., Sevier Orogenic Belt of south-eastern Idaho, western Wyoming, and northern Utah) were synchronous with the culmination of seaway advancement. The fold-and-thrust belt is characterized by sled-runner thrust faults that are directed eastward and merge into a décollement near the top of the crystalline Precambrian basement. Major thrust systems are younger to the east, and the shortening history extends from ~119 to ~52 Ma. The Late Cretaceous culmination of magmatism in the Cordilleran Magmatic Arc (~100–85 Ma) coincides with intense shortening in the fold-and-thrust belt. One tectonic model argues for a close tie between Cretaceous magmatism in the California arc and continental lithospheric underthrusting beneath the arc (so-called A-type subduction). Although Sevier belt thrusting was initiated in mid-Cretaceous time, earlier (Jurassic) back-arc shortening is well documented in central Nevada (e.g., the Luning-Fencemaker fold-and-thrust belt).

While Late Cretaceous magmatism occurred in the Cordilleran Arc and shortening took place in the Sevier Orogenic Belt, regional metamorphism, large-scale folding, and the generation of peraluminous granitic rocks (commonly containing two micas, garnet, ±sillimanite) characterized the deep crust of the hinterland (Figure 3). The regional thrust faults of the Sevier Belt root into this igneous–metamorphic infrastructure, and remobilized Precambrian basement rocks were involved in both the plastic deformation and deep-crustal anatexis. Juvenile magmatic additions from the mantle did not play a significant role in the petrogenesis of the granitic rocks. Tectonic thickening coupled with dehydration melting during late decompression were the key processes responsible for metamorphism and anatexis in the Sevier hinterland. The deep-crustal rocks of the Sevier hinterland are exposed in windows developed during Tertiary crustal extension.

Laramide Orogeny

Distribution of igneous activity in the Cordillera of the western United States changed dramatically near the end of the Cretaceous Period. At ~75 Ma, magmatism in the Sierra Nevada batholith ended, and magmatism migrated eastward into the Rocky Mountains and beyond. This change in the geographic distribution of igneous activity in the Southern Cordillera is roughly synchronous with the Laramide orogeny of the Rocky Mountains. In the Rocky Mountain foreland, the Laramide Orogeny is characterized by the development of basement-involved uplifts and adjacent deep basins during Late Cretaceous through Early Eocene time (Figures 3 and 4). This 'thick-skinned' tectonic style is dramatically different from the contemporaneous 'thin-skinned' style of the Sevier fold-and-thrust belt. Although both deformations may be broadly related to plate tectonic processes near the continental margin, the local decoupling levels for these foreland deformation belts are different. The decoupling zone for the Sevier fold-and-thrust belt lies above the Precambrian basement except in the more interior (western) parts of the belt, whereas seismic-reflection studies show the decoupling zone for the basement-involved Laramide uplifts to be rooted into the deep crust.

The typical plate tectonic explanation for both the Late Cretaceous change in geographic distribution of Cordilleran magmatism and development of a thick-skinned tectonic style in the eastern Rocky Mountains involves a change to a shallow-dipping subduction mode. In this interpretation, subduction occurs at a shallow depth beneath the overriding plate in a wide segment of the orogen that extended from south-western Montana to central New Mexico (Figure 4). Why such segmentation of the subduction system would occur along the strike of the orogen is a major unanswered question in Cordilleran tectonics. The Andean orogenic system of South America is commonly proposed as a present-day analogue for the Late Cretaceous–Early Tertiary orogen of western North America. In the present Andean system, segmentation of the subduction system may be related to the character of the subducting plate; i.e., the presence of an oceanic plateau or aseismic ridge. The age of the subducted oceanic lithosphere may also be important

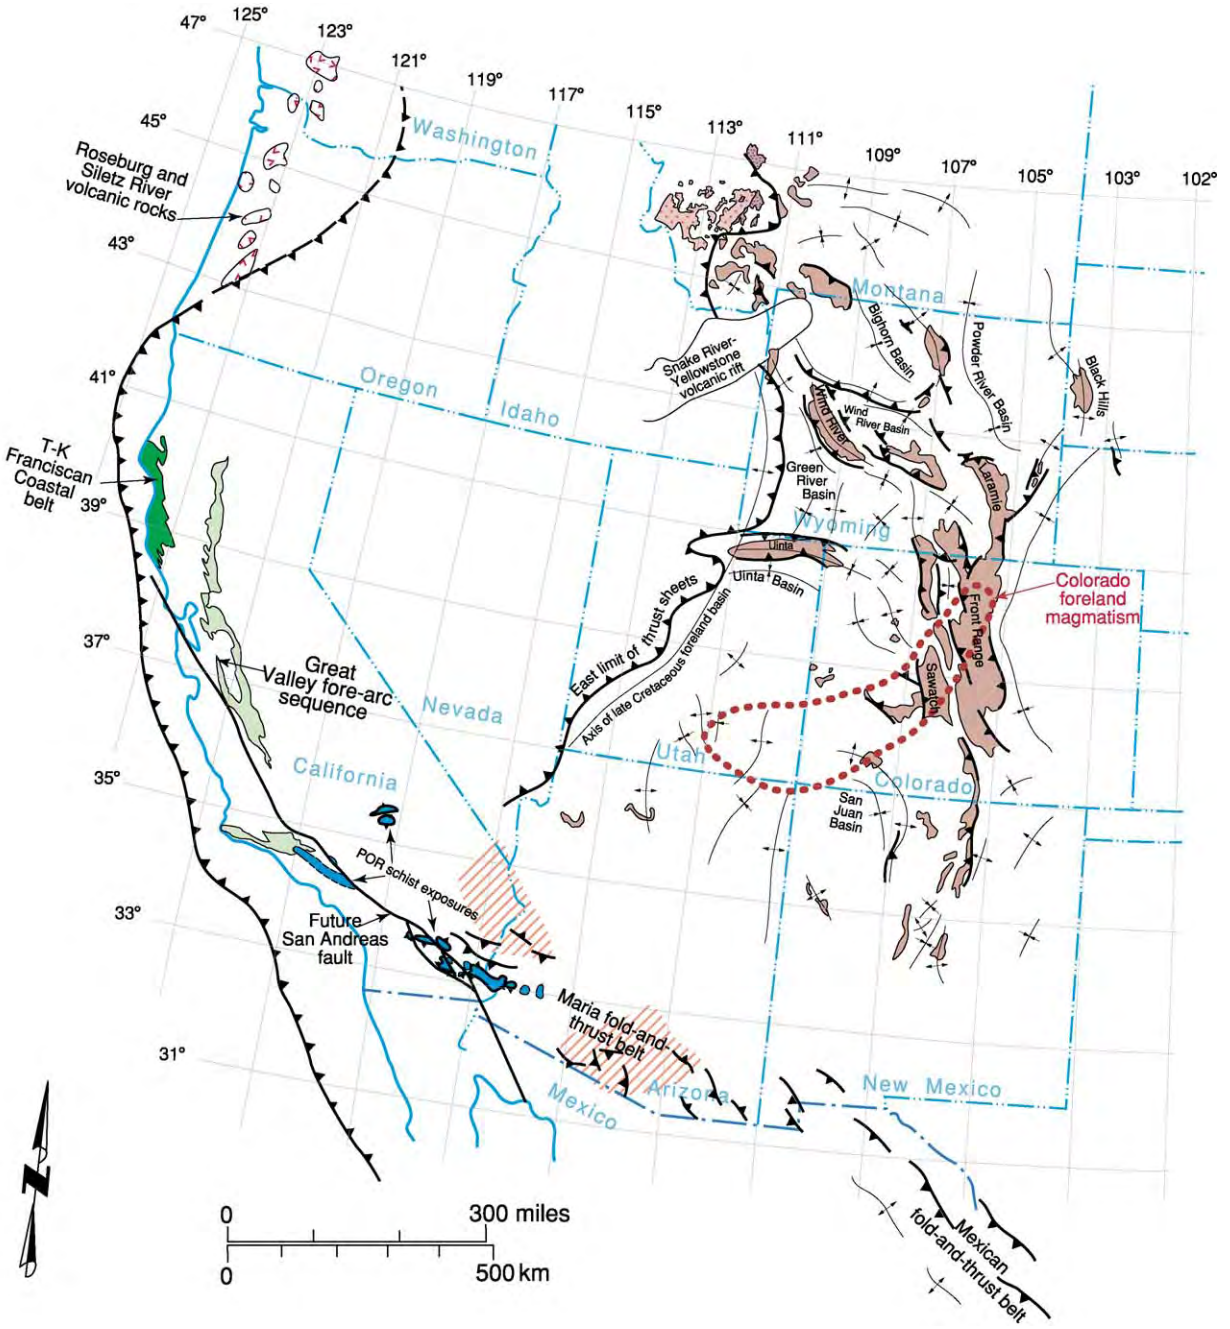

Figure 4 Distribution of the effects of the Late Cretaceous Early Palaeogene Laramide Orogeny in the south western part of the western North American Cordillera. T K, Tertiary Cretaceous; POR, Pelona Orocopia Rand; oblique red lines denote areas of late Cretaceous, high grade, regional metamorphism.

in the segmentation process, because young lithosphere is more buoyant than old, dense lithosphere. In the southern Andes, the absence of Quaternary volcanic centres in the western part of the orogen and development of basement-involved uplifts (Sierras Pampeanas) in the eastern part of the orogen coincide with the subduction of the Juan Fernandez Ridge and an eastward shift in subduction-related seismicity.

Additional evidence for a shallow-dipping subduction during Late Cretaceous–Early Palaeogene time in the Southern Cordillera is provided by a series of windows in southern California that expose oceanic rocks (Pelona, Orocopia, and Rand schists) beneath an upper plate of continental-affinity rocks. These windows are the product of Cenozoic deformation (both extensional and contractional) and provide

exceptional exposures of underthrusted, Late Cretaceous–Early Tertiary oceanic rocks that apparently underlie much of southern California and adjacent south-western Arizona.

Post-Laramide, Early Cenozoic Magmatic and Tectonic History

The post-Laramide Cenozoic history of the Southern Cordillera is characterized by new patterns of magmatism and tectonic strain. The throughgoing tectonic belts, which characterized Late Mesozoic time, were replaced by domains of extension, contraction, and strike–slip deformation. During mid-Eocene time, a broad belt of magmatism extended from southern British Columbia into central Idaho and north-western Wyoming, and a roughly contemporaneous zone of magmatism existed in southernmost Arizona and New Mexico and extended farther south into Mexico (Sierra Madre Magmatic Zone). These zones of Eocene magmatism were separated by a broad amagmatic corridor in the west–central United States that became the site of a large, Middle Eocene lake system. Accompanying the mid-Eocene magmatism in the Pacific north-west, metamorphic core complexes developed in areas of large-magnitude crustal extension. Typical complexes are characterized by a hanging wall of upper crustal rocks, sometimes including syntectonic volcanic and sedimentary deposits, separated from a footwall of mid-crustal igneous and metamorphic rocks by a plastic-to-brittle, normal-sense shear zone. Younger rocks are commonly structurally emplaced on older rocks, and brittle deformation features, including low-angle detachment faults, are superposed on the crystal-plastic deformation of the normal-sense, mylonitic shear zone. This northern belt of magmatism and accompanying localized, large-magnitude crustal extension migrated southward in Late Eocene and Early Oligocene time. Initiation of core-complex development in the eastern Great Basin was later than in the Pacific north-west, and large-magnitude crustal extension continued into the Early Miocene in the Ruby–East Humboldt and Snake Range core complexes (eastern Nevada). During the Late Eocene through Early Miocene, enormous amounts of volcanic ejecta erupted as ash-flow tuff sheets in the Great Basin (Nevada and western Utah). This 'ignimbrite flare-up' has significant implications for the crustal composition of the Great Basin, including substantial mafic magmatic intra- or underplating of the extended crust of the region. Volcanic ash from these enormous eruptions spread eastward in the upper atmosphere and formed a conspicuous air-fall component in post-Laramide, Late Eocene to Miocene strata of the Rocky Mountains (especially in Wyoming and environs). By Early Miocene time, the northern and southern magmatic zones had merged, and a continuous Neogene magmatic arc could be traced from the early Western Cascades arc into the Mojave–Sonoran Volcanic Zone. Numerous examples of Miocene core-complex development are well documented from south-eastern California across southern Arizona and into Sonora, Mexico. Still younger examples of core-complex development (Late Miocene to Pleistocene) are present in other areas of large-magnitude extension in Southern Cordillera, such as the ongoing rifting of continental crust in the northern Gulf of California, Mexico, and in the Salton Trough, California.

Elevations on the Colorado Plateau range from approximately 1.5 to 3.5 km, with the highest elevations typically associated with igneous centres such as the San Francisco volcanic field in northern Arizona. In deep canyons (e.g., the Grand Canyon), the elevation is considerably less than 1.5 km. The average elevation of the plateau is ~2 km, and the crustal thickness is ~45 km. Stratified rocks exposed on the plateau indicate that the area was near sea-level for much of the Phanerozoic and that uplift occurred after the deposition of Upper Cretaceous marine sedimentary rocks. The western and southern margins of the plateau are delineated by normal-fault systems related to the Basin and Range Province, whereas its northern and eastern margins merge into the eastern Rocky Mountains. The south-eastern margin of the Colorado Plateau in central New Mexico is delineated by normal faults related to the Rio Grande rift. The processes that facilitated uplift of the Colorado Plateau remain controversial, as well as the age or ages of uplift. One tectonic model relates the uplift of the plateau to eastward, intracrustal flow toward the Colorado Plateau from the overthickened, Sevier hinterland (now part of the Basin and Range Province). Another model argues for uplift related to lithospheric attenuation as a by-product of shallow-dipping subduction associated with the Laramide Orogeny. Still other tectonic models favour a polyphase uplift history: initially during the Laramide Orogeny and subsequently in the Late Cenozoic as part of a regional uplift, including the Southern Rocky Mountains and Great Plains. Clearly, the cause of the uplift of the Colorado Plateau remains a major unresolved problem in Southern Cordilleran tectonics.

As the San Andreas Fault (transform) system developed off the west coast of Mexico, and the triple junction between the North American, Pacific, and Juan de Fuca plates (Mendocino triple junction) migrated north-westward, the Neogene magmatic arc was shut off at its south end. In a broad area east of the late Western Cascade Arc, the Columbia River

flood basalt province developed between ~17 and 14 Ma. Basaltic dike swarms of this age are present in north–central Nevada and indicate the initiation of rifting in that area that eventually produced the Late Cenozoic Basin and Range Province.

Late Cenozoic Tectonic/Volcanic Systems and Seismicity

The Late Cenozoic tectonic evolution of the Southern Cordillera is dominated by four large-scale, tectonic/volcanic systems: (1) the San Andreas transform Fault and north-westward migration of the Mendocino triple junction, (2) the crustal extension in the Basin and Range Province and Rio Grande rift, (3) the north-east propagation of the Yellowstone hotspot track and concurrent north-west-propagation of the Newberry volcanic trend, and (4) the Cascadia subduction zone and volcanic arc. The development of these features was in part concurrent, and elements of all four systems are presently active. A relationship between the San Andreas transform-fault system and crustal extension in the Basin and Range Province has been suggested in several analyses of the Late Cenozoic tectonic history of the Southern Cordillera. However, effects associated with plate boundary slip are significant only in the south-western Basin and Range Province (e.g., eastern California shear zone). Late Cenozoic, regional crustal extension characteristic of the Basin and Range Province reflects the removal of the Farallon slab and subsequent asthenospheric upwelling coupled with north-west retreat of the Pacific Plate with respect to the interior of the North American Plate. At ~5 Ma, the Baja California peninsula was rifted from mainland Mexico when the San Andreas fault system shifted inland from a former position on the Pacific side of the peninsula. The north-western separation of Baja California from the mainland is an example of the interplate transfer of continental lithosphere.

The present-day seismicity of the Southern Cordillera is concentrated in belts at least partly related to fundamental plate tectonic boundaries (Figure 5); these boundaries are either strike–slip or convergent. Off the western coast of Oregon, seismicity is related to the Cascadia subduction zone and the Blanco Fracture Zone. Farther south, in western California and offshore, the Mendocino triple junction and San Andreas Fault system are the loci of present-day seismicity. Still farther south along the western coast of Mexico, seismicity is related to convergence associated with the Middle America Thrust.

Other prominent belts of seismicity are within the North American Plate and include the eastern California shear zone and its extensions into western Nevada (e.g., Walker Lane). The seismicity associated with this intraplate tectonic zone is interpreted as distributed strain associated with the plate boundary zone. Still another prominent zone of intraplate seismicity is the Intermountain seismic belt. It can be traced from southern Utah into western Montana and is particularly prominent in the Yellowstone National Park area. This belt of seismicity reflects a combination active normal faulting along the eastern margin of the Basin and Range Province (e.g., Wasatch front) as well as magmatism related to the Yellowstone hotspot.

Ouachitas

K C Nielsen, The University of Texas at Dallas, Richardson, TX, USA

Introduction

The Ouachita orogenic belt extends approximately 2100 km along the southern margin of North America (Figure 1). These Palaeozoic sedimentary rocks are associated with the rifted cratonic margin developed during Late Proterozoic to Early Cambrian time. Two promontories, Alabama and central Texas, and two re-entrants, Arkansas/Oklahoma and West Texas, characterized this margin. The Ouachita Mountains of Arkansas/Oklahoma and the Marathon uplift of West Texas developed in these re-entrants. While stratigraphic evidence suggests some regional adjustments coeval with the earlier stages of Appalachian tectonics, the Early Palaeozoic succession of the Ouachita orogen primarily records a long period of stable carbonate deposition along the continental shelf and slow deep-water clastic sedimentation off the shelf. This pre-orogenic phase ended abruptly in the Lower Carboniferous. At that time, the Ouachita basin began subsiding rapidly in response to closure of the Iapetus Ocean and the assembly of Pangaea (*see* **Pangaea**). A thick succession of mud-rich turbidites filled the basin, beginning at various times during the Early Carboniferous (Mississippian). The oldest deformation of this sequence is inferred from the Mississippian clastic wedge of the Black Warrior basin. Additionally, some authors have suggested that early folding documented in the metasediments of the uplifted Ouachita facies may correlate to early subduction in the Ouachita basin. The Late Carboniferous (Pennsylvanian) synorogenic sediments continued filling the basin and were translated inboard over the coeval shelf sequence, forming a generally north-verging fold and thrust belt. Subsidence within the associated foreland basins suggests a diachronous character to this advancing thrust system, beginning in the Late Mississippian in the east and in the Middle Pennsylvanian in the foreland of Oklahoma. Stratigraphic constraints indicate that thrusting ended in the Late Pennsylvanian in Oklahoma while thrusting continued in West Texas until the Lower Permian. The classic Permian carbonate succession unconformably overlies the deformed Marathon sequence. During the later stages of the deformation, basement cored uplifts developed in the Ouachita Mountains of Arkansas and Oklahoma, creating large north-east-trending uplifts. Timing of these uplifts is debateable, but suggests post-thrust deformation and a significant shift in regional shortening, possibly coincident with the later stages of the Alleghanian orogen of the southern Appalachian Mountains.

Unconformable Mesozoic units overlie approximately 80% of the Ouachita Orogenic Belt. Two large exposures, the Ouachita Mountains of Oklahoma and Arkansas and the Marathon uplift of West Texas, provide the bulk of our knowledge about the belt (Figure 1). Geophysical and well data provide the remainder of the database. Two important references serve as the foundation for discussion about the Ouachita orogenic belt and the

interested reader should consult these. The seminal work of Flawn and his colleagues in 1961 provided a complete review of the mountain belt and has been a cornerstone for all subsequent work. 28 years later, the Geological Society of America published a thorough update of the Ouachita Orogen. This discussion is synthesized from these sources.

Cambrian Continental Margin

The trace of the Ouachita Orogen is irregular (Figure 1) and this spatial distribution is directly related to the Late Proterozoic–Early Cambrian rifting of the North American Craton. From central Alabama and the junction with the Appalachian Mountains, the fold and thrust belt extends WNW across the Mississippi embayment into Arkansas and Oklahoma. There the trend shifts to the SSW, extending from Oklahoma into central Texas. At that point the trend shifts westerly continuing into West Texas, only to turn south again near the Marathon Uplift. The mountain belt extends a few hundred kilometers into Mexico before it is obscured by a Mesozoic tectonic overprint. This orthogonal pattern of recesses and salients reflects the rifting geometry along the southern margin of North America during the Late Precambrian and Early Cambrian. The spreading ridge for this rifting is inferred to be subparallel to the east coast of North America and to the south-trending margin in Texas (Figure 1). The connection between Alabama and Oklahoma and between central and West Texas are considered to have been transform boundaries. The Southern Oklahoma aulacogen is coeval with this rifting event and continues the WNW trend of the transform boundary into the craton. Additional Late Precambrian intracratonic rifting has been documented in the Mississippi Valley; the grabens trend NNE from the Ouachita Front through eastern Arkansas and western Tennessee. Igneous rocks exposed in the southern Oklahoma aulacogen reveal a 570–525 Ma bimodal volcanic package consistent with the rift model. Approximately 1 km of Cambrian clastic units in the Mississippi Valley graben indicate additional regional extension. However, outside these rift zones, including the Ouachita Orogen, there is little evidence of this rift sequence.

Stratigraphy

A fairly consistent lithostratigraphic succession characterizes the Palaeozoic sequence of the Ouachita Orogen. These sediments were deposited in two distinct phases. A pre-orogenic package consists of carbonate shelf sediments north and west of the continental margin and a deep-water shale, sandstone, and chert sequence on the continental slope or rise south and east. The second phase is dominated by syn-orogenic turbidites filling the basin and fluvial-deltaic sediments covering the shelf.

Pre-Orogenic Sequence

A classic carbonate shelf sequence accumulated on the craton over the Precambrian basement during the Early to Middle Palaeozoic (Figure 2). A thin basal sandstone unit is in contact with the Precambrian basement. This sandstone is overlain by a transgressive carbonate facies. In the Southern Oklahoma aulacogen, this carbonate succession is approximately 3.5 km thick and coeval sequences on the craton is approximately 1 km thick (Figure 2). Within the Arkoma Basin, this sequence is 1.2 km thick and about 2 km thick in the Black Warrior Basin. In many places, such as the Arkoma Basin, this pre-orogenic package records nearly continuous deposition and consistent thickness. The section in the Black Warrior Basin records influences of the Taconic Orogeny (Upper Ordovician) along the south-east margin of the basin and reveals more rapid deposition of the Devonian chert sequences along the south-west margin.

Within the Ouachita Basin, south and east of the rift margin, approximately 2–4 km of 'Ouachita facies' accumulated in generally deep marine settings (Figure 2). These shale, sandstone, and chert units currently form most of the exposures in the central uplifts of the Ouachita Mountains. Basinal pre-orogenic units have been subdivided into a lower shale-dominated section with two sandstone units followed by an upper black siliceous shale and chert succession with one interbedded sandstone (Figure 2). The change in lithology is interpreted as a function of progressively slower depositional rate and a similar subsidence history can be seen off the east coast of North America on the Blake Plateau. Current directions for the turbidites in the pre-orogenic sequence indicate that much of the deposition was coming from the north, but that the Silurian Blaylock Sandstone was sourced from the south-east: therefore the basin may have been two-sided during the pre-orogenic phase. The transition between shelf and deep water deposits is missing in the Oklahoma salient, due to subsequent shortening of the sequences. In the Marathon Region, there is a thinner pre-orogenic sequence that can also be described in two phases (Figure 2). The early units, in contrast to the Ouachita Mountains, include a lower turbidite, an overlying deep-water carbonate sequence (Marathon Formation) with overlying deep-water shale, calcarenite, conglomerates, and boulder beds. The upper phase is a chert and limestone sequence, similar in character to the chert sequence in the Ouachita Mountains. There has been significant debate about whether these cherts were deposited in shallow or deep-water settings. There is little argument about the fact that they record a long period of very slow sedimentation.

Syn-Orogenic Sequence

The tectonic picture changed dramatically in the Lower Carboniferous and this is reflected in the stratigraphic sequence. The subsidence rate and sediment input increased. The result was a rapid change up-section to deep-water shales and sandstones with interbedded debris flows. Within the Ouachita Basin, this contact appears to have been gradational, although some chert breccias have been found near the base of the section. These turbidite sequences filled the basin from east to west throughout the Carboniferous. Thickness estimates vary, but generally range from 12–14 km of section in the Ouachita Mountains where four major units are identified: Stanley and Jackfork Groups, Johns Valley, and Atoka Formations. The Stanley Group is the oldest of these flysch units, extending from the Middle to Late Mississippian. The characteristic lithologies include shale, sandstone, tuff, impure chert, and siliceous shale. Olistostromal deposits are frequent and several thin volcaniclastic units are found near the base of the Stanley Group around the Broken Bow Uplift. Gradationally overlying the Stanley Group, the Jackfork Group is characterized by prominent ridge-forming sandstone units. The Johns Valley Formation is distinguished from the underlying, gradational Jackfork Group by the presence of abundant exotic boulders and associated contorted shale. These boulders are correlated to the shelf sequence along the North American margin as well as the pre-orogenic Ouachita facies. These boulder beds are concentrated along the north-west margin of the thrust belt. The overlying unit is the widely spread Atoka Formation. Within the Ouachita Basin, the Atoka Formation is a typical turbidite, with nearly equal proportions of sandstone and shale. The maximum thickness of 8.5 km is found in the frontal Ouachita Mountains, but 2.5–4.9 km of coeval deltaic sandstones are found across the Arkoma Basin. The Atoka Formation thickens across regional, down-to-the-south normal faults, generated by tectonic loading of the continental

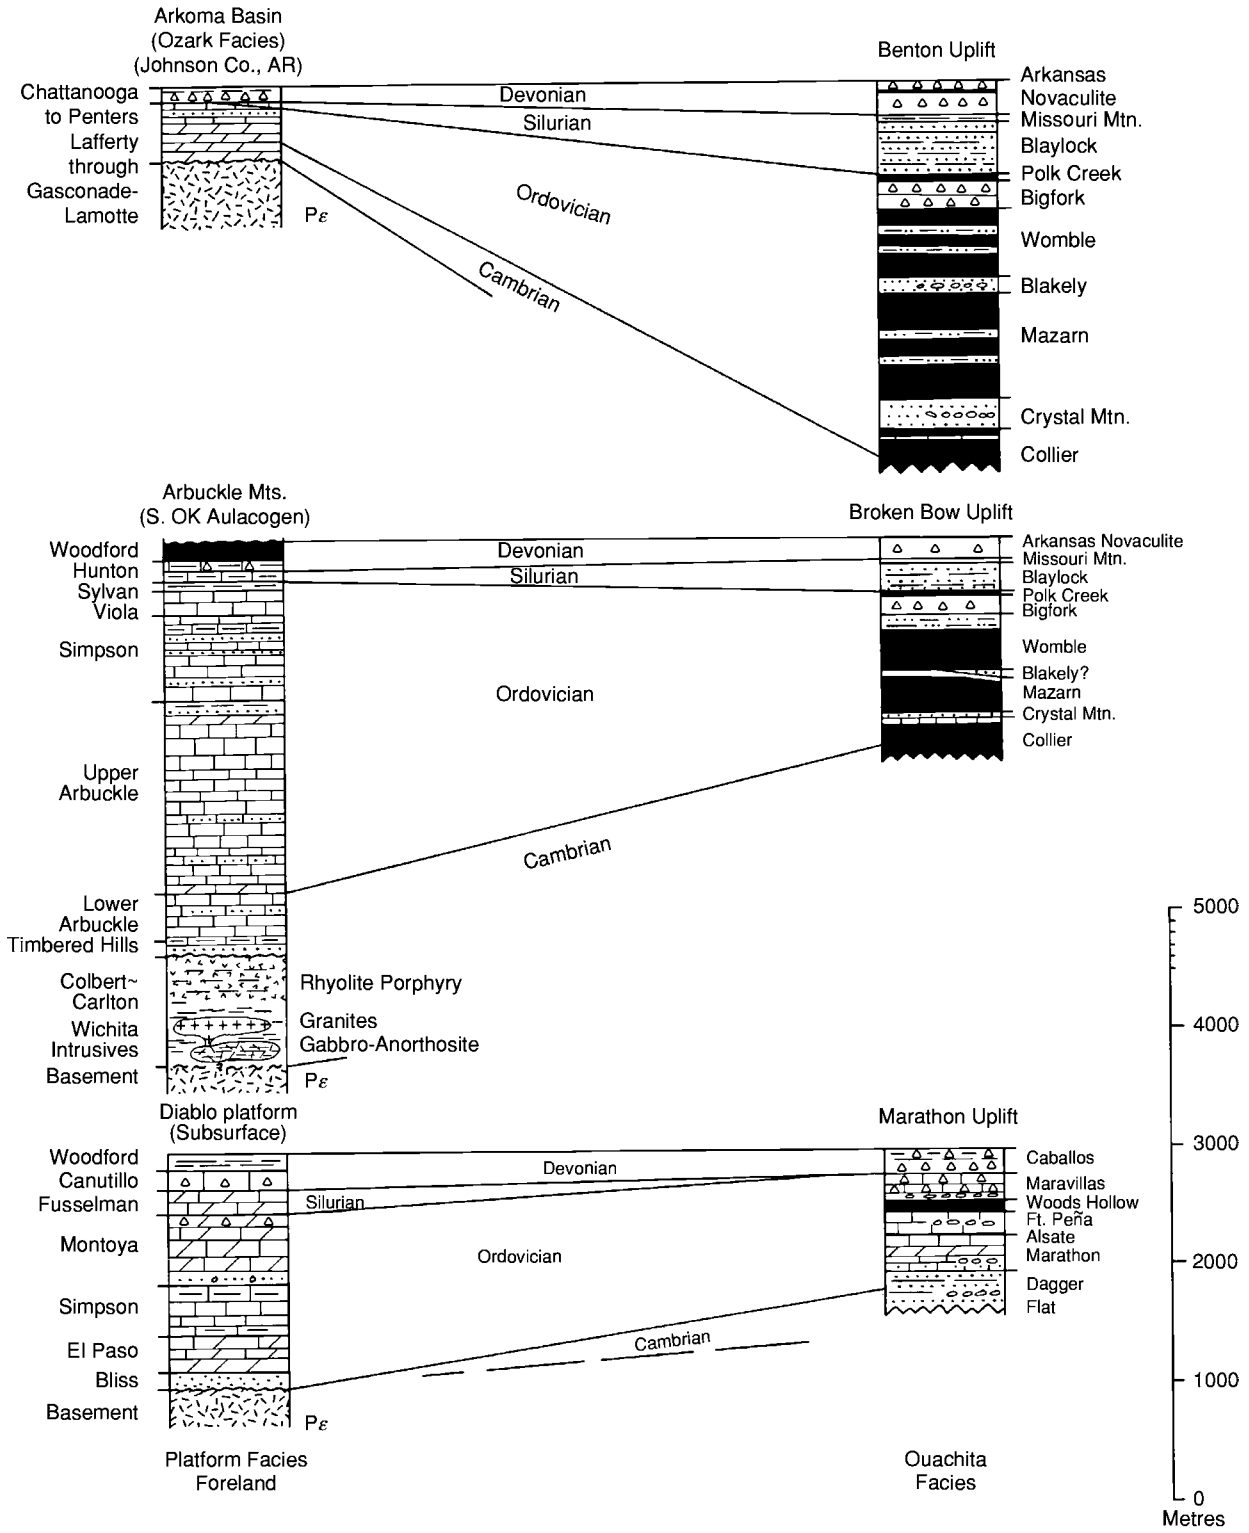

Figure 2 Representative lithological columns of the pre orogenic sequences at various settings along the Ouachita Orogen. (After Arbenz, 1989.)

margin. A northward migrating depositional centre characterizes the syn-orogenic sequence. The Stanley Group is 3.3 km thick just north of the Broken Bow Uplift. The Jackfork Group reaches a maximum thickness of 2.1 km along the axis of the Ouachita Mountains, and the Atoka Formation is thickest in the frontal Ouachita Mountains. While the entire section is allochthonous, these displaced depocentres are believed to be in relative order. Within the thrust belt, the Atoka Formation is the youngest deformed unit, but in the Arkoma Basin the Atoka Formation is overlain by additional deltaic deposits of Late Pennsylvanian Carboniferous age. The syn-orogenic sequence of the Marathon Uplift is also dominated by turbidite deposition but the sequence is thinner (Figure 3). The lower turbidite is 2.0 km thick in the eastern portion of the basin and thins to approximately 100 metres of shale in the west. There are abundant soft sediment deformational features in the section and these indicate extension parallel to the north-west trending palaeocurrents. The Tesnus Formation extends through the Mississippian into the Early Pennsylvanian and is overlain by the Dimple Limestone. This thin carbonate turbidite contains a clast assemblage of cratonic shelf rocks. The palaeocurrent data confirms a north-west source. The Haymond Formation is a repetitive siliciclasitc turbidite package that maintains a consistent 1.2 km thickness across the Marathon Basin. In this case, the palaeocurrents are trending WSW. The Haymond Formation includes important boulder beds that yield Early Palaeozoic rocks representing the pre-orogenic sequence and a full range of exotic rock types including various igneous clasts, some of which are Siluro-Devonian. These exotic clasts are commonly interpreted to have come from a southern source. The youngest unit in the Marathon Basin is Latest Pennsylvanian molasse type of sediments of the Gaptank Formation.

Regional Subdivisions

The Ouachita Orogen can be subdivided into four parts. The eastern section extends from central Mississippi north-westwards into Arkansas. This section is entirely in the subsurface. North of the tectonic front, a passive margin carbonate shelf of Cambrian to Early Mississippian age is overlain by Late Mississippian to Middle Pennsylvanian shallow marine to deltaic sediments. This sequence dips beneath the tectonic front which translates deep-water undifferentiated mudstones, cherts, and sandstones of the Ouachita facies.

The Ouachita Mountains represent the largest outcrop area along this orogenic belt (Figure 1). Similar to the pattern documented to the east, the carbonate shelf and overlying Carboniferous clastic sequences are structural below the allocthonous Ouachita facies. A minimal estimate for this translation is in the order of 100 km and maybe much greater. The Ouachita Mountains are commonly subdivided into the frontal imbrication zone between the Choctaw/Y-City and Windingstair faults, the central zone extending southward to the Broken Bow-Benton Uplifts, and then the Athens Plateau south of the uplifts. The imbrication zone is characterized by closely spaced thrust sheets made up of the younger Carboniferous units. The central zone, on the other hand, contains older Carboniferous units folded into a few long wavelength (8–16 km), north vergent synclines each truncated by a large thrust fault. The uplift areas trend ENE obliquely across the general east–west structural fabric of the Ouachita Mountains. These uplifts expose intensely deformed Ouachita facies and the Lower Stanley Group. The deformational history is more complicated than seen in the overlying central zone with at least three folding events and associated cleavage development recognized. Two distinctive aspects of these older rocks include a significant development of southerly verging folds and a disharmonic relationship to the large-scale folds of the central zone. The uplifts are also the location of low-grade metamorphism as reflected in recrystallized cherts (novaculite), chlorite growth, vitrinite reflectance, and ubiquitous quartz veins. The maximum temperature for these metasediments approach 300°C in the southern Broken Bow and eastern Benton Uplifts (Figure 4). The Athens Plateau has a structural style similar to the central zone to the north-west, northerly verging faults-truncating the Carboniferous sequence.

Within Texas, the Ouachita Orogen has been traced almost 1000 km in the subsurface. The structural subdivisions of the Ouachita Mountains have been extended (Figure 1). In this case, the 'frontal zone' includes all of the unmetamorphosed northerly verging structures inboard of the uplifts. The 'interior' zone is correlated to the uplifts of the Ouachita Mountains and includes deformed metasediments presumed to be equivalent to the pre-orogenic sequence. The Athens Plateau sequence is defined as the 'southern Carboniferous province' in the subsurface, but is only documented immediately south of the exposed Ouachita Mountains. The frontal zone varies in width and can be followed south to central Texas. The most distinctive structural element in the frontal zone is the leading thrust as this boundary is clearly proven by drilling. The interior zone extends from the Broken Bow Uplift, but is not continuous across north-east Texas (Figure 1). In general, the

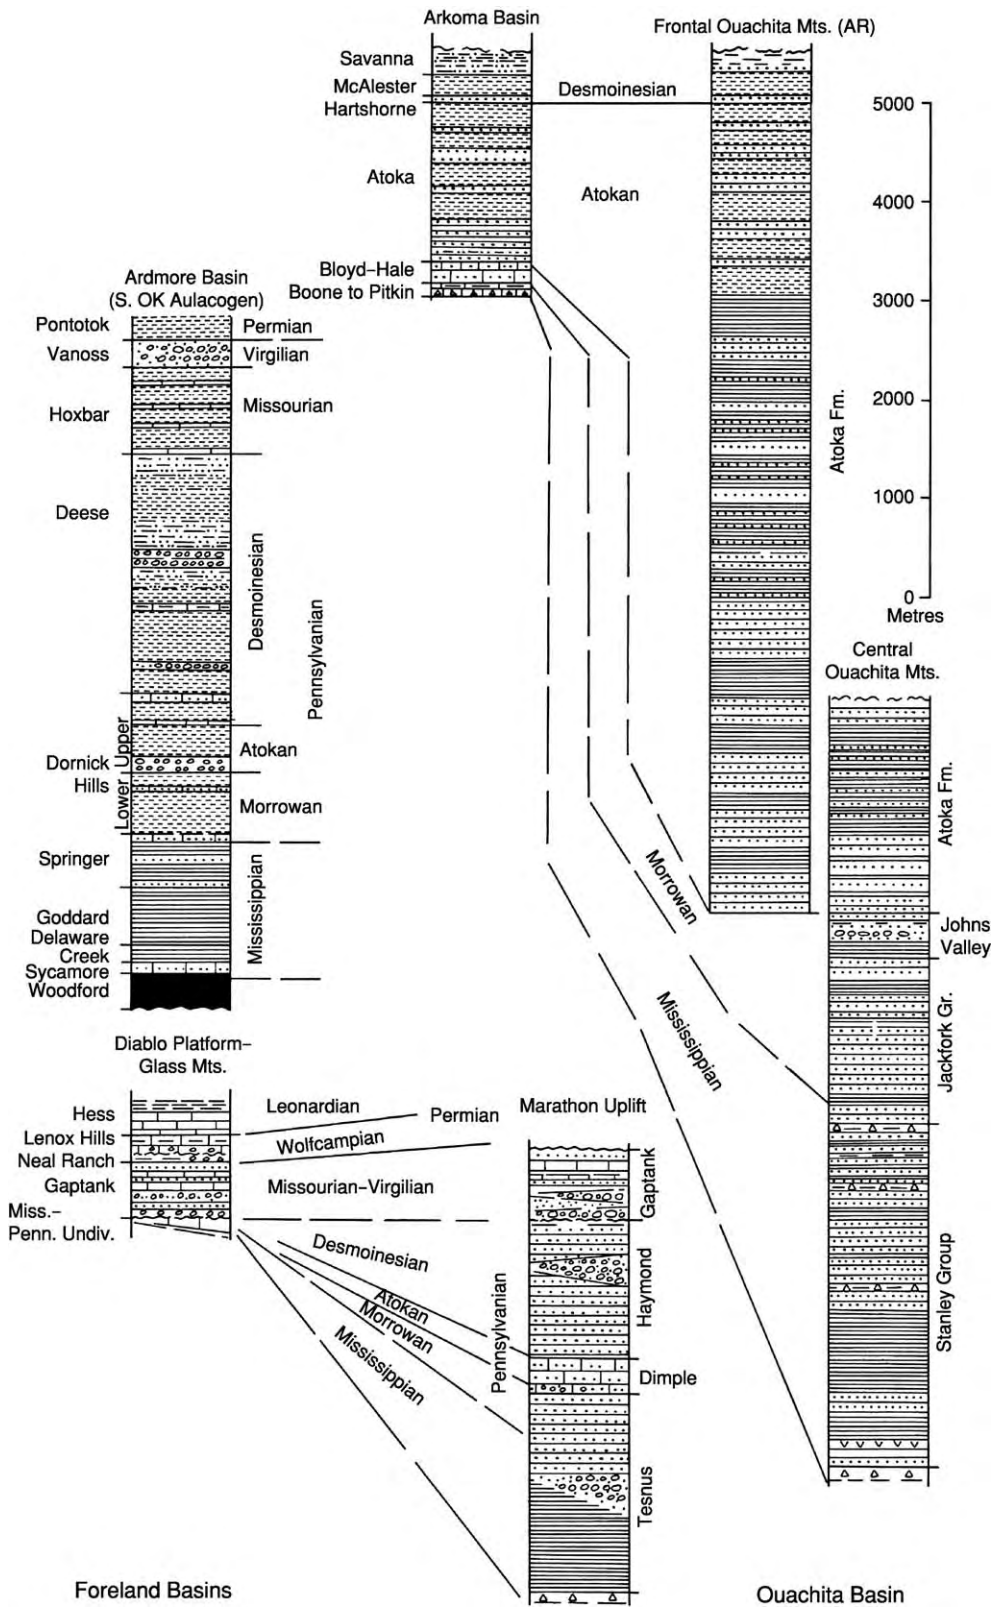

Figure 3 Representative lithological columns of syn orogenic sequences showing the transition from the craton to the Ouachita Basin. (After Arbenz, 1989.)

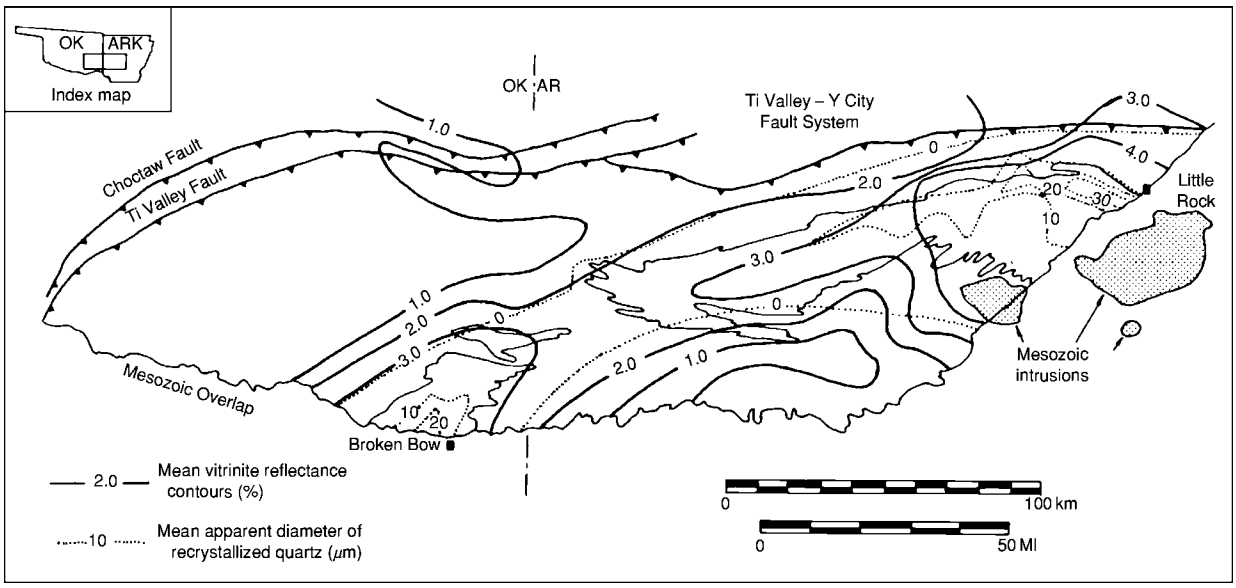

Figure 4 Thermal maturity of exposed strata of the Ouachita Mountains. (After Viele and Thomas, 1989.)

interior zone follows the frontal zone and together they form an 80 km wide belt. The frontal zone appears to be cut out in south-central Texas only to reappear east of the Marathon Uplift. Two notable uplifts are documented along this subsurface trend: the Waco Uplift along the south-trending section and the Devils River Uplift along the westerly-trending section. The first is interpreted to be a segment of the North American Craton thrust inboard carrying an overlying allocthonous section of Ouachita facies. The second uplift is an approximately 120 km by 50 km northwest-trending Precambrian block juxtaposed to the Carboniferous foreland basin.

The last segment of the Ouachita Orogen is located in West Texas and includes the exposures of the Marathon Uplift and two smaller outcrops to the south-west (Figure 1). Similar to the Ouachita Mountains, the entire outcrop belt of Marathon Uplift is allochthonous. This area is correlated to subsurface frontal zone. The stratigraphic sequence is similar to that of the Ouachita Mountains. The folding style is directly related to the nature of the lithologic package, long wavelength folds in the thick flysch sequence and complex, tight folding and faulting in the pre-orogenic sequence. The measured shortening has been utilised to restore this belt to a palaeogeographic position as much as 200 km to the south-east.

Five foreland basins are an integral part of the Ouachita Orogen (Figure 1). From east to west, these include the Black Warrior, Arkoma, Fort Worth, Kerr, and Val Verde basins. The Black Warrior Basin is critical in that it is bordered on two sides by convergent zones; the Ouachita thrust faults cut the southwest side of the basin and the Appalachian thrust belt on the south-east intersects these faults. The Black Warrior Basin is a homocline dipping gently towards the tectonic front and extending beneath the front. This homocline rises up to a large domal structure, the Nashville Dome, to the north. The pre-orogenic sequence rests on Precambrian basement and is dominated by carbonate shelf deposition. The Upper Mississippian-Pennsylvanian syn-orogenic clastic wedge progrades north-eastward. This section thickens towards the tectonic front and is consistent with tectonic loading at a convergent margin. The other foreland basins have similar geometries and pre-orogenic successions. They differ primarily in the nature of the syn-orogenic sequence, both in timing and depositional environments.

Regional Geophysics

The Bouguer anomaly map represents the most extensive geophysical data set for the region (Figure 5). A positive anomaly associated with the interior zone can be followed from central Arkansas through Texas into the Marathon region. The extension of this belt from Arkansas into Mississippi is more obscure. While uplifted basement blocks, mafic intrusions, and metamorphism contribute to the anomaly, the anomaly requires a major transition in crustal structure

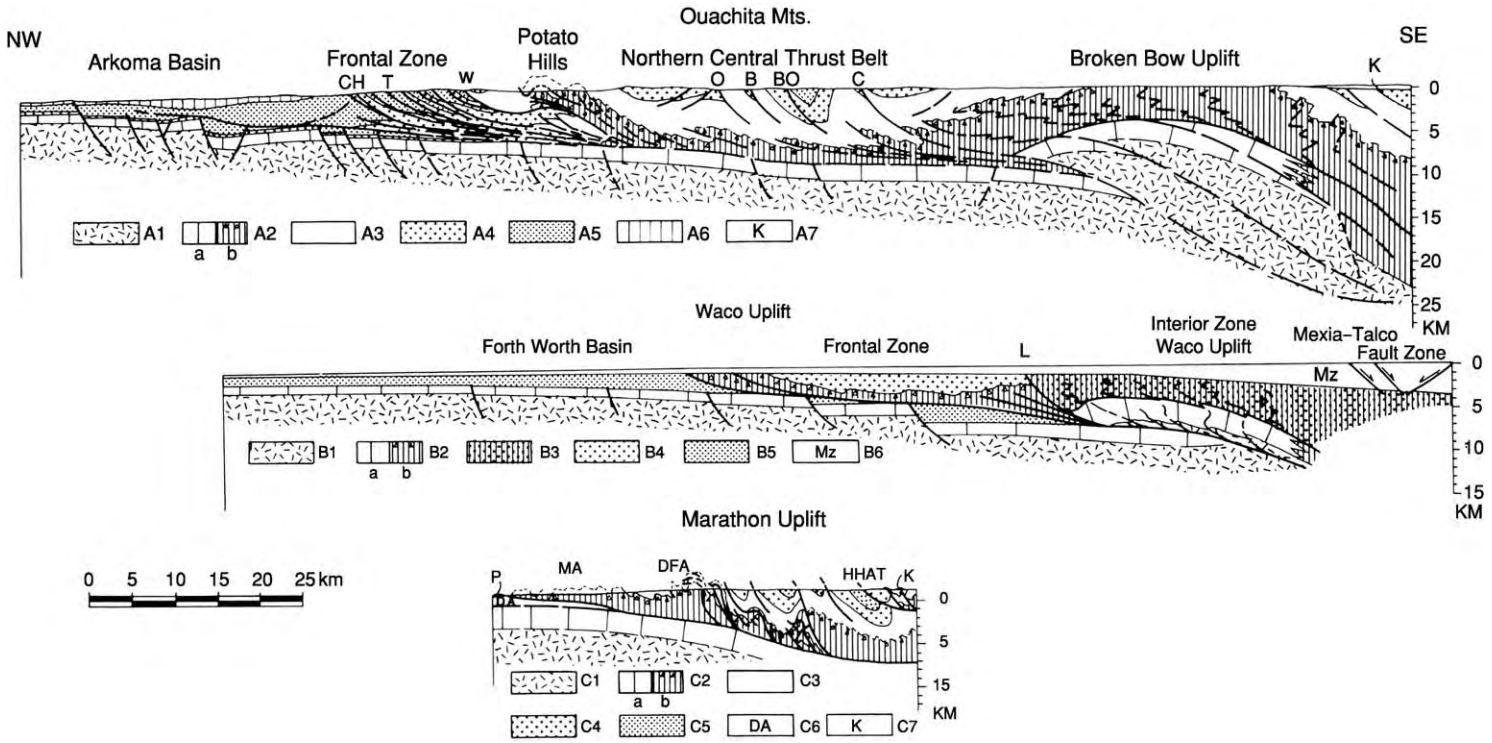

Figure 5 Generalized cross sections across the Ouachita Orogen in Oklahoma and Texas. (From Hatcher *et al.*, 1989) (Modified from Arbenz, 1989.)

across this trend. In other words, it is proposed that this anomaly represents the Early Palaeozoic continental margin. Of similar amplitude is the northwest-trending positive anomaly associated with the Southern Oklahoma aulacogen (Figure 6). Allowing for the uplifted Precrambrian blocks and mafic intrusions, this implies significant crustal modification during rifting. The aulacogen trend is clearly developed from the Panhandle area of Texas southeastward to the Ouachita Orogen where the two trends form a distinctive X-pattern. Closed gravity minima are observed for three of the foreland basins: Arkoma, Fort Worth, and Kerr basins. Gravity lows are noted in the Black Warrior and Val Verde basins, but the pattern is more subdued. Of these Basins, the Arkoma Basin is the most dramatic (~80 mgal). Interestingly, the lowest values of this minimum are located just north of the Broken Bow Uplift where a steep gradient is also apparent. This pattern argues for a thick sedimentary section in the central Ouachita Mountains, some of it possibly below the allocthonous Ouachita facies. The Benton, Broken Bow, and Waco uplifts are actually located on the gradient inboard of the interior zone anomaly. Thus, these uplifts have a similar density to the Ouachita facies; that they are not deeply rooted in the basement and have been translated significant distances. In addition, the uplifts probably reflect late stage compressional deformation along the transitional crust of the continental margin. In contrast, the Devils River Uplift does reveal a distinct positive anomaly related to the large Precambrian block.

Regional seismic data is widely scattered. Early refraction and surface wave studies document a normal continental crust north and west of the margin and an ambiguous noncratonal crust model south of the margin. The COCORP line in southwestern Arkansas is the longest line across the fold and thrust belt. Crustal models based on the COCORP and additional data to the south show an increase in velocities, which have been interpreted to be interleaved granitic and basaltic crust. In this area, the Early Palaeozoic transitional crust is thought to be preserved; and the deformed Palaeozoic section is detached and transported northward over the continental margin. Seismic reflection data support the allocthonous, northerly verging geometry of this fold and thrust belt. Additional features identified in

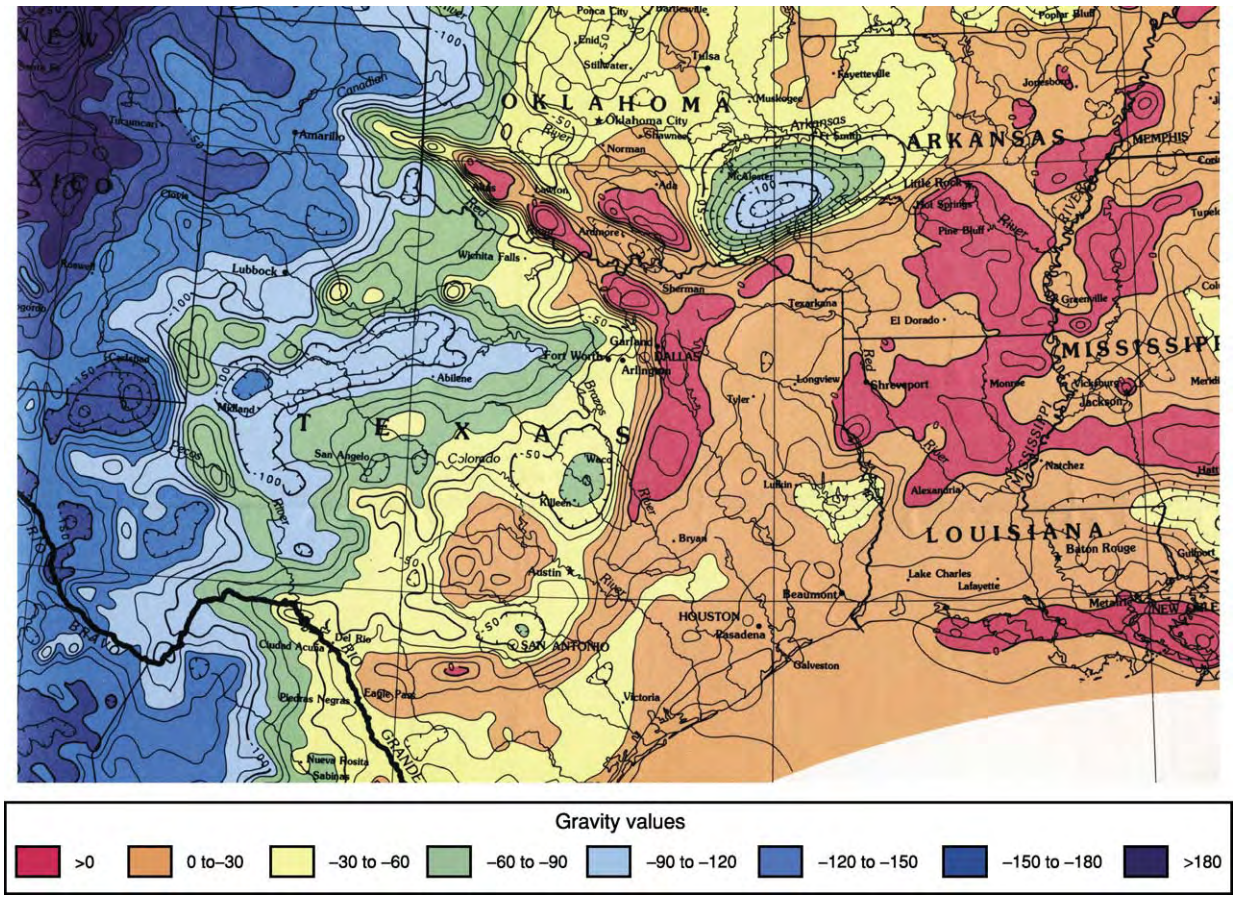

Figure 6 Bouguer Anomaly Map of south central North America. Contour Interval is 10 Milligals. (After Keller *et al.*, 1989.)

the COCORP line are the basement cored uplift, Early Palaeozoic sections overlying a presumed Precambrian basement, allocthonous Ouachita facies structurally overlying the Early Palaeozoic section, and a tectonically thickened section of Carboniferous units south of the uplift. A final feature identified in the subsurface is a successor basin of Late Pennsylvanian sediments in unconformable contact with the deformed Carboniferous units south of the Ouachita Mountains (Figure 1).

Tectonic Synthesis

Representative cross-sections provide a clear picture of the structural style of the Ouachita Orogenic Belt (Figure 6). Common to these sections is the dominant thin skin style of deformation. The amount of translation is minimally 50 to 100 km; the greatest of these displacements appear to be in the salients. The foreland basin reveals the tilt of the basement and the pre-orogenic sequence towards the tectonic zone. Also, the strongly asymmetric nature of the foreland basin is outlined. In the Ouachita Mountains, the extremely thick sedimentary succession north of the Broken Bow Uplift is illustrated along with the large folds of the central zone. The basal detachment is above the shelf sequence, possibly with a Carboniferous section also in the footwall. Commonly, the detachment is interpreted to extend over the basement uplift. The pattern is similar in the Waco Uplift, although the basement block is much thinner. The Marathon cross-section is limited to the exposed uplift and reflects a style similar to the frontal zone of the Ouachita Mountains, but well data has extended the thrust further to the south where some metamorphic rocks have been associated with the 'interior zone'.

The Ouachita Orogen represents the imprint of the collision of North America, South America, and possibly several small continental blocks and/or island arcs. The specific nature of these blocks is debatable; however, there is agreement about the general timing. Initial subsidence is recorded by the shift from the Devonian chert and siliceous shale deposition to the Carboniferous turbidite sequence. In the Ouachita Mountains, this transition is in the Lower Mississippian. Similar timing is envisioned for the Caballos Novaculite of the Marathon region. Coincident with the change in the basin, the shelf areas of the Black Warrior Basin experienced a change from the Lower Mississippian shallow marine chert and limestone to an Upper Mississippian clastic wedge. This Mississippian clastic wedge prograded northeastward, reflecting a source to the south-west. In the Arkoma Basin, however, the shelf was stable with Mississippian shallow marine limestone grading southward into mudstones. A second clastic wedge in the Black Warrior Basin of Pennsylvanian age is more extensive, and merges with a another wedge prograding from the Appalachian tectonic front. Within the Arkoma Basin, deltaic sedimentation on a stable shelf continued until Middle Pennsylvanian (Lower Atokan). This was followed by the development of down-to-south normal faults and syn-orogenic deposition. Thrust faults truncate the Pennsylvanian sediments in the foreland basins. The Arkoma Basin is divided into a southern compressional zone and a northern extensional zone related to plate loading and normal fault development. The youngest units of the Arkoma Basin involved with the Ouachita Orogenesis are mid-Desmoinesian (Late Pennsylvanian). Coincident with this compression is the development of a successor basin south of the exposed Ouachita Mountains. Desmoinesian shallow marine deposits rest unconformably on deformed Ouachita Carboniferous units. In the Marathon area the compressional deformation is subdivided into two phases. The first phase corresponded with the folding of the Dimple Limestone, formation of the Val Verde foreland Basin, and the transition syn- to post-orogenic sediments (Gaptank Formation). The timing of this phase is Middle to Upper Pennsylvanian. The younger phase deformed these folded and faulted Pennsylvanian units as part of the development of the Dugout Creek Thrust. This younger phase extended into the Early Permian (Wolfcampian).

While initial subsidence appears to be nearly coincident along the length of the Ouachita Basin, the compressional events began earlier in the east (Middle Mississippian). It has been suggested that this early phase was related to a collision with an island arc along the south-east margin of North America. The 'two tier' fold style developed in the Ouachita Mountains is interpreted as reflecting deformation in two distinctly different settings. The earliest deformation involved Cambrian through to Early Mississippian basinal sediments. Tight folds and faults developed in a growing accretionary wedge above the oceanic and transitional continental crust. The remainder of the Carboniferous flysch sequence was then deposited over these deformed units and the entire accretionary prism was thrust onto the southern margin of North America in the Late Pennsylvanian. As mentioned above, the final stages of thrust faulting were Desmoinesian in the Ouachita Mountains. The principal thrusting began about this time in West Texas and continued into the Early Permian. Therefore a diachronous model is commonly applied to the Ouachita Mountains, closing from east to west. Thrust faults of the Appalachian Alleghenian

Orogeny truncate the Ouachita trends in the Black Warrior Basin. The final stages of deformation in the Ouachita Mountains are also documented in the rotated folds and cleavages of the Broken Bow and Benton uplifts. These basement cored structures trend ENE and reflect a rotation of the principal shorten direction. It has been proposed that these uplifts represent the far-field effects of the Alleghenian collision to the south-east. Various microplates have been proposed to account for the translation of the Ouachita facies inboard over the coeval shelf sequences. Collectively these have been identified as the Sabine Plate and represent elements trapped between South and North America during the assembly of Pangaea. Subsequent Mesozoic rifting associated with the development of the Gulf of Mexico have unfortunately obscured these relationships.

Southern and Central Appalachians

R D Hatcher, Jr, University of Tennessee, Knoxville, TN, USA

> The Appalachian Chain is the most elegant on Earth, so regularly arranged that its belts of formations and structures persist virtually from one end to the other. . . . But the apparent simplicity is deceiving; actu ally it is full of guile, and its geology has aroused contro versies as acrimonious as any of those in our science.
>
> (Philip B King, 1970)

Introduction

The exposed Appalachians extend from Alabama to Newfoundland, with buried components extending eastward and southward beneath the Gulf and Atlantic coastal plains, and the Atlantic continental shelf (Figure 1). The southern and central Appalachians reach their greatest width in Tennessee, the Carolinas, and Georgia. To the north, the chain reaches its narrowest point at the latitude of New York City, and from there it widens northward again into New England. Physiographical provinces from north-west to south-east include the Cumberland–Allegheny Plateau, Valley, and Ridge from Pennsylvania southward, the Blue Ridge from South Mountain in southern Pennsylvania to northern Georgia, and the Piedmont from New Jersey to Alabama. Basins filled with Late Triassic–Early Jurassic sedimentary (and some volcanic) rocks that formed prior to the opening of the present Atlantic Ocean are superposed on the Piedmont from North Carolina northward. Physiographical provinces to the west correspond roughly to geological provinces, but there is little correspondence with geological provinces in the interior of the chain. The southern Appalachians contain the highest mountains in the entire chain. Though there is one mountain (Mt Washington, New Hampshire) in New England with an elevation greater than 6000 ft (~2000 m), and none farther north, there are at least 39 named peaks in the southern Appalachian Blue Ridge of western North Carolina and eastern Tennessee with elevations exceeding 6000 ft. Topographic relief here can exceed 5000 ft (1600 m).

The Appalachians were created following the rifting of the Rodinia supercontinent during three or more Palaeozoic orogenic events: the Ordovician–Silurian Taconian, the Devonian Acadian and Devonian–Mississippian Neoacadian, and the Pennsylvanian–Permian Alleghanian orogenies (Figure 2). All orogenies were diachronous. The character of the orogen changes roughly at the latitude of New York City, from one constructed largely from west to east to the north, to an orogen built from the inside out to the south, with the exception of the Alleghanian Thrust Belt that extends up the Hudson River Valley to just south of Albany, New York (Figure 3).

Philip King doubtlessly had the southern and central Appalachians in mind when he made his observation about the Appalachians. These mountains have been studied for over 150 years, and several fundamental concepts in geological science were developed in the process. The continentward segment of the chain consists of a foreland fold–thrust belt that changes style within; it is fold-dominated from Pennsylvania to south-west Virginia, thrust-dominated from south-west Virginia to Alabama, and fold-dominated again in Alabama (Figure 3). This along-strike change in character is related to changes in mechanical stratigraphy, to relationships of the shape of the original continental margin, and to the shape of the Gondwanan indenter that collided with Laurentia at the end of the Palaeozoic. The internal parts of the chain to the east initially consist of deformed rifted margin sedimentary rocks and recycled Grenville basement. These give way eastward to accreted terranes of distal Laurentian metasedimentary oceanic and arc-affinity material (Tugaloo, Chopawamsic, Potomac, and Baltimore terranes), then a sequence of mid-Palaeozoic metasedimentary rocks (Cat Square Terrane), and a truly exotic peri-Gondwanan (Pan-African) Carolina–Avalon Superterrane of Neoproterozoic to Ordovician arc volcanic and volcaniclastic rocks, including the Smith River allochthon (Figure 3). The subsurface Suwannee Terrane lies south of an east- and west-trending suture zone in southern Georgia and Alabama (Figure 4), and contains Gondwanan-affinity basement and cover sedimentary rocks to the south. The Appalachian collage records a complete Wilson Cycle of the opening and closing of a series of Palaeozoic oceans, starting with rifting of the supercontinent Rodinia and ending with the assembly of the supercontinent Pangaea.

The reference frame used throughout this article is the present geography. However, the equator trended north–south (present geographic frame), bisecting North America during the Early and Middle Palaeozoic. Laurentia rotated counterclockwise during the Middle to Late Palaeozoic, bringing the continent into its present orientation, but still at equatorial

latitude. Most subsequent movement of Laurentia during the Mesozoic and Cenozoic has been northward to its present location north of the equator.

Neoproterozoic to Ordovician Iapetan Margin Development and Destruction

Rifting of Rodinia

Supercontinent Rodinia formed 1.2–1 billion years ago (Ga) as a product of the worldwide Grenvillian Orogeny. The continent remained intact for ~300 million years (My) and then rifted apart at ~750 Ma in western and north-eastern North America, but failed rifting occurred at ~735 Ma in the southern and central Appalachians. Failed rifting, however, produced the alkalic A-type Crossnore plutonic–volcanic suite; the Grandfather Mountain and Mount Rogers Formation marine, non-marine, and glaciogenic sedimentary and bimodal volcanic rocks in North Carolina, Tennessee, and Virginia; and the Robertson River igneous complex in central Virginia. Successful rifting of Rodinia along the entire southern-central Appalachian margin occurred at ~565 Ma, with basins that deposited the Ocoee Supergroup in Tennessee, North Carolina, and Georgia, and the Catoctin volcanic–sedimentary assemblage in Virginia. Neither of these assemblages is physically connected, because initial rifting created an irregular margin in south-eastern Laurentia, leaving basement highs that separated rift basins.

Deposition of the Ocoee Supergroup locally reached thicknesses exceeding 15 km, with most of the thickness contained in the Great Smoky Group. The Ocoee Supergroup contains three groups: (1) the Snowbird Group, which rests unconformably on Grenvillian basement, (2) the Great Smoky Group, which nowhere has been observed in direct contact with basement rocks and is faulted onto the Snowbird Group rocks, and (3) the Walden Creek Group, which conformably overlies both the Great Smoky Group and the Snowbird Group, revealing an extraordinarily complex relationship between the components of the Ocoee Supergroup. The Snowbird Group consists of immature basal sandstone overlain by much cleaner quartz arenite to arkosic sandstone, then a pelitic unit. The Great Smoky Group consists of a rapidly deposited deep-water sequence of immature greywacke and pelite (some of which was deposited in an anoxic environment), minor amounts of cleaner sedimentary rocks, and polymictic vein quartz-dominated conglomerate that also contains quartzite, sandstone, granitoid, black shale rip-ups, and variably textured limestone and dolostone clasts. The Walden Creek Group consists of banded chlorite–sericite slate that contains minor amounts of limestone overlain by shale, clean sandstone, and limestone. The latter unit has yielded soft-bodied wormlike fossils, and possible ostracodes and inarticulate brachiopods, indicating a Cambrian (probably Tommotian) age. Coarse polymictic vein quartz-dominated conglomerate facies also occur within this unit, and again the clasts are

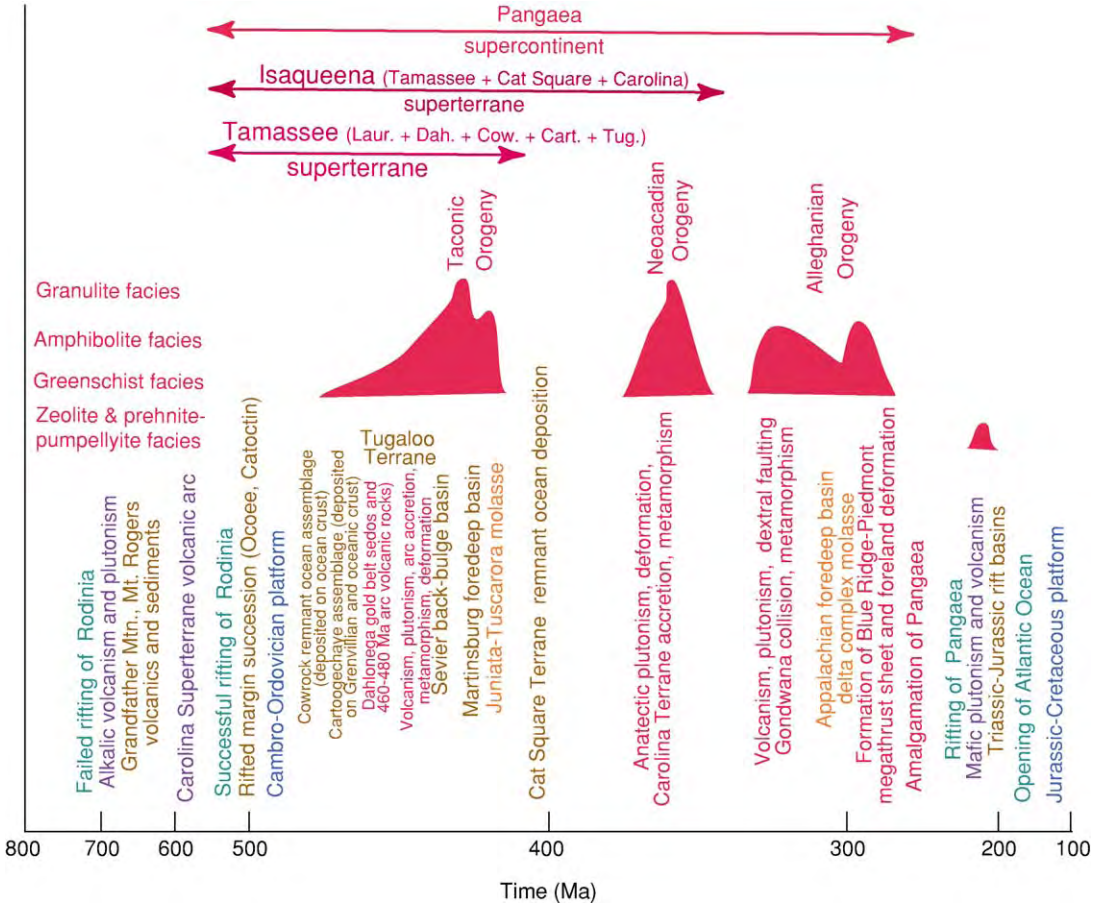

Figure 2 Events distributed through time in the Appalachian Wilson Cycle. High points on the curves denoting orogenies indicate locations of maxima in time and maximum pressure and temperature conditions. Compressional events and related activities are red; arc and rifted margin volcanism is purple; clastic wedges are brown and orange; carbonate platforms are blue; rifting events are green. Note that the horizontal scale is expanded between 500 and 200 Ma.

dominated by vein quartz; several textural and compositional variations of limestone and dolomite; and quartzite, sandstone, and black shale rip-ups. Many of the conglomerates clearly were deposited in channels; armoured mudballs have been observed in at least one palaeochannel. Though the Ocoee Supergroup thins gradually southward to near Cartersville, Georgia, its thickness rapidly decreases northward from its maximum of 15 km in the Great Smoky Mountains National Park, to zero south-east of Johnson City, Tennessee.

In central Virginia, the Ocoee-equivalent ~565-My-old Catoctin Formation consists of basalt and rhyolite, with some interlayered clastic sedimentary rocks that are locally underlain by an older suite of immature rift-related sedimentary rocks (Snowbird Group equivalent?). East of the Blue Ridge anticlinorium in northern North Carolina and Virginia is a sequence of distal, deeper water clastic sedimentary and rift-related volcanic rocks, the Ashe–Alligator Back-Lynchburg sequence. More distal eastward and south-eastward equivalents of these metasedimentary and metavolcanic rocks (Ashe–Tallulah Falls–Sandy Springs) have been recognized in the eastern Blue Ridge and Inner Piedmont from the Carolinas to Alabama. They are overlain by Cambrian–Ordovician(?) metasedimentary rocks (Candler, Chauga River), and by Middle Ordovician(?) mid-oceanic ridge basalt-arc volcanic rocks (Slippery Creek–Poor Mountain–Ropes Creek). Farther east in the Virginia Piedmont is a sequence of felsic–mafic volcanic rocks from ~470 Ma (Chopawamsic) that were intruded by plutons at ~455 Ma, then overlain by fossiliferous Late Ordovician (Ashgill) fine-grained clastic rocks comprising the Chopawamsic Terrane.

The Lower Cambrian Chilhowee Group was deposited on the Laurentian margin during the rift-to-drift transition, and consists of upward-maturing alternating sandstone and shale units. The lowest unit consists of immature sandstone and greywacke with some basalt. The upper part of the Chilhowee Group

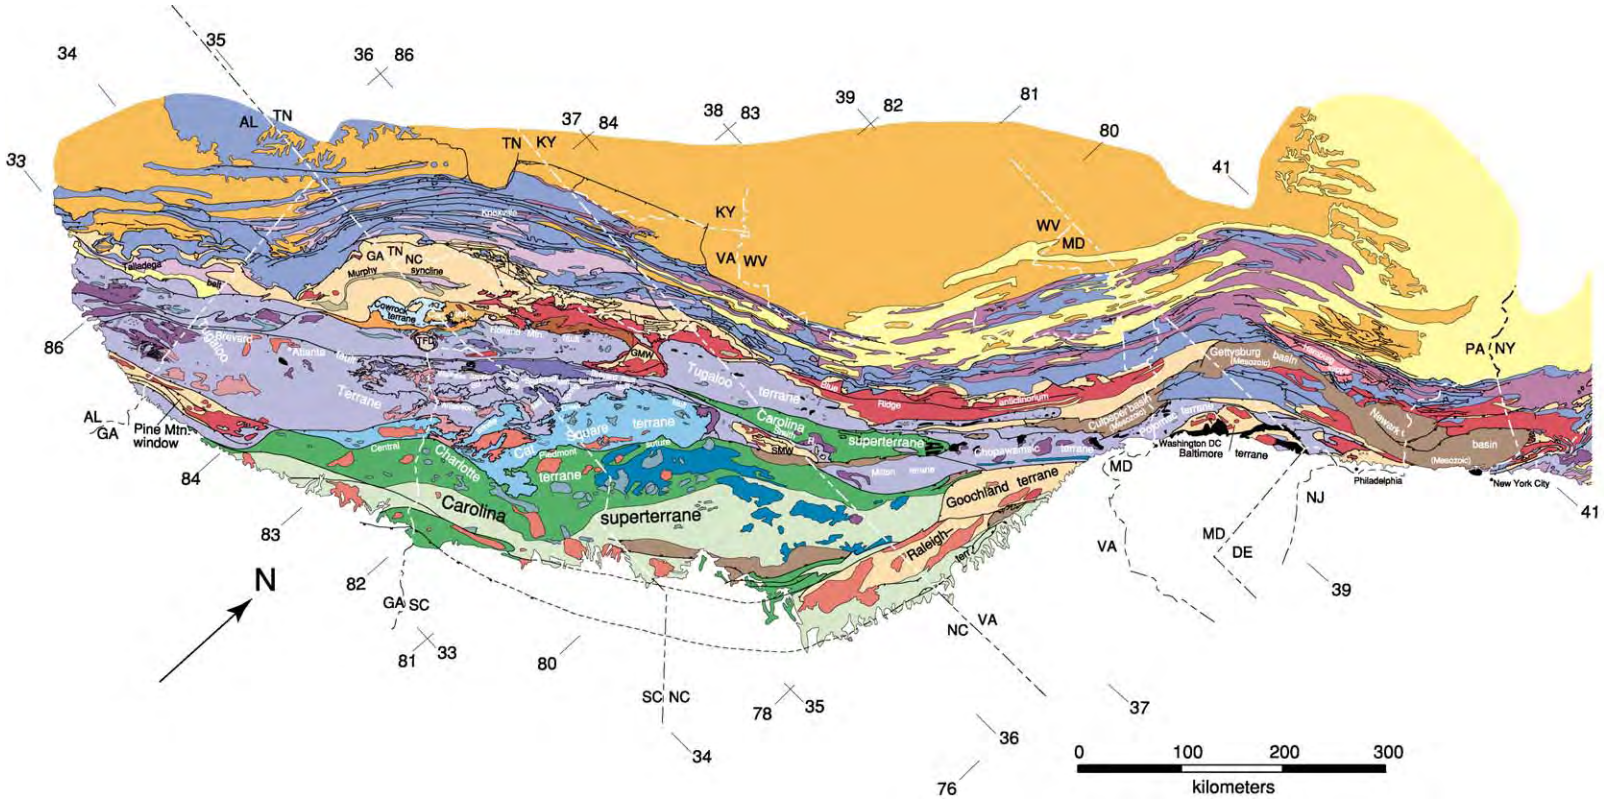

Figure 3 Tectonic map of the southern and central Appalachians. GMW, Grandfather Mountain window; SMW, Sauratown Mountains window; TFD, Tallulah Falls Dome; Cart. Terr., Cartoogechaye Terrane. Colour key: ultramafic rocks are black; Alleghanian clastic wedge is orange (to north west); Acadian clastic wedge is light yellow (north eastern and south western parts of map); Middle Ordovician (Sevier, Blountian) clastic wedge is lavender; Upper Ordovician Silurian Martinsburg Tuscarora (type Taconian) clastic wedge is wine; Cambro Ordovician platform rocks are dark blue; rifted Laurentian margin Neoproterozoic to Cambrian clastic and volcanic rocks are tan; Murphy syncline is olive green with lavender in centre (imbedded in tan in Georgia and North Carolina); 1.1 Ga (Grenvillian) rocks are red; pre Grenvillian 1.8 Ga Mars Hill Terrane is brown orange (next to large red area in the Blue Ridge); Cowrock Terrane is light blue (in Georgia and North Carolina); Cartoogechaye Terrane is light orange (in Georgia and North Carolina); Dahlonega gold belt is burnt orange (Georgia and North Carolina); Hamburg Klippe is pink (north eastern part of map); high grade parts of Carolina Superterrane are dark green; low grade parts of Carolina Superterrane are light green; Neoproterozoic pluton is light grey (north west of GMW); Neoproterozoic to Early Cambrian plutons (Carolina Superterrane) are dark blue green; Ordovician plutons are dark purple; likely Ordovician and Silurian plutons are medium purple; Devonian plutons dark gray green; Carboniferous to Permian plutons are red orange; Late Triassic Jurassic sedimentary and volcanic rocks are brown. Scale 1:2 500 000.

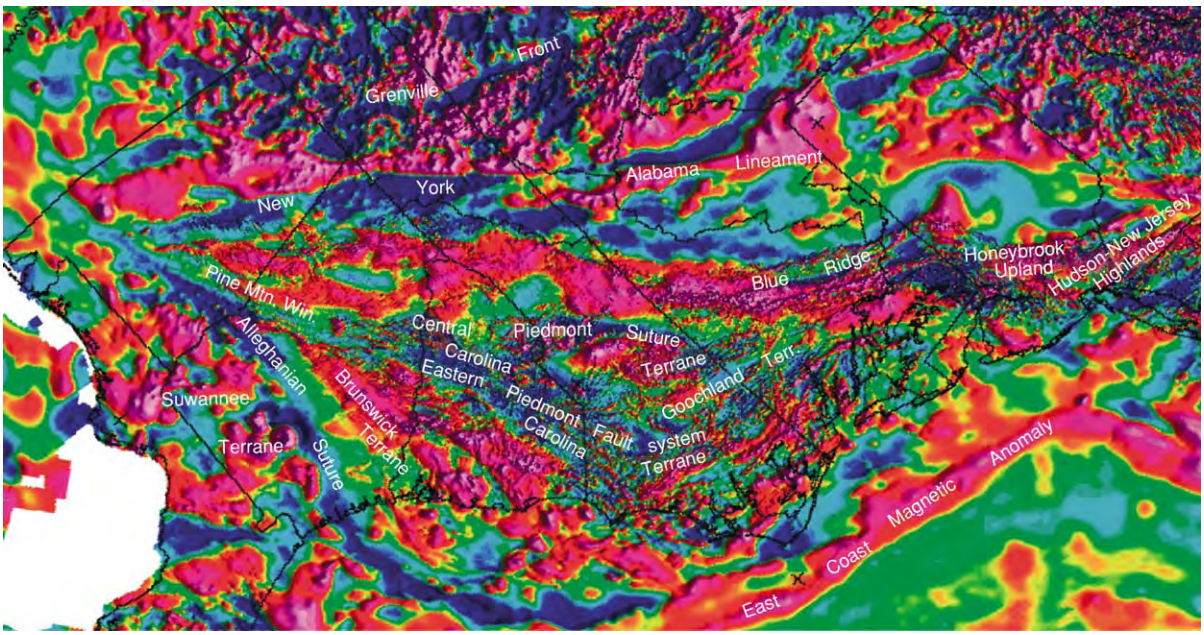

Figure 4 Magnetic map of major crustal features in southern and central Appalachia. Magnetic anomalies are shown in spectral colours, with red indicating highs and blue indicating magnetic lows. Image from the United States Geological Survey.

was probably deposited along the open-ocean margin, because it grades upward into the first successful carbonate bank assemblage. Both the Chilhowee Group and the overlying Shady (–Tomstown–Dunham) Dolomite are continuous throughout the Appalachian margin.

Passive Margin Evolution

Once the first carbonate bank was established, the south-eastern Laurentian margin continued to develop, with pulses of clastic sediment derived from the eroding Grenvillian mountains of progressively lower relief. From Late Cambrian to earliest Middle Ordovician time, carbonate deposition transgressed across the entire margin into the central interior of North America, extending westward as far as present-day westernmost Texas, and northward into southern and eastern Canada. This formed the first extensive carbonate platform across much of interior Laurentia. Following this great incursion of shallow-water marine carbonate deposition into interior North America, the entire carbonate platform was uplifted and a karst surface formed over all, except for an area in northern Virginia, Maryland, and Pennsylvania. Carbonate deposition resumed during the Middle Ordovician (Llanvirn). Shortly afterwards, the eastern margin began rapidly to subside as Ordovician volcanic arcs were obducted onto the eastern Laurentian margin (Figure 5). A foredeep formed in front of the arriving thrust sheets, to the west of that a forebulge, and a back-bulge basin formed ~200 km to the west into the platform. This

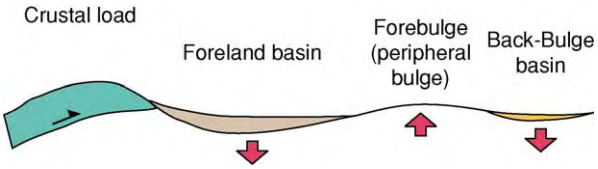

Figure 5 Ordovician loading of the Laurentian margin by obducted volcanic arcs, producing a foredeep basin, forebulge, and a back bulge basin farther into the continent.

back-bulge basin accumulated >3 km of clastic sediment in the southern Appalachians, forming the Sevier clastic wedge that graded westward into the thin platform limestone sequence. Potassium (K)-bentonite beds (Late Llanvirn) from continuing volcanic activity to the east were deposited throughout the southern and central Appalachians and on the adjacent platform to the west.

The younger (Caradocian) Martinsburg clastic wedge formed a thin successor basin atop the Sevier wedge in the southern Appalachians, but accumulated ~5 km of deep-water turbidic clastics in Pennsylvania, probably in a true foredeep. The Martinsburg assemblage graded upward into the shallower water Ashgill Juniata red-bed succession, and then into the Llandoverian Clinch–Tuscarora quartz arenite and Shawangunk Conglomerate (to the north-east). Though the source of the clastic sedimentary assemblage in the Sevier back-bulge and Martinsburg foredeep basins was clearly to the east, detrital zircon suites contain

no Palaeozoic components. All are dominated by zircons derived from Grenvillian and older Laurentian sources, suggesting provenance from exhumed and cannibalized platform, and rifted margin sedimentary and volcanic rocks. Clasts in Llanvirn polymictic conglomerates in the Sevier Basin sample platform carbonate and older lithologies, but none are derived from sources in the Taconian Orogen. Detrital zircon suites from the rifted margin succession (Ocoee Supergroup, Ashe Formation, and equivalents) across the southern Appalachian Blue Ridge and western Inner Piedmont (Tugaloo Terrane) are all dominated by zircons from ~1.1 Ga, with smaller components of zircons from 1.3–1.5 Ga. Dahlonega gold belt detrital zircons, though also dominated by 1.1- to 1.4-Gy-old components, contain components from 2.7–2.9 Ga, 1.9–2.2 Ga, and 650–700 Ma. These rocks were traditionally considered only a more distal facies of the Ocoee Supergroup, but detrital zircons suggest they may be more exotic. In addition, the Dahlonega gold belt contains an arc complex from 460 and 480 Ma.

Taconic Events

The Taconic Orogeny is clearly diachronous in the southern and central Appalachians, with earlier pulses beginning in the Late Arenig in the southern Appalachians and the younger event—the type Taconic Orogeny—beginning sometime in the Llandeilo or Caradoc in the central Appalachians. Corresponding suites of plutons, penetrative deformation, and metamorphism to conditions as high as granulite facies were a product of subduction, obduction, and arc accretion. The 455- to 460-My-old plutonic–volcanic suite (Hillabee, Ropes Creek, Poor Mountain, Chopawamsic, Baltimore) in the southern and central Appalachians has a mid-oceanic ridge basalt (MORB) to arc affinity. At that time, the Neoproterozoic to Cambrian rifted margin assemblage was A-subducted beneath the arc, penetratively deformed, and metamorphosed to mid-crustal metamorphic assemblages.

During the Taconic events, the Laurentian margin underwent A-subduction and several oceanic and arc assemblages were obducted onto the margin, with accompanying emplacement of the Cowrock, Cartoogechaye, and Tugaloo Terranes in the southern Appalachians, and the Chopawamsic, Potomac, and Baltimore Terranes in the central Appalachians (Figure 3). In New Jersey and eastern Pennsylvania, Grenvillian basement was remobilized in the core of the recumbent Musconnectong Nappe. Basement was also remobilized to the north-east (Hudson–New Jersey Highlands) and south-west, forming external massifs in the core of the Blue Ridge from Virginia to Georgia. Internal massifs in the eastern Virginia Goochland Terrane, the Tugaloo Terrane west of the Brevard fault zone in the Carolinas and north-eastern Georgia, and possibly in the Pine Mountain window in Georgia and Alabama were remobilized, although remobilization of basement in the latter may be younger (see later).

A suite of thrust sheets carrying deep-water sedimentary rocks was emplaced onto the New England and Canadian Maritimes margin at this time, locally carrying oceanic crust and mantle in ophiolite sheets (Quebec and Newfoundland). These extend into the central Appalachians as the Hamburg Klippe in New Jersey and the south-eastern Pennsylvania Piedmont. None has been identified farther south. Other premetamorphic thrusts formed at this time from the Pennsylvania Piedmont southward. Amalgamation of old and new crust generated during the Taconian events formed a superterrane along the south-eastern Laurentian margin.

Cat Square Terrane

Deposition continued until post-430 Ma in the still-open remnant of the Theic Ocean that lay between south-eastern Laurentia and the approaching Carolina Superterrane. Here a sequence of immature deep-water sandstones (subgreywacke to greywacke) and pelites that today consist of aluminous schist and biotite gneiss were probably deposited on oceanic(?) crust. Detrital zircons include the usual prominent 1.1- to 1.4-Ga suite, but with the addition of major components of zircons from 600, 500, and 430 Ma, along with small populations of zircons from 1.9–2.2 and 2.7–2.9 Ga. This diverse population suggests sediment was derived from both Laurentia and Carolina. Presence of younger zircons precludes docking of the Carolina Superterrane before the Late Devonian or Early Carboniferous.

Pine Mountain Terrane

The Pine Mountain Terrane in west-central Georgia and eastern Alabama is a complex window exposing 1.1-Gy-old Grenvillian basement and a thin cover sequence of Early Palaeozoic(?) schist, quartzite–dolomite, and a higher schist. The window is framed by the dextral Towaliga and Goat Rock and Dean Creek faults to the north and south, respectively, but is closed by the Box Ankle Thrust at the east end. All of these faults yield Alleghanian ages, but the Box Ankle Fault was emplaced at sillimanite-grade pressure and temperature (P–T) conditions, whereas the Towaliga and Goat Rock(?) faults moved during garnet-grade conditions, and the Dean Creek Fault moved under chlorite-grade conditions (the same as the Modoc, farther east). Detrital zircons from the

cover-sequence quartzite inside the window yield the usual dominance of ages from 1.1 Ga, but a significant component of zircons from 1.9–2.2 Ga occur there, suggesting a Gondwanan provenance for this sequence and basement. If this is a rifted block of Gondwanan basement, the emplacement kinematics would be very complex, because of the Late Palaeozoic ages of all of the faults framing the window. This basement block and its cover have traditionally been considered Laurentian and the cover sequence is thought to be metamorphosed platform rocks. It remains a suspect terrane.

Peri-Gondwanan Carolina Superterrane

Coeval with the rifting of Rodinia was the development of a number of Peri-Gondwanan terranes in the intervening oceans separating Laurentia from Gondwana. All of these terranes developed proximal to Gondwana, formed composite superterranes, and were accreted to the Laurentian assemblage during the mid-Palaeozoic. Peri-Gondwanan components located in the southern and central Appalachians consist of the Carolina Superterrane and outlier Smith River allochthon (Figure 3). The Neoproterozoic component of the Carolina Terrane consists of a mafic to felsic volcanic arc assemblage and associated volcaniclastic sedimentary rocks. A number of plutons were generated in the range of 550–600 Ma and intruded into the underpinning of the arc complex. This assemblage was metamorphosed during the Cambrian because plutons from 530 Ma cut upper amphibolite to greenschist facies metamorphic rocks. Neoproterozoic Ediacaran metazoan fossils have been identified on bedding planes in low-grade felsic volcanic rocks near Durham, North Carolina.

Overlying the arc complex is a sequence of Cambrian and possible Ordovician clastic sedimentary rocks. A Middle Cambrian Acado-Baltic (*Paradoxides*) fauna occurs in these sedimentary rocks in South Carolina, and Ordovician conodonts have also been reported in another part of the sequence in North Carolina. The high-grade western Carolina Superterrane contains a 350- to 360-My-old metamorphic overprint and numerous younger (Devonian to Carboniferous) granitoids probably related to the mid-Palaeozoic to Late Palaeozoic docking of the Carolina Terrane. The greenschist and lower grade central and eastern Carolina Terrane consists mostly of volcanic and volcaniclastic rocks interrupted by the Alleghanian Kiokee Belt metamorphic core. South-east of this metamorphic core are more low-grade volcanic and volcaniclastic rocks.

Mid-Palaeozoic Sedimentation and Neoacadian Docking of the Carolina Superterrane

Evidence for the Acadian Orogeny from 410–380 Ma in the southern and central Appalachian internides is mostly lacking. A suite of granitoid plutons from 374–382 Ma (Rabun, Pink Beds, Looking Glass, Mt Airy, Stone Mountain) intruded the eastern Blue Ridge of the Carolinas and Georgia, and a suite of anatectic granitoids (Toluca) from 380 Ma exists in the Cat Square Terrane. The Catskill delta spread Middle and Upper Devonian sediment from New England into New York and Pennsylvania, but pinches to the south. Late Silurian–Early Devonian sedimentary rocks comprise the Talladega Group in Alabama. Deposition of the Upper Devonian–earliest Carboniferous Chattanooga–Brallier (and equivalents) black shale unconformably on folded and faulted Silurian and older rocks on the platform may be an indicator of the Neoacadian Orogeny in the internal parts of the southern and central Appalachians.

Detrital zircon ages require that the Cat Square Terrane lying immediately east of the Tugaloo Terrane and west of Carolina (Figure 3) be accreted during the mid-Palaeozoic to Late Palaeozoic. Anatectic granites formed at ~380 and 366 Ma. Metamorphic rims on zircons, not only in the Cat Square Terrane, but also throughout the Tugaloo Terrane, along with deformed 366-My-old plutons in the Cat Square Terrane, indicate peak metamorphism occurred from 360–350 Ma. U/Pb thermal ionization mass spectroscopy (TIMS) ages on monazite yield similar 360 (and 320) Ma ages. Metamorphism to upper amphibolite and granulite facies conditions probably corresponds to time of docking of the Carolina Superterrane, whereby the previously assembled superterrane plus the Cat Square Terrane were A-subducted beneath Carolina, achieving the burial depths necessary to produce wholesale migmatization in the Inner Piedmont and eastern Blue Ridge.

The Inner Piedmont, which now consists of the Cat Square and the eastern Tugaloo Terrane, records a unique pattern of crustal flow that probably is the key to the docking kinematics of the Carolina Terrane. This flow pattern, from south-east to north-west, consists of a north-west-directed suite of thrust sheets that to the west became south-west directed as they were buttressed against the eastern Blue Ridge rocks along the Neoacadian Brevard fault zone. The docking process was probably thus oblique transpressional, beginning in the north and propagating south-westward. As the Carolina Superterrane subducted the components previously joined to Laurentia, the

Inner Piedmont may have decoupled to form an orogenic channel through which the partially melted plastic mass escaped and extruded south-westward.

The western boundary of the Tugaloo Terrane is the Chattahoochee–Holland Mountain fault in the eastern Blue Ridge, which truncates the 374-My-old Rabun Granodiorite. This fault transported migmatitic kyanite to sillimanite-grade Tugaloo Terrane rocks over staurolite–kyanite–sillimanite-grade rocks of the Dahlonega gold belt in southern North Carolina and northern Georgia, and was tightly folded after emplacement. The Chattahoochee–Holland Mountain must therefore be either a Neoacadian or an Alleghanian fault. Though the detrital zircon suites in the Tugaloo Terrane have quite uniform ages and probably reflect a Laurentian source, both Ordovician and Devonian plutons in the western Tugaloo Terrane contain a wide range of inherited components, from dominant 1.1-Gy-old to Archaean zircons. In contrast, almost none of the Ordovician (~466 Ma) and Devonian (~380 Ma) plutons in the eastern Tugaloo and Cat Square Terranes contain any inheritance. The magmas in the western Tugaloo Terrane must have passed through an appreciable thickness of old crust, whereas the magmas crystallizing the plutons in the Inner Piedmont east of the Brevard fault zone, which were generated in more oceanic to arc environments, did not pass through older continental crust on their way to crystallization. Inner Piedmont and eastern Blue Ridge rocks cooled sufficiently to block the metamorphic zircon rims and monazite from 360–350 Ma, and the western Carolina Superterrane recorded $^{40}Ar/^{39}Ar$ cooling from 350 to 360 Ma. Both terranes were reheated at 325 Ma, probably marking the initial collision of Gondwana with Laurentia. The 350- to 360-Ma event actually records the first thermal connection between the Inner Piedmont and the Carolina Superterrane.

Late Mississippian to Permian Alleghanian Zippered Collision with Gondwana and the Amalgamation of Pangaea

Actual collision of Gondwana with crust amalgamated during the Early to Middle Palaeozoic orogenies began the final chapter in the formation of the Appalachian Mountain chain. This collision was oblique, transpressive, rotational, and involved north-to-south collision zipper-like closing of Gondwana with the previously assembled Laurentian–Peri-Gondwanan collage. Initial collision produced a suite of largely S-type granites. Additionally, the Brevard Fault zone was reactivated dextrally under chlorite-grade conditions, and additional dextral faults—the Hylas and other components of the eastern Piedmont Fault system (Roanoke Rapids, Nutbush Creek, Modoc, Augusta, Towaliga, Goat Rock, Bartlett's Ferry)—formed as crustal blocks attempted to escape from the collision zone by moving south-westward from the vicinity of present-day northern Virginia–Maryland–Pennsylvania–New Jersey. In addition to the 325-My-old plutonic suite, a younger suite of plutons from 300–265 Ma is largely confined to the Carolina Terrane. These plutons were likewise generated during various stages of collision. A fault-bounded metamorphic belt, the Kiokee–Raleigh–Goochland Terrane extending from Georgia to the eastern Virginia Piedmont (Figure 3), was also generated during the early and middle stages of collision. Here low-grade Carolina Terrane rocks were metamorphosed to middle to upper amphibolite facies assemblages. In South Carolina and Georgia, the north-west flank of this metamorphic belt consists of the dextral Modoc Fault, whereas the down-to-the-south Augusta fault comprises the south-eastern flank. The Modoc Fault has been traced south-westward to the south-eastern flank of the Pine Mountain window in Georgia and Alabama, where it joins the Dean Creek Fault.

The collision process with its accompanying faulting and other indications of compression caused the interior of the mountain chain to be uplifted beginning in the Late Mississippian (about 325–320 Ma). The uplift process was complex and is recorded by current indicators, variable sediment thickness, and decreased maturity of sediments that demonstrate the orogen was unroofed piecemeal from Alabama to Pennsylvania. At that time, a near-sea level delta formed on the western flank of the chain on the Laurentian margin and the first sediments that contain Palaeozoic detrital zircons were deposited from Alabama to Pennsylvania. The transition from marine to non-marine depositional conditions took place from the Late Mississippian into the Early Pennsylvanian, and abundant land plants formed the coal and the associated sedimentary rocks of the Appalachian Basin.

The final stage of the Alleghanian scenario involved head-on collision of south-eastern Laurentia with Gondwana (Figure 6). The major product of head-on collision is the Blue Ridge–Piedmont megathrust sheet that transported crust amalgamated during all previous Palaeozoic events at least 350 km onto the North American platform. The Brevard Fault remained a suitably oriented weak fault and was again reactivated, this time as an out-of-sequence thrust in the interior of the megathrust sheet The Late Mississippian to Permian clastic wedge was

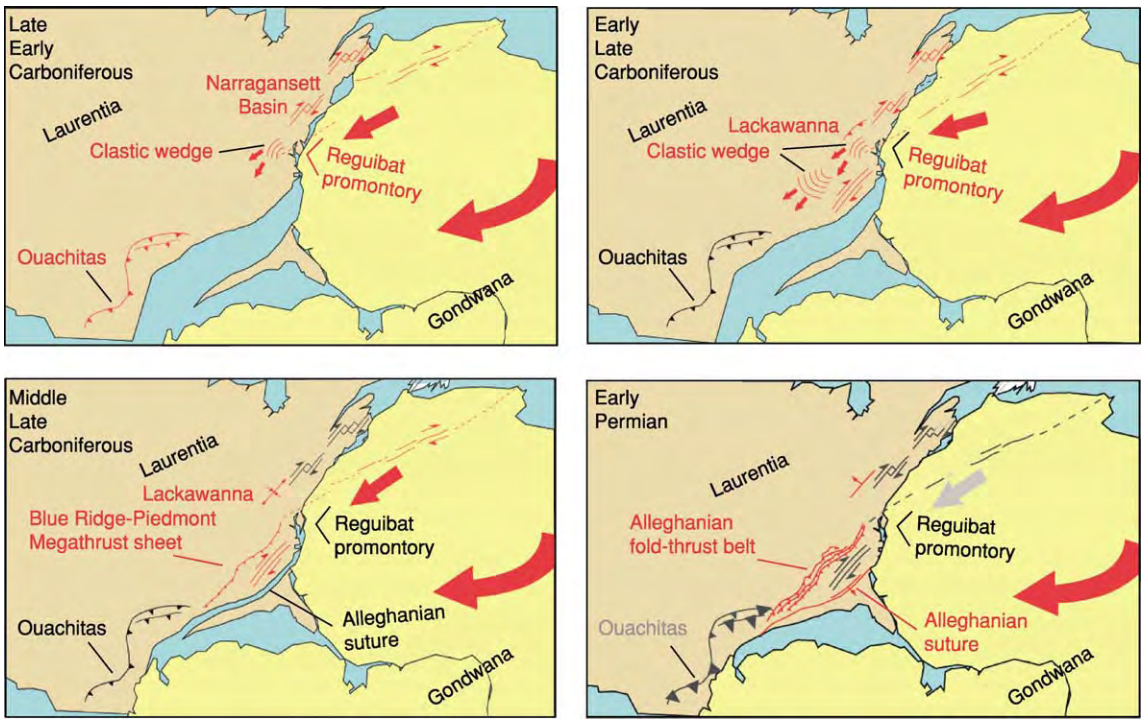

Figure 6 Rotational transpressive collision of Gondwana with Laurentia to form the Supercontinent of Pangaea at the end of the Palaeozoic. Features in red were active at the time indicated. Reproduced with permission from Catalán JRM, Hatcher RD Jr, Arenas R, and García FD (eds.) (2002) *Geological Society of America Special Paper 364*. Boulder, CO: Geological Society of America.

ultimately deformed as the Blue Ridge Piedmont megathrust sheet pushed into the continent, deforming the platform into a foreland fold–thrust belt. In addition, the delta complex that had formed to the west of the rising mountain chain was ultimately deformed. Though final collision was head-on and the megathrust sheet moved westward, uplift of the interior of the chain was non-uniform. The oldest parts of the delta complex are in the southern part of the orogen, possibly related to uplift and erosion of the earlier Ouachita Orogen. This part of the foredeep was superseded to the north by a younger delta complex that fed south-westward along the trough of the foredeep.

The collision was finished about 265 Ma, forming Supercontinent Pangaea and completing the Palaeozoic Wilson Cycle of opening and closing of oceans. The subsurface Suwannee Terrane south of the almost east- and west-trending suture in southern Georgia and Alabama consists of Gondwanan basement and cover Ordovician to Devonian sedimentary rocks of West African affinity. These rocks were left on the Laurentian side in the wake of the breakup of Pangaea. The southern and central Appalachians constitute a microcosm in the assembly of all existing continents along the huge suture zone that extends from south-eastern Laurentia through North-west Africa, western Europe, and the Ural Mountains in Russia.

Breakup of the supercontinent began during the Late Triassic, at ~50 My following the amalgamation of Pangaea, beginning the initial stages of opening of the present Atlantic Ocean. The assembly of Pangaea took place over a span of at least 100 My, but ironically, its breakup occurred over a much shorter timespan. This contrasts with the ≥200-My time-frame for assembling Rodinia and the 300 My that it took for it to break apart.

Northern Appalachians

C R van Staal, Geological Survey of Canada, Ottawa, ON, Canada

Introduction

The Appalachian Orogen is a remarkably linear, north-east-trending, Palaeozoic mountain belt that generally follows the eastern seaboard of North America, with the segment between Long Island Sound and Newfoundland (Figure 1) being referred to as the Northern Appalachians. Prior to the Mesozoic opening of the Atlantic Ocean, the Appalachians continued into the Caledonides of the British Isles and Scandinavia, forming a long linear mountain chain that was created by the closing of the Iapetus (Cambrian–Early Devonian) and Rheic (Devonian–Carboniferous) Oceans.

Iapetus started to open at the end of the Neoproterozoic (about 570 Ma) as a result of the final breakup of the supercontinent Rodinia, and had achieved a width of about 5000 km by the end of the Cambrian (500–490 Ma). The south-facing margin of ancient North America (Laurentia), which was then situated near the equator in a roughly east–west orientation, defined the northern limit of Iapetus. The northern margin of Gondwana, a large continent centred on the south pole and comprising present-day Africa, Australia, Antarctica, India, and large parts of South America, represented the southern limit of Iapetus (Figure 2). The large Gondwanan landmass was assembled as a result of late Neoproterozoic to Early Cambrian collisions; thus the opening of Iapetus overlapped in time with the final assembly of Gondwana. The Rheic Ocean opened when the Avalonian microcontinent rifted from Gondwana during the Early to Middle Ordovician. The Rheic Ocean was host to several small continental terranes, including Meguma, which were accreted to Laurentia before the final Carboniferous arrival of Gondwana and the formation of the Pangaean supercontinent.

Tectonostratigraphical Divisions

The tectonic architecture and the evolution of the distinctive rock assemblages in the Northern Appalachians are generally described within a framework of tectonostratigraphical zones and subzones. The concept of zonal divisions, based on sharp contrasts in lithology, stratigraphy, fauna, structure, geophysics, plutonism, and metallogeny of Early Palaeozoic and older rocks, was first introduced more than 30 years ago by Harold Williams, following detailed studies of the well-exposed coastal sections in Newfoundland. The identification of these zonal divisions throughout the Northern Appalachians implies a common geological evolution within each zone and highlights the usefulness of each in tectonic analysis.

From west to east, the Northern Appalachians have been divided into the Humber, Dunnage, Gander, Avalon, and Meguma zones (Figure 1). The Humber

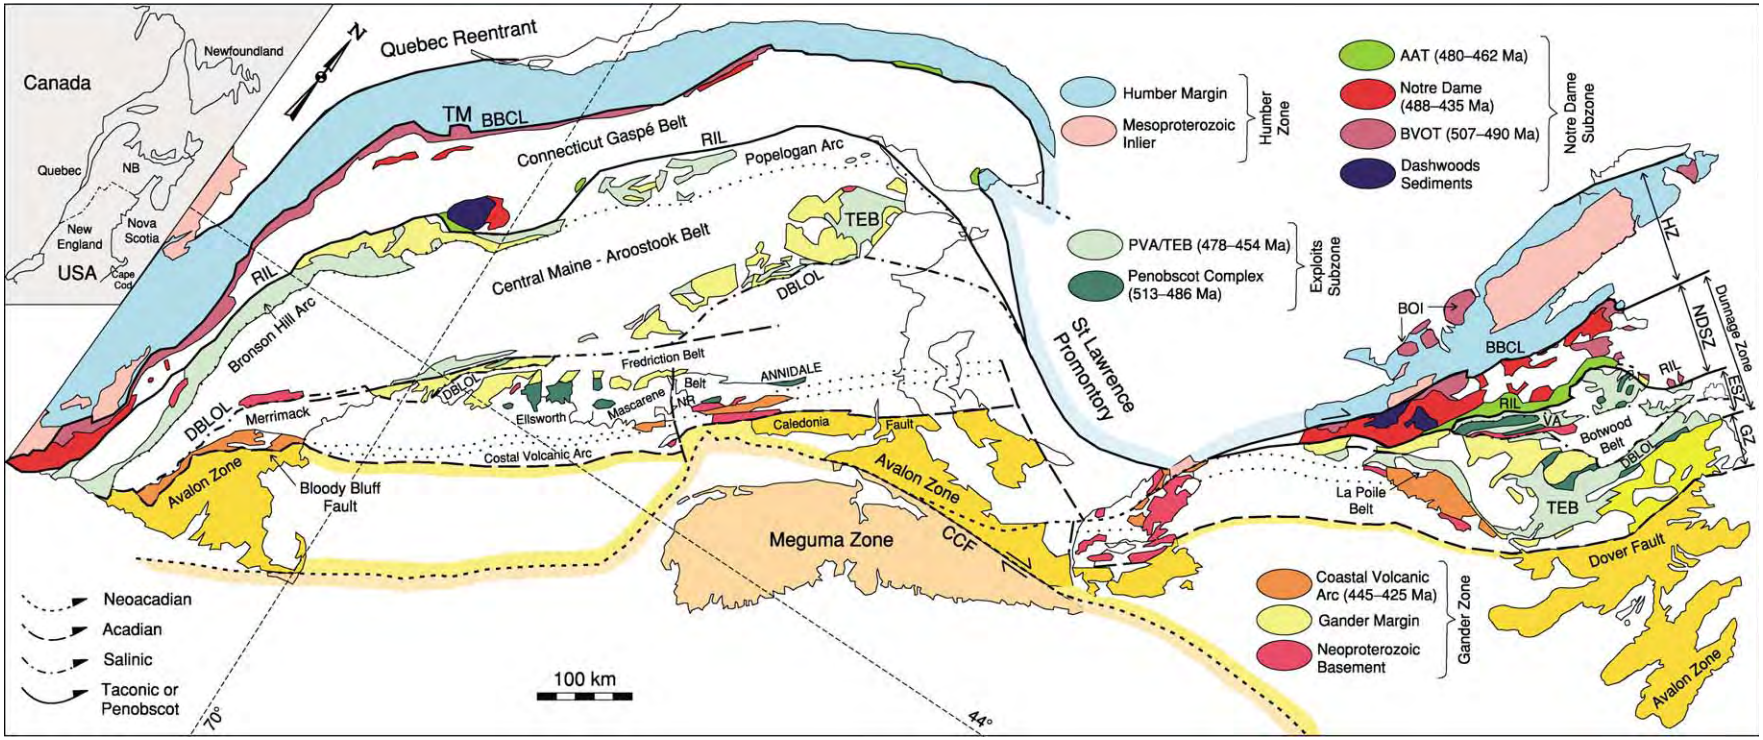

Figure 1 Tectonostratigraphic map of the Northern Appalachians. Zonal divisions are principally based on sharp contrasts in Lower Palaeozoic geology; the main belts of Siluro Devonian sedimentary and volcanic rocks are outlined in white. The major structures and principal orogenic events responsible for their formation are indicated by line patterns. The extension of structures off the land is based on geophysical interpretation and well data. Figure 2 Early Cambrian (around 540 Ma) palaeogeography of the Iapetus Ocean. Seafloor spreading that led to the opening of Iapetus started at around 570 Ma. Aval., Avalonia; Carol., Carolina; DA, Dashwoods; Gand., Ganderia; Hól., Hólanda; Pc, Precordillera Terrane. Meguma was probably situated further east, just outside the field of view, along the north African margin of Gondwana near elements of Armorica. Hólanda and Precordillera are peri Laurentian microcontinents like Dashwoods but ended up in Baltica and the South American part of Gondwana, respectively, after the closure of Iapetus. Made with the help of Conall MacNiocaill.

Zone represents the peripheral part of the Laurentian Craton, which was involved in Appalachian orogenesis. The Gander, Avalon, and Meguma zones represent peri-Gondwanan microcontinents that accreted to Laurentia during the Early to Middle Palaeozoic (450–380 Ma). The Dunnage Zone contains the remnants of oceanic terranes that formed within the realm of the Iapetus Ocean, and is subdivided into the Notre Dame and Exploits subzones.

Orogenesis (the combined effects of spatially and temporally associated deformation, metamorphism, magmatism and sedimentation) was mainly confined to the central portion of the Northern Appalachians, often referred to as the Central Mobile Belt.

Humber Zone

The Humber Zone is mostly underlain by a Late Neoproterozoic–Ordovician rifted passive margin sequence deposited on Laurentian basement that had experienced multiple orogenic events during the Mesoproterozoic (around 1.5–0.95 Ga), culminating in the Grenville orogeny (around 1.2–0.95 Ga). These basement rocks are exposed in several windows from Newfoundland to southern New York state. Its Late Neoproterozoic–Palaeozoic cover preserves evidence of rifting, development of a warm-water carbonate shelf and slope, and conversion into a convergent margin. Rift-related magmatism took place intermittently during an approximately 70 Ma time-span during the latest Neoproterozoic (620–550 Ma) and was coeval with the deposition of consanguineous clastic sedimentary rocks. Exactly when during this time interval the opening of the Iapetus Ocean began is at present unclear, but palaeomagnetic and geological arguments suggest that it occurred at around 570 Ma. Several lines of evidence suggest that the final stage of rift magmatism (555–550 Ma) and the subsequent Early Cambrian (around 540 Ma) transition from rift to drift sedimentation preserved in Newfoundland, Quebec, and New England (Figure 3), relates to the departure of a small microcontinent, referred to as Dashwoods. This event thus postdates the seafloor spreading associated with the earlier opening of Iapetus. Dashwoods equates

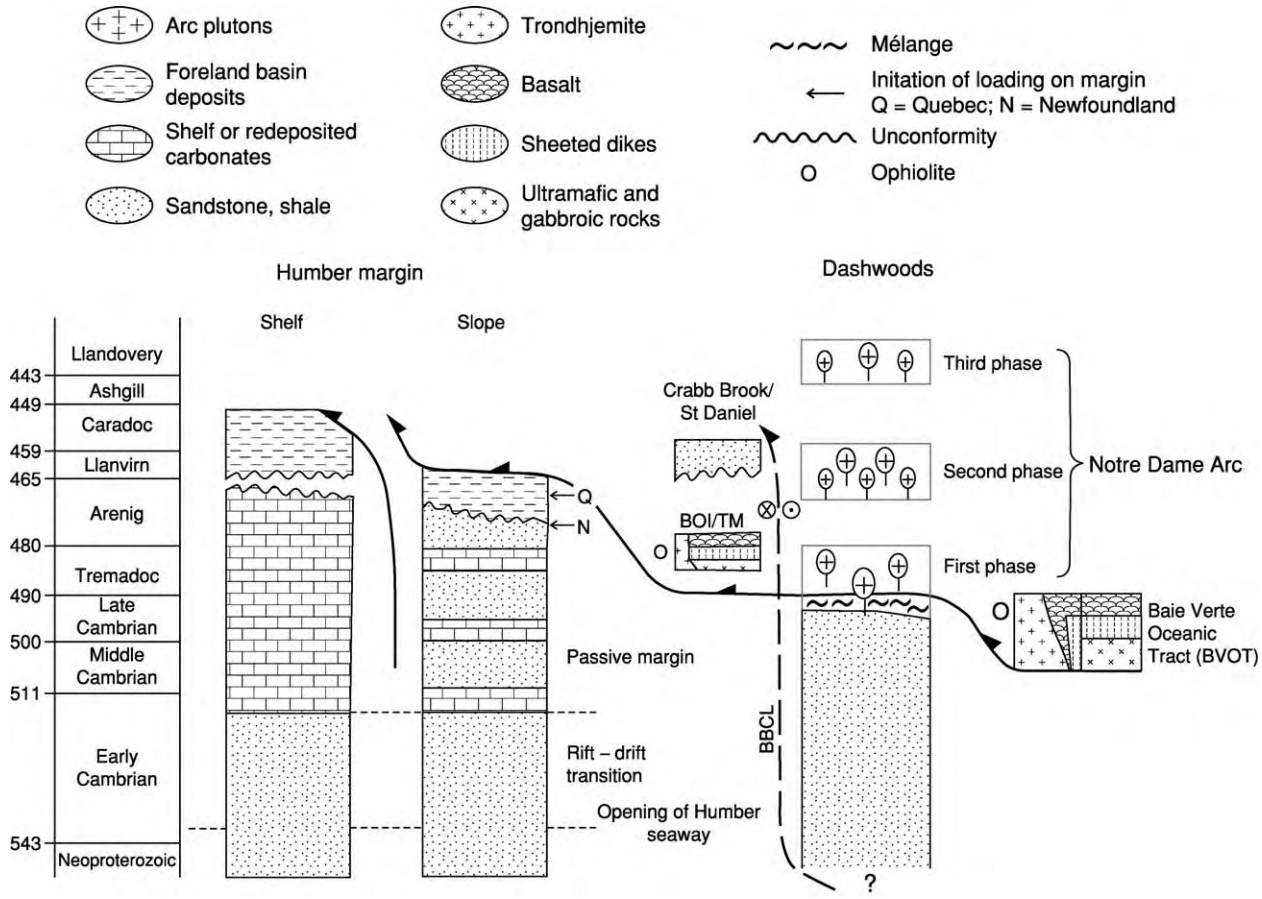

Figure 3 Tectonostratigraphic relationships pertinent to the convergence between the Baie Verte Oceanic Tract and Dashwoods, and between Dashwoods and the Humber margin. East directed subduction started in the Middle Cambrian immediately outboard of the Dashwoods microcontinent and led to underthrusting of the Dashwoods microcontinent beneath the Baie Verte Oceanic Tract (BVOT). The Bay of Islands (BOI) and Thetford Mines (TM) ophiolites formed during local rifting and concurrent seafloor spreading of the allochthonous BVOT after the Dashwoods microcontinent was subducted beneath the BVOT and the east directed subduction zone stepped back into the Humber seaway. The Crabb Brook and St Daniel were deposited in piggyback basins formed during obduction of the ophiolites onto the Humber margin. BBCL, Baie Verte Brompton Camerons Line.

to the Boundary Mountain Terrane in New England. Spreading between Laurentia and the Dashwoods microcontinent was either very slow or aborted soon after formation, because faunal and palaeomagnetic data suggest that the Dashwoods was separated from Laurentia by only a narrow oceanic seaway (the Humber Seaway). The along-strike extent of the Dashwoods is uncertain. Isotopic evidence for the involvement of Laurentian crust in the generation of Early to Middle Ordovician magmatic rocks of the Notre Dame Arc and Laurentian rift-related clastic rocks positioned in an upper plate setting during the Taconic Orogeny (Figures 1 and 3) suggests that this microcontinent extended southward into New England.

The conversion of the Humber passive margin into a convergent margin is indicated by cratonward migration of a foreland basin formed in response to tectonic loading of the margin by an overriding ophiolite terrane (Figure 3). Foreland-basin development was immediately preceded by uplift and local karst erosion due to the passage of a peripheral bulge across the margin. This process started in the Middle to Late Arenig (around 474 Ma) and lasted at least until the Late Caradoc (around 450 Ma) in Newfoundland. Loading of the margin started slightly later in Quebec and New England (Figure 3) probably owing to the presence of the Quebec Reentrant–St Lawrence Promontory pair (Figure 1).

Dunnage Zone

Palaeomagnetic, fossil, and other geological evidence indicates that the oceanic terranes of the Dunnage zone (Figure 1) can be separated into peri-Laurentian (Notre Dame Subzone) and peri-Gondwanan (Exploits Subzone). Detailed geochemical studies have revealed that virtually all the preserved oceanic rocks have compositions typical of suprasubduction zone

settings (i.e. fore-arc, arc, and back-arc). True oceanic lithosphere formed at mid-oceanic spreading centres, far removed from continental margins and subduction zones, is either very rare or has been lost during subduction.

Notre Dame Subzone The Notre Dame Subzone (Figure 1) lies immediately east of the Humber Zone, from which it is separated by a complex and long-lived fault zone, the Baie Verte–Brompton–Camerons Line. The Notre Dame Subzone comprises several unrelated Middle Cambrian to Middle Ordovician (507–462 Ma) oceanic terranes and an important continental magmatic arc (the Notre Dame Arc), which was intermittently active between 488 and 433 Ma (Figure 3). Rocks of the Notre Dame Subzone can be traced from south-western Connecticut through western New England and Quebec into Newfoundland (Figure 1), where they are best exposed and studied. Rocks belonging to the Notre Dame Arc are commonly referred to as the Shelburne Falls Arc in New England. The eastern boundary of the Notre Dame Subzone with the Exploits Subzone is marked by a major suture (the Red Indian Line) that juxtaposes rocks formed on opposite sides of the Iapetus Ocean (Figure 4).

The oldest oceanic rocks in the Notre Dame Subzone occur in the Middle to Upper Cambrian (around 507–490 Ma) Baie Verte Oceanic Tract, which mainly represents an infant arc terrane (wide zone of supra-subduction-zone oceanic lithosphere created during and shortly after the initiation of subduction, before the establishment of a well-defined linear narrow arc axis). The Baie Verte Oceanic Tract was obducted on to the Dashwoods shortly after formation owing to eastward-directed (present coordinates) subduction initiated close to Laurentia. Stitching plutons of the first phase of the Notre Dame Arc (around 488 Ma) indicate that obduction in Newfoundland took place during the latest Cambrian. Rare evidence of Late Cambrian tectonometamorphic events and the age range of Early Ordovician arc plutonism in New England and Quebec suggest that there was little diachroneity in this process along the length of the Northern Appalachians. The first phase of Notre Dame Arc magmatism resulted from the stepping back of subduction into the Humber seaway, transferring the Dashwoods microcontinent from a lower-plate to an upper-plate setting (Figure 3). Closure of the Humber Seaway brought Dashwoods back to Laurentia in the late Arenig (475–470 Ma) and started the Taconic orogeny. The Taconic Orogeny was accompanied by the second phase of Notre Dame Arc magmatism (469–458 Ma) and intense deformation and Barrovian metamorphism of the Dashwoods, including the rocks generated during the first phase of the Notre Dame Arc development.

A younger, unrelated, oceanic terrane, the Annieopsquotch accretionary tract, is situated along the eastern margin of the Notre Dame Subzone, immediately west of the Red Indian Line (Figure 4). The Annieopsquotch accretionary tract comprises a tectonic collage of Arenig–Llanvirn (480–462 Ma) infant arc, arc, and back-arc terranes that formed as a result of west-directed subduction outboard of the Dashwoods. Ultramafic rocks are rarely preserved in the Annieopsquotch accretionary tract, in contrast to the Baie Verte Oceanic Tract, probably because their accretion to the Dashwoods involved underthrusting and structural underplating rather than obduction. Accretion of the Annieopsquotch accretionary tract to Laurentia started at around 470 Ma, suggesting a causal relationship to the Taconic, Laurentia–Dashwoods, collision further west, and ended before 455–450 Ma, when the leading edge of the Exploits subzone (Popelogan–Victoria Arc) started to accrete to Laurentia. The Annieopsquotch accretionary tract is poorly preserved in New England, mainly because the Red Indian Line is here largely buried and/or obscured by Mid-Palaeozoic cover sequences and tectonism. The Red Indian Line approximately follows the eastern boundary of the Connecticut–Gaspé Belt (Figure 1) and is locally marked in Maine by mélanges and ophiolitic rocks.

The Notre Dame Subzone experienced both uplift and subsidence during the Late Ordovician and Silurian, and is locally overlain by a marine to terrestrial Silurian volcanosedimentary sequence. Terrestrial rocks are dominant in Newfoundland, while marine deposits characterize New England and Quebec.

Notre Dame Arc magmatism had ended by the early Silurian and was replaced by a phase of Early to Late Silurian (433–424 Ma) bimodal within-plate volcanism and plutonism; the latter has been ascribed to breakoff of the west-dipping, down-going slab responsible for accretion of the Annieopsquotch accretionary tract, the Exploits Subzone, and the Gander Zone. Early Devonian (Acadian) orogenesis, very penetrative in the adjacent Exploits Subzone and Gander Zone, is weak or absent, showing that the locus of orogenesis had shifted to the south-east by Late Silurian times. Mild orogenesis returned by the Middle to Late Devonian (Neoacadian, 395–350 Ma).

Exploits Subzone The oldest known subduction-related rocks preserved in the Exploits Subzone have Lower Cambrian to Tremadoc (513–486 Ma) ages and compositions typical of an arc or back-arc setting. Some of the rocks have compositions and stratigraphies typical of ophiolite complexes, while

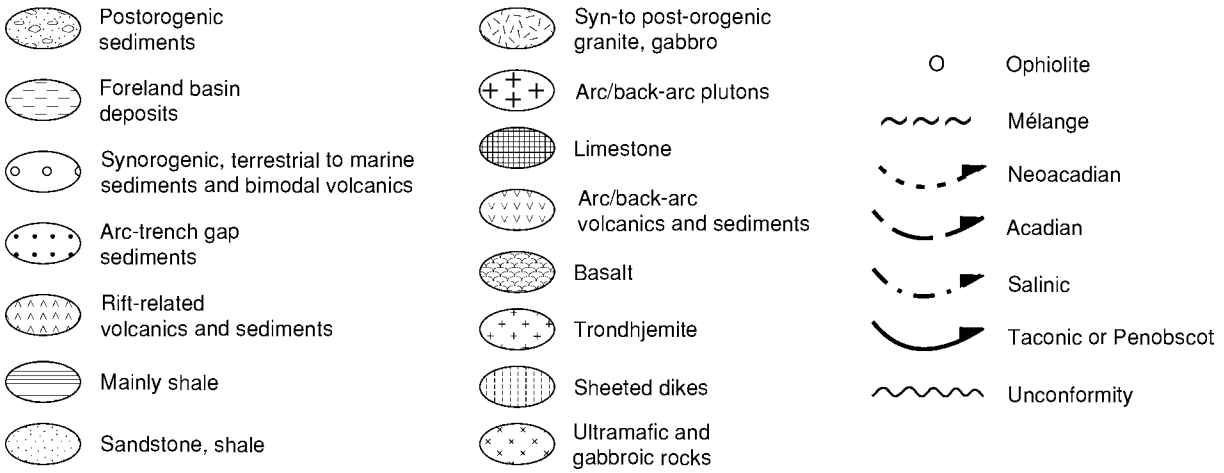

Figure 4 Tectonostratigraphic relationships pertinent to the closure of the main tract of the Iapetus Ocean, the Tetagouche Exploits back arc basin, and the oceanic crust that separated Ganderia from Avalonia and Avalonia from Meguma. The Red Indian Line marks the site of the collision between the Notre Dame and Popelogan Victoria arcs. The line patterns of the major structures correspond to those in **Figure 1**. The arrows on the faults indicate the polarity of subduction and/or thrusting. Obliquity of collision and subsequent strike slip fault reactivation is indicated by the symbols on each side of the major faults: a point represents moving towards and a cross moving away from the viewer. BBCL, Baie Verte Brompton Camerons Line. BVOT, Baie Verte Oceanic Tract. LP, La Poile Belt volcanic rocks; M, Mascarene belt; PVA, Popelogan Victoria Arc; TEB, Tetagouche Exploits back arc basin.

others have close spatial associations with felsic-arc plutonic rocks that are at least as old as 565 Ma (Figure 4). The latter probably represent ensialic basement and suggest that at least some of these rocks are not truly oceanic. Coeval and lithologically similar Cambrian arc or back-arc volcanic rocks and associated Neoproterozoic plutonic rocks also occur in the Gander Zone (see below), particularly in southern New Brunswick (e.g. Annidale and New River Belts) and adjacent Maine (Ellsworth Belt) (Figure 1). Collectively, these rocks have been interpreted as an arc–back-arc complex, the Penobscot Complex, formed near the leading edge of the Gondwanan margin on which the arenites and shales of the Gander Zone (see below) were deposited. Stitching plutons and isotopic evidence show that the Cambrian oceanic rocks of the Penobscot Complex were obducted onto the continental-margin rocks of the Gander Zone before 474 Ma, during the Penobscot Orogeny (Figure 4).

The composite crust of the Penobscot Complex and the Gander Zone sedimentary rocks are disconformably overlain by younger rocks related to the Arenig–Llanvirn ensialic Popelogan–Victoria Arc/Tetagouche–Exploits back-arc system, which was active between 478 and 454 Ma. The Popelogan–Victoria Arc/Tetagouche–Exploits back-arc system has been traced from Newfoundland through central New Brunswick into Maine, mainly on the basis of a remarkably consistent and distinct lithological association of coeval plutonic, volcanic, and sedimentary rocks. Correlations further to the south into Massachusetts become progressively more difficult, owing to a lack of age control and the presence of substantial cover sequences. The Popelogan–Victoria Arc is probably continuous with the Bronson Hill Arc, whereas most of the products of the Tetagouche–Exploits back-arc have been buried beneath the Siluro-Devonian cover sequences of the Central Maine and Merrimack Belts (Figure 1). The Popelogan–Victoria Arc had migrated to a mid-Iapetus position by at least the late Llanvirn (around 462 Ma), according to faunal and sparse palaeomagnetic evidence, while the passive-margin side of the Tetagouche–Exploits back-arc, which was deposited on Gander-Zone rocks, was positioned further south owing to subduction-zone retreat and concurrent back-arc spreading. Rifting and seafloor spreading in the Tetagouche–Exploits back-arc is necessary to account for the formation of Llanvirn back-arc oceanic crust (464–459 Ma), which is locally preserved as incomplete ophiolite complexes and large structural slices of highly tectonized back-arc oceanic basalt and gabbro in mélange belts in New Brunswick and Newfoundland. Fossil and palaeomagnetic evidence suggest that the Tetagouche–Exploits back-arc nowhere achieved a width of more than about 1000 km (largely based on the assumption that the pelagic larvae of animals such as brachiopods could traverse oceans up to this width, but no further).

Gander Zone

The Gander Zone (Figures 1 and 4) is defined by a distinct monotonous sequence of Lower Cambrian to

Tremadoc (520–480 Ma) arenites and shales, capped by Tremadoc black shale. This sequence can be traced from north-east Newfoundland into New England and is generally accepted to represent the outboard part (outer shelf to slope) of a passive margin built on Gondwanan continental crust. This inference is based on an extensive set of isotope, geochemical, detrital mineral, palaeomagnetic, and fossil data. The sedimentary source area has to be cratonic and contain Archean, Palaeo-, Meso-, and Neoproterozoic rocks. Based on a process of elimination, this craton is generally inferred to be Amazonia, although other Gondwanan sources cannot be ruled out.

With the possible exception of a few outcrops in southern New Brunswick, the basement on which this sedimentary sequence was deposited is not exposed. However, spatially associated Late Neoproterozoic to Early Cambrian arc rocks sporadically exposed in the Gander Zone are, on the basis of distinct isotope, geochemical, and age data, inferred to represent basement. The basement rocks show many similarities in their Neoproterozoic history to coeval rocks of the adjacent Avalon Zone, from which they are separated by a major long-lived ductile–brittle fault zone (Dover–Caledonia–Bloody Bluff Fault), but have experienced a very different Cambrian to Early Devonian evolution. Avalon developed a shale-rich platformal sedimentary succession during the Early Palaeozoic and did not experience orogenesis until the Latest Silurian–Early Devonian Acadian Orogeny. Gander, on the other hand, experienced multiple phases of arc magmatism and orogenesis from the Cambrian to the Silurian (Figure 4). Furthermore, Nd-isotope data indicate that their Precambrian basements are strikingly different. Hence, the Gander and Avalon zones are considered to represent two distinct Gondwanan microcontinents during the Palaeozoic (Ganderia and Avalonia, respectively). Ganderia was accreted to Laurentia in two stages. The leading edge of Ganderia, with the Popelogan–Victoria Arc suprastructure (Figure 4), accreted to Laurentia in the Late Ordovician. Convergence between Ganderia and Laurentia continued, leading to final closure of the Tetagouche–Exploits back-arc by the late Early Silurian (430–425 Ma). During this collision with Laurentia, a Late Ordovician to late Early Silurian (445–425 Ma) extensional arc–back-arc system (coastal volcanic arc/Mascarene–La Poile back-arc basin) was constructed on its southern margin (Figures 1 and 4) owing to convergence between Avalonia and Ganderia. This arc–back-arc system forms a narrow volcanic–plutonic belt that roughly follows the coastline of New England and maritime Canada to southern Newfoundland.

Avalon Zone

The exposed rocks of the Avalon Zone mainly represent the suprastructure of the microcontinent Avalonia. Its distinctive rocks have been traced from the British Isles into Massachusetts, and mainly comprise Neoproterozoic dominantly juvenile arc-related volcanosedimentary successions and associated plutonic rocks, which experienced a complicated and long-lived Neoproterozoic tectonic history that largely predates the opening of Iapetus. Characteristic of the Avalon Zone is the deposition of a Cambrian–Lower Ordovician shale-rich platformal sedimentary sequence that locally includes rift-related volcanic rocks (Figure 4). Fossil and palaeomagnetic data show a strong connection with Gondwana during this period. However, starting in the late Early Ordovician, the data indicate that Avalon started to drift north independently across Iapetus. Early to Middle Ordovician rift-related volcanic rocks (479–460 Ma), preserved in the Avalonian successions of Nova Scotia and New Brunswick, support this assertion. The accretion of Avalonia to Ganderia, and by implication Laurentia, is poorly constrained, because the oldest preserved sedimentary and magmatic (stitching plutons) linkages have Middle to Late Devonian ages. Palaeomagnetic and structural evidence, particularly relating to the Late Silurian (422–418 Ma) start of the inversion of the Mascarene–La Poile back-arc basin on the southern edge of Ganderia and the ages of syntectonic plutons, suggest however that collision started during the latest Silurian and culminated in the mainly Early Devonian (418–395 Ma) Acadian Orogeny.

Meguma Zone

The Meguma Zone represents the most outboard terrane in the northern Appalachians. It is exposed on land only in southern Nova Scotia, but its regional extent is much larger. It has been traced offshore by an impressive set of geophysical and well data from the southernmost part of the Grand Banks south-east of Newfoundland, across the Scotian Shelf and the Gulf of Maine, to southernmost Cape Cod. The basal part of the exposed Meguma zone comprises a thick latest Neoproterozoic to Early Ordovician turbiditic sandstone–shale sequence of the Meguma Supergroup, which was deposited on the continental rise and/or slope to outer shelf of a Gondwanan passive margin. A combination of detrital-zircon, sedimentological, and sparse fossil data suggest a north-west African provenance, but the dataset at present is small and other parts of Gondwana cannot be ruled out as source areas. The Meguma Supergroup is disconformably overlain by Late Ordovician

to Early Devonian shallow-marine dominantly siliciclastic sedimentary rocks, which are locally interlayered with rift-related bimodal Early Silurian (442–438 Ma) volcanic rocks. The Meguma Zone experienced intense orogenesis during the late Early Devonian to Early Carboniferous (395–350 Ma; Neoacadian orogenesis). Fossil evidence (fish and crinoid) suggests that, during the Late Silurian, Meguma was close to Avalonia and/or Baltica, and separated from Gondwana. When combined with the magmatic evidence for Late Ordovician rifting and Neoacadian orogenesis, this suggests that Meguma was a microcontinent or part thereof (perhaps Armorica) during at least the Silurian and Devonian, as Gondwana was not accreted to Meguma until the Carboniferous–Permian Alleghanian Orogeny.

Overview and Summary of the Tectonic Evolution of the Northern Appalachians

The oldest orogenic events associated with the closure of Iapetus are the Late Cambrian–Early Ordovician (495–484 Ma) accretion of the Baie Verte Oceanic Tract to the Dashwoods and the Penobscot complex to Ganderia, with the Baie Verte Oceanic Tract and the Penobscot complex both in upper-plate settings (Figures 3 and 4). Exposed, inferred Ganderian, basement locally contains evidence of older Early Cambrian orogenesis, but this is probably related to peripheral subduction around the Gondwanan continent outside the realm of Iapetus. The accretions of the Baie Verte Oceanic Tract and the Penobscot complex were nearly coeval, but took place on opposite sides of the Iapetus Ocean, when the ocean was at its widest. Because these events took place shortly after the initiation of subduction on either side of the ocean, they signal a major plate reorganization that changed Iapetus from an Atlantic-type ocean into a Pacific-type ocean. Time constraints provided by stitching plutons indicate that both accretionary events were short-lived, forming mélanges and ductile–brittle deformation, and did not lead to any significant regional metamorphism.

The first major orogenic event recorded in the Northern Appalachians was the Early to Middle Ordovician (474–455 Ma) Taconic Orogeny, which principally resulted from closure of the Humber seaway and accretion of the Dashwoods microcontinent to Laurentia. Closure of the Humber Seaway initiated loading of the Humber margin, initially by emplacement of oceanic terranes, some of which are younger than the Baie Verte Oceanic Tract (484–479 Ma). These younger oceanic terranes, which include the Bay of Islands and Thetford Mines ophiolites in Newfoundland and Quebec, respectively, formed either during the initiation of subduction in the Humber Seaway or as a result of localized pericratonic seafloor spreading in pull-aparts or above embayments in the downgoing plate. The Taconic Orogeny culminated in imbrication, folding, and locally intense Barrovian metamorphism, mainly in upper-plate rocks associated with the Dashwoods. Age constraints on Taconic metamorphism (470–455 Ma) are remarkably consistent along the length of the orogen.

Docking of Dashwoods was rapidly followed by accretion of the Annieopsquotch accretionary tract between 470 and 460 Ma and the Popelogan–Victoria Arc at 455–450 Ma to composite Laurentia along its ocean-facing eastern margin. The effects of these accretionary events, which are centred on the Red Indian Line, are difficult to separate from those of the orogenesis accompanying the Dashwoods–Laurentia collision to the west. Since separation of these events on the basis of kinematic arguments is often impossible outside Newfoundland, these events are included in the Taconic orogeny. Structural relationships and the presence of young supra-subduction-zone oceanic rocks (480–464 Ma) in the Annieopsquotch accretionary tract indicate that a new west-dipping subduction zone had formed in the Arenig to the east of Dashwoods. Accretion involved south-east-verging duplex-style thrust complexes, folding, mélange development, and a sinistral oblique reverse shear zones.

The Popelogan–Victoria Arc was formed in the Early Arenig (at about 478 Ma) on the leading edge of Ganderia after the Penobscot orogeny. It was active until the Late Caradoc and formed above an east-dipping subduction zone. Upper-plate extension and rifting as a result of slab rollback dispersed the Popelogan–Victoria Arc into Iapetus and formed a wide (up to 1000 km) Japan Sea-style back-arc basin (Tetagouche–Exploits back-arc) that was partly underlain by Llanvirn oceanic crust.

The opposite subduction polarities associated with the Annieopsquotch accretionary tract (west-dipping) and the Popelogan–Victoria Arc (east-dipping) require that the Red Indian Line marks a collision between two arc terranes (Figure 4). Structural and seismic-reflection data in central Newfoundland indicate that the Popelogan–Victoria Arc was partly subducted beneath the Annieopsquotch accretionary tract. Palaeomagnetic evidence suggests that between 480 and 450 Ma these two subduction zones consumed approximately 3000 km of ocean, implying a minimum closure rate of around 10 cm yr^{-1} in the main Iapetus tract. The remaining tracts of Iapetus (Humber Seaway, Tetagouche–Exploits back-arc, and the ocean

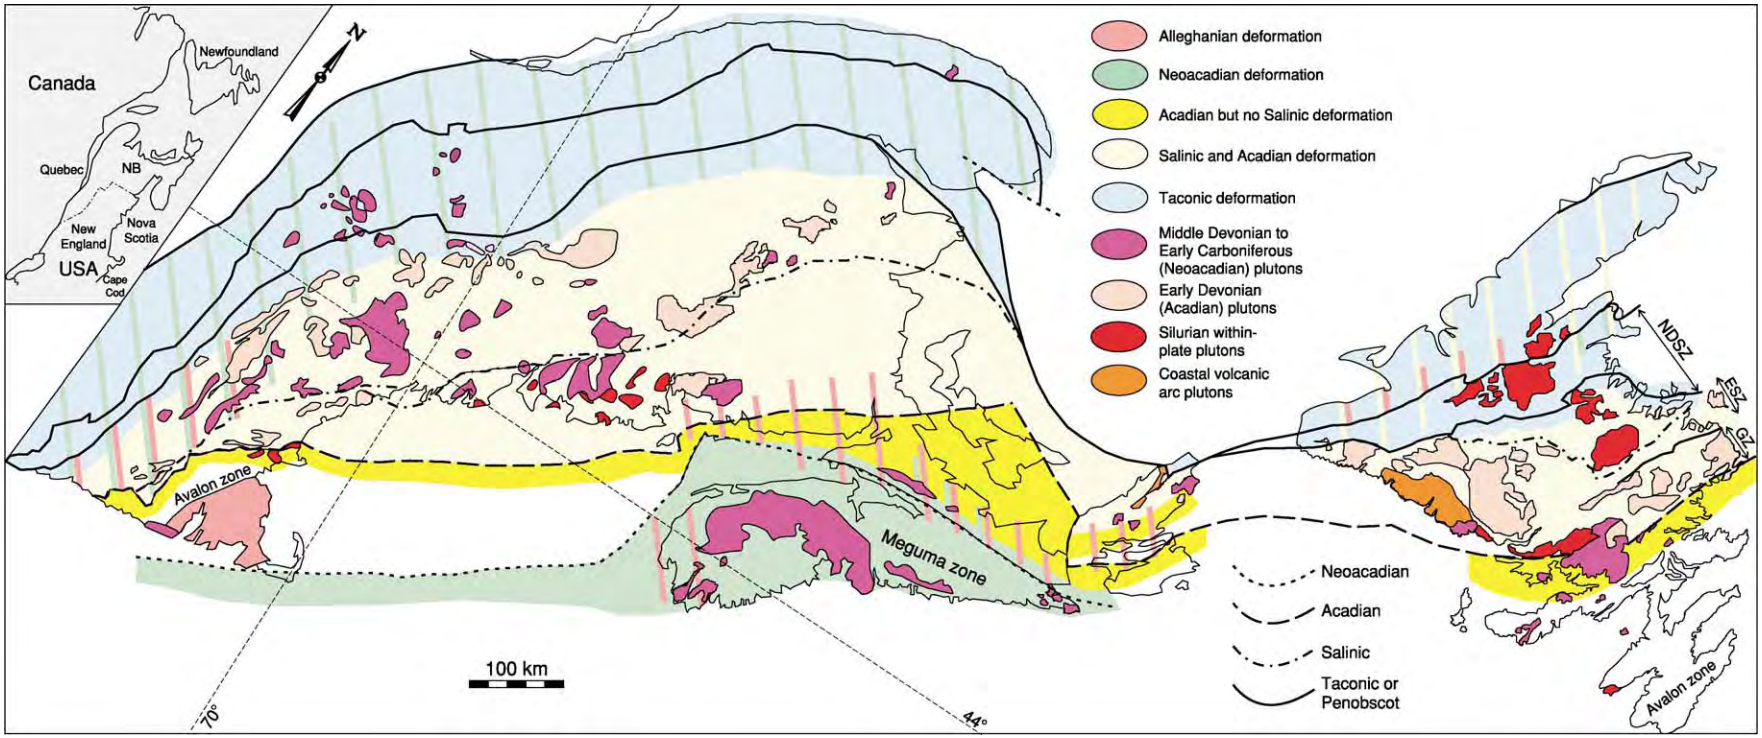

Figure 5 Map of the Northern Appalachians showing the spatial and temporal distributions of deformation, associated metamorphism, and Siluro Early Carboniferous plutons. For abbreviations see **Figure 1**.

basin separating Avalonia and Ganderia) had a combined width in the order of 2000 km.

After accretion of the Popelogan–Victoria Arc to Laurentia, the west-dipping subduction zone stepped back into the Tetagouche–Exploits back-arc. Late Ordovician–Early Silurian mélanges, blueschists, and foredeep deposits leave little doubt that subduction continued. Closure of the Tetagouche–Exploits back-arc in the Early Silurian (around 430 Ma) accreted the bulk of Ganderia firmly to Laurentia along the Dog Bay–Liberty–Orrington Line. This event, the Salinic Orogeny, was contemporaneous in Newfoundland, New Brunswick, and Maine. Although mainly restricted to rocks east of the Red Indian Line, localized Salinic-age deformation west of this suture is probably related (Figure 5).

Sinistral oblique accretion of Avalonia to Laurentia started at around 421 Ma, shortly after the docking of Ganderia. This caused inversion of the Mascarene–La Poile back-arc basin in southern New Brunswick, Maine, and Newfoundland and led to penetrative orogenesis of Ganderian, including its Siluro-Devonian cover, and, to a much lesser extent, immediately adjacent Avalonian rocks. This collision is the Acadian Orogeny as defined in its type area along the south coast of New Brunswick and neighbouring Maine. It produced polyphase folding including an early phase of large south-east-verging fold nappes and thrusts, a north-west-verging retrowedge also involving fold nappes and ductile thrusts, high-temperature metamorphism, and extensive syntectonic granitic plutonism with bimodal magmatism developing later on. Acadian orogenesis finished before the end of the Early Devonian and did not extend west of the Red Indian Line, other than as localized faulting and development of clastic wedges in foreland basins. Subsequent late Early Devonian to Early Carboniferous Neoacadian orogenesis is present throughout most of the Northern Appalachians (Figure 5) and is at least in part related to the docking of Meguma to the Laurentian margin. The Neoacadian Orogeny was accompanied by a westerly progradation of clastic wedges and granitic magmatism in western New England and maritime Canada and widespread dextral transpression.

The Carboniferous–Permian Alleghanian Orogeny was due to tectonic processes related to the oblique convergence and collision of Gondwana with Laurentia, which is in an upper-plate setting in the Northern Appalachians. Dextral strike-slip faulting and the development of intermontane transtensional basins prevailed during the Early Carboniferous. Transpressional inversion of these basins involved several stages during the late Early Carboniferous to Middle Permian and was accompanied locally by intense deformation and metamorphism near the boundary between the Avalon and Meguma zones. Intense late Alleghanian orogenesis accompanying renewed north-directed underthrusting of Avalonian and Ganderian rocks beneath Laurentia occurred in southern New England, but is absent elsewhere.

The temporal and spatial relationships of the tectonic events discussed above indicate that the Northern Appalachians are an example of a Palaeozoic accretionary orogen, punctuated by the accretion of small suprasubduction-zone terranes and five collisional events related to the arrival of four microcontinents (Dashwoods, Ganderia, Avalonia, and Meguma) and finally Gondwana at the Laurentian margin. Laurentia was thus progressively expanding oceanwards concurrent with an eastward shift of the locus of orogenesis (Figure 5).

Glossary

Boundary Mountain Terrane Equivalent of Dashwoods microcontinent in New England-Southern Quebec. Is inferred to underlie most of the Connecticut-Gaspè Belt

Ganderia Gondwanan-derived microcontinent. Characterized by island arc and back-arc magmatism during the Early Palaeozoic.

Atlantic Margin

D R Hutchinson, US Geological Survey, Woods Hole, MA, USA

Published by Elsevier Ltd.

Introduction

The North American Atlantic Continental Margin stretches between Florida and Newfoundland and extends from on land, near the exposed Mesozoic Newark basins, to offshore, near the western limit of the abyssal plain. It is a classic example of a passive or trailing-edge continental margin, in which continental rifting followed by seafloor spreading, sedimentation, and subsidence are the primary controls on margin morphology, tectonics, and sedimentary style. At almost 4500 km long, the margin considered here spans climatic zones from subtropical off the coast of Florida to subarctic off the coast of Newfoundland. During Mesozoic continental separation, the rifting style changed from volcanic, during the North America–Africa separation, to non-volcanic, during the North America–Europe separation. Sediments in the five major offshore basins contain varying volumes and ages of evaporite, carbonate, coarse terrigenous, and fine siliciclastic deposits.

This margin is documented by one of the most thorough high-quality publicly available geological and geophysical datasets of any continental margin in the world. Exploration began in the 1960s, when the new theory of plate tectonics ignited an excitement about Earth science and stimulated a new generation of enthusiastic scientists to rethink how the Earth was formed. The Arab Oil embargo in the 1970s led to the initiation and funding of a sustained period of continental-margin exploration aimed at understanding energy resources in US domestic frontier environments, such as the unexplored continental margins. Finally, the adoption of the United Nations Convention on the Law of the Sea in 1982 provided the legal basis for nations to claim up to 200 nautical miles (or more) for their exclusive economic use. Together, these three events made exploration of the vast

submerged portion of the North American Atlantic Continental Margin possible. This article summarizes the diverse geology of this passive margin discovered during the last 40 years of scientific research.

Morphology of the Margin

The bathymetry of the North American Atlantic Continental Margin (Figure 1) shows a continental shelf that dips gently seawards, an abrupt shelf–slope break at a depth of about 100–200 m, a steep and sometimes dissected continental slope, and, finally, a gently sloping rise that merges with the abyssal plains of the deep ocean. The Blake Plateau is an exception to this morphology. It is a submerged platform at a depth of about 800–1200 m, which ends abruptly in a near-vertical escarpment that descends to more than 5000 m. The morphology at the north and south ends of the margin reflect modification by climatic zonation. For example, between New England and Newfoundland, the margin was shaped by Pleistocene glaciation (*see* **Sedimentary Processes:** Glaciers): banks, channels, ridges, knolls, rocky outcrops, and troughs are observed. In contrast, off the coast of Florida, subtropical reef growth, carbonate deposition, submarine carbonate lithification (*see* **Minerals:** Carbonates), and carbonate solution in deep water have led to oversteepened slopes.

Superimposed on the broad climatic effects are features resulting from oceanographic, geological, and tectonic modifications. The oceanographic processes that modify the seafloor are primarily tides, waves, and currents (for example, creating mobile sand bodies atop Georges Bank and around Sable Island). In deeper water, the Blake Outer Ridge (Figure 1) was formed by a huge sediment drift deposited at the confluence of southwards-flowing and northwards-flowing deep currents.

Perhaps the most striking features of the North American Atlantic Continental Margin are the many submarine canyons that incise the continental slope and rise between Cape Hatteras and Newfoundland.

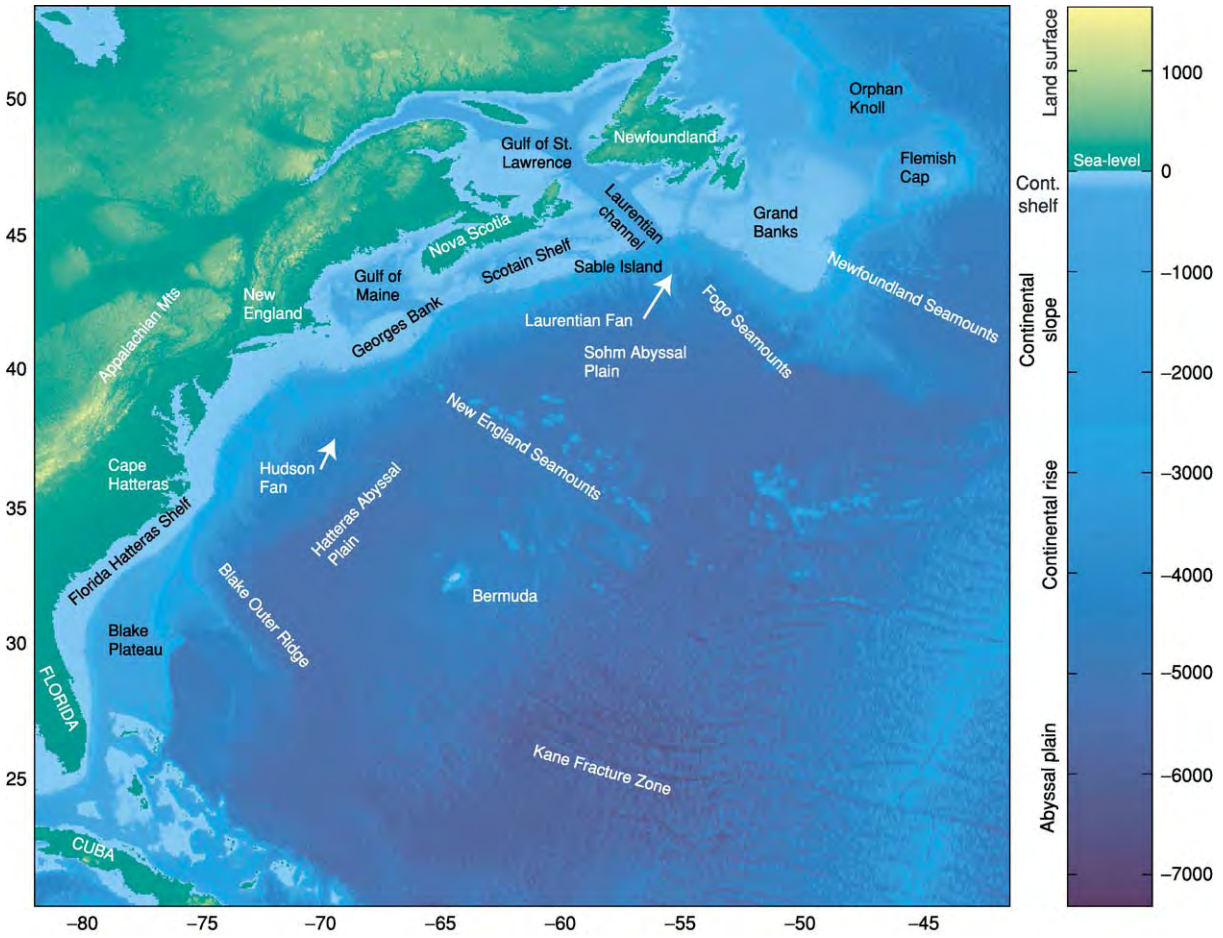

Figure 1 Bathymetric map of the North American Atlantic Continental Margin. Bathymetry was generated using ETOPO2 values with shaded relief. (ETOPO2 provides $2' \times 2'$ depth and elevation values, from NOAA/National Geophysical Data Center.)

More than 200 canyons can be identified on the upper slope off the US margin. Many of these canyons also indent the shelf edge. The largest canyon system, the Hudson Shelf Valley and Canyon, can be traced back to the mouth of the Hudson River (Figure 2). Abundant slumps, debris-flow deposits, and other evidence of mass movement are seen on the sides of many canyons. Fewer canyons exist on the lower slope because the canyons coalesce there. The lower slope and rise also contain large submarine fan deposits (e.g. the Laurentian and Hudson Fans off Newfoundland and New York, respectively).

Deeper-water geological processes are reflected in the presence of three seamount (*see* **Seamounts**) chains that impinge upon the margin: the New England Seamounts off Georges Bank, the Fogo Seamounts south of the Grand Banks, and the Newfoundland Seamounts off Newfoundland. A rifted continental fragment forms the submerged circular platform of Flemish Cap.

Several large landslides (*see* **Sedimentary Processes: Landslides**) also modify the margin morphology. The undated Cape Fear slide (Figure 3), south of Cape Hatteras, extends downslope for more than

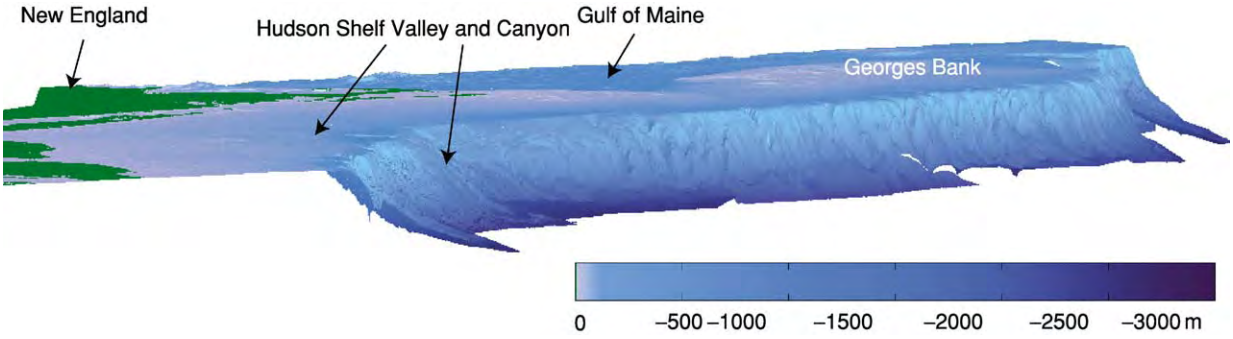

Figure 2 Perspective view of the canyons on the continental margin using bathymetric values from the NOAA coastal relief model (90 m × 90 m grid).

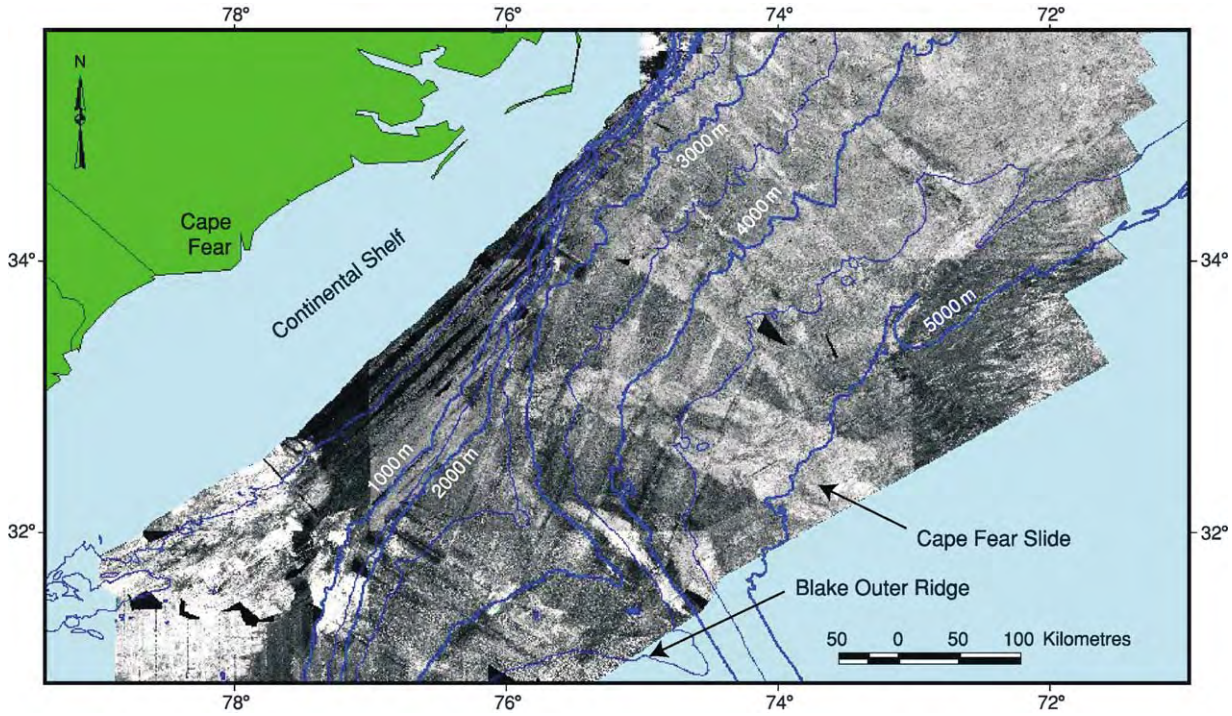

Figure 3 GLORIA side scan sonar image of the continental slope along a segment of the south eastern US margin, showing the Cape Fear slide, an undated massive submarine landslide south east of Cape Hatteras, NC. Dark grey areas are regions of low backscatter signal, commonly from fine grained deposits; light grey areas are regions of high backscatter signal, commonly from coarse grained deposits. The Cape Fear slide appears as a light grey region.

300 km between about 1200 m and 5500 m water depth. Off Newfoundland, the slides, turbidites, and other mass-flow bedforms resulting from the 1929 earthquake on the south-eastern Grand Banks can be identified in water depths from about 500 m to 3000 m.

Tectonic Evolution

The North American Atlantic Continental Margin is the product of continental rifting and seafloor spreading (*see* **Plate Tectonics**), which began in the Mesozoic between North America, Africa, and, eventually, Europe. Rifting is the phase of stretching and fracturing of continental crust that culminates in seafloor spreading (drifting), which creates new oceanic crust as the continental blocks move apart. These tectonic processes are directly responsible for the modern configuration of basins, platforms, magnetic anomalies, and oceanic fracture zones along the margin (Figure 4).

Early Triassic rifting began in an extensive interior mountain range in the supercontinent of Pangaea (*see* **Pangaea**) (Figure 5A). A series of rift basins formed between what are now the Gulf of Mexico and the Bay of Biscay. Rifting intensified in the Late Triassic (Norian), and true seafloor spreading progressed from the south at about 200 Ma to the north at about 185 Ma in what is now maritime Canada. Spreading near Newfoundland initially did not continue north of the Gibraltar transform zone at the northern edge of the African block. The Grand Banks were located north of the Gibraltar transform and, although extended during this time, behaved as a unit with Gibraltar and the European Plate.

Rifting and drifting along the entire margin are inferred to have overlapped during the Early Jurassic. A major basaltic extrusion event is recorded in the rift basins at about 200 Ma (Early Jurassic). Basalt flows are exposed throughout the Newark Supergroup. Numerous feeder dykes can be mapped in the exposed rocks surrounding the rifts (e.g. Shelburne Dyke in Nova Scotia, the Great Dyke in the Carolinas). These dykes probably also exist beneath the submerged continental margin, but are difficult to map beneath large thicknesses of postrift sediments. Rifting ceased during the Middle Jurassic.

The East Coast Magnetic Anomaly (ECMA; Figure 4), marks the western edge of the oceanic crust. The oldest oceanic crust near the ECMA was created during the Jurassic magnetic quiet zone and, therefore, is does not contain datable seafloor magnetic anomalies. The oldest seafloor-spreading isochron that can be identified on both sides of the Atlantic is M25 (about 156 Ma, Late Jurassic).

During the Middle and Late Jurassic, the continents dispersed and readjusted to tectonic events that were occurring in other parts of the fragmenting remnants of the Pangaean supercontinent. The initially shallow and restricted ocean basins deepened and widened as North America and Africa separated. In the Late Jurassic, a major plate (*see* **Plate Tectonics**) reorganization between North America and Europe rejuvenated synrift basins that initially formed in the Triassic on the Grand Banks of Canada (e.g. Jeanne d'Arc Basin). This rifting ended when seafloor spreading began between the Grand Banks and Iberia during the early Barremian (126 Ma, Early Cretaceous), initiating the final separation of Europe from North America (Figure 5B). Another plate reorganization in the Early Cretaceous (middle Aptian, about 110 Ma) completed the separation of North America from Europe when the northern part of Flemish Cap (and Orphan Knoll) separated from the Rockall region of the north-west European margin as seafloor spreading began in the Labrador Sea.

Alkaline basaltic magmatism, not obviously associated with breakup, created the New England Seamounts, (*see* **Seamounts**) which extend from the continental slope (Bear Seamount) to the foothills of the Mid-Atlantic Ridge. The age of the seamount chain has been difficult to establish, but it is now generally felt to have formed episodically between the Early Jurassic (125 Ma) and the middle Cretaceous (90–82 Ma). A younger, middle Cretaceous age for some of the White Mountain magma series in New Hampshire indicates that this younger magmatic pulse may have extended inland.

The Cenozoic has been a period of stable plate configurations, in which the Atlantic Ocean has widened and deepened. There are two exceptions to this otherwise stable tectonic regime. First, the Labrador spreading centre was abandoned and the Norwegian and Arctic Oceans began opening in the Late Paleocene. This gave rise to the mid-ocean ridge configuration that persists today between Newfoundland and Florida (Figure 5C). Second, at least two large bolides hit the margin (*see* **Impact Structures**). One excavated a crater 85 km wide beneath Chesapeake Bay in the late Eocene (35 Ma; Figure 6). A second smaller impact structure, 45 km wide, called the Montagnais structure, was formed at about 51 Ma near the shelf–slope break off Nova Scotia.

Passive Margin Structure

During the last 200 Ma, three major tectonic processes have affected the structure of the North American Atlantic Continental Margin: rifting, which broke apart Pangaea, thinned the continental crust by

(Reproduced from Poag CW, Koeberl C, and Reimold WU (2004) *The Chesapeake Bay Crater: Geology and Geophysics of a Late Eocene Submarine Impact Structure.* New York: Springer Verlag.)

variable amounts, and created numerous synrift basins; drifting, which created hot new oceanic crust initially adjacent to the rifted continent and now far away along the Mid-Atlantic Ridge; and passive subsidence, caused by cooling of the lithosphere and loading of the crust by sediments, which resulted in the development of large offshore sedimentary basins. Superimposed on these first-order lithospheric events are various oceanographic, magmatic, fluvial, eustatic, sedimentary, diagenetic, and biological processes that have also affected the final shape of the margin. The resulting structure of the margin is an alternating sequence of platforms, which have relatively little sedimentary cover, and basins, which contain enormous thicknesses of sediment (Figure 4).

Mesozoic rifting created the exposed basins of the Newark Supergroup (Figure 4). These fault-bounded basins and/or half-grabens form a linear chain along the exposed part of the margin. The basins contain deposits up to several kilometres thick. Similar synrift basins have been detected seismically and drilled near the coast and beneath the continental shelf. The best-known of these offshore basins is the petroliferous Jeanne d'Arc basin on the Grand Banks, in which the thickness of sediment exceeds 14 km. Synrift deposits are inferred to underlie the deepest portions of the margin, but have not yet been sampled. Synrift basins are also known on the conjugate north-west African continental margin.

A prominent margin-wide unconformity separates the synrift basins from the overlying postrift sedimentary units and is called the postrift or the breakup unconformity (Figure 7). Consequently, sedimentary-thickness maps of the margin often include only those units above the postrift unconformity (i.e. postrift deposits). The postrift unconformity may become a conformable surface within the deepest sediments in the centres of the postrift basins, but evidence for this is ambiguous, because seismic imaging in these deeper regions is often of poor quality and drilling data are lacking. Beneath the Grand Banks, the postrift unconformity is termed the Avalon unconformity.

Above the postrift unconformity, five major sedimentary basins have been documented. From north to south, they are the Scotian basin, Georges Bank basin,

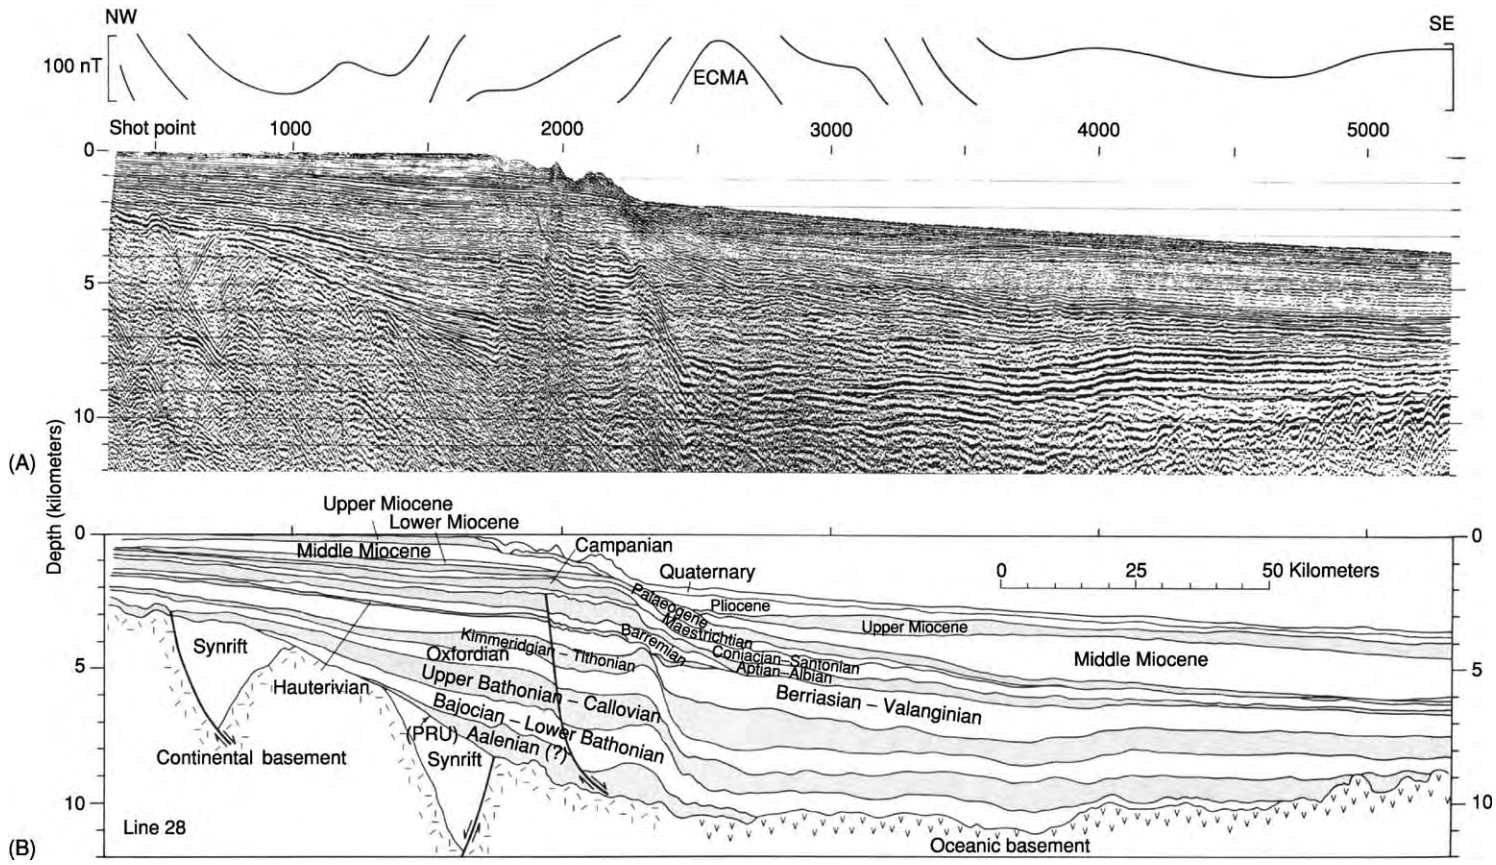

Figure 7 Stratigraphic cross section across the southern Baltimore Canyon trough. (A) Uninterpreted multichannel seismic reflection data. In: Poag CW and de Graciansky PC (eds.) *Geologic Evolution of Atlantic Continental Rises*, pp. 100 156. New York: Van Nostrand Reinhold.)

Baltimore Canyon trough, Carolina trough, and Blake Plateau basin (Figure 4). In plan view, they range in shape from nearly circular (Blake Plateau basin) to extremely elongated (Carolina trough). In cross section (Figure 7), the basin fill is roughly lens shaped, thinning towards both the continent and the ocean. Maximum sediment thickness also varies, from more than 15 km in the Baltimore Canyon trough and Scotian basin to less than 9 km in the Georges Bank basin. The composition of the basin fill is variable, and the sediment is often distributed among several sub-depocentres that together make up a basin complex.

The basins are bounded on their sides by structural highs, which often coincide with major faults. These faults both segmented the margin during rifting and coincided with (and perhaps localized) fracture zones in the newly forming oceanic crust. Most of the fracture zones can be mapped continuously from magnetic-anomaly offsets to the present Mid-Atlantic Ridge and are used as flow-lines of plate movement in plate-tectonic and palaeoenvironmental reconstructions of the ocean basin. Fracture-zone faults near the margin are mostly deeply buried, but they can be identified in the seafloor morphology near the mid-ocean ridge (e.g. Kane Fracture Zone; Figure 1).

Landwards of the large postrift basins are structural platforms. These are, from north to south, the Bonavista, LeHave, Long Island, Carolina, and Florida platforms. These regions may contain locally thick synrift deposits (e.g. the Jeanne d'Arc basin) but generally consist of prerift crystalline basement at shallow depths. Postrift deposits are thin (less than 4 km) and represent the onlapping edges of much thicker offshore units. Coastal-plain deposits are the exposed portions of these thinner younger Mesozoic and Cenozoic units. A hinge zone frequently marks the transition from a platform to a basin, i.e. where sediment thickness changes abruptly. These platforms are also affected by eustatic changes; hence, many parts of the sedimentary section are missing. The platforms are underlain by crystalline rocks from older Palaeozoic orogenies that built the Appalachian, Caledonian–Variscan, and Mauritanian mountains of North America, Europe, and Africa, respectively. The basin-bounding faults of the synrift basins frequently reactivate deeper basement faults and structures.

Variations in the amount of crustal stretching can be seen in cross sections through different parts of the North American Atlantic Continental Margin (Figure 8). Three crustal types are shown: oceanic crust, which is 5–6 km thick and similar to normal oceanic crust; transitional crust, which is generally less than 20–25 km thick, changes thickness rapidly, and has seismic velocities intermediate between those of oceanic and continental crust; and thinned continental crust, which is 30–35 km thick and may contain synrift basins but otherwise appears to be continental in seismic-velocity character (i.e. the platforms). ('Seismic' is used throughout this article to include coincident reflection and refraction techniques, unless otherwise noted.) A fourth type of crust, which is not shown on these cross sections, is normal continental crust, which would be 40–45 km thick, as found in continental interiors. The change from one crustal type to another may be abrupt or gradational and depends on the geological, tectonic, magmatic, and thermal history of the margin prior to and during breakup.

The transform margin of the southern Grand Banks basin (Figure 8) changes abruptly from continental crust to oceanic crust across a 40 km wide zone, whereas most of the basins have transitional crust that is 100–200 km wide (Scotian basin, Georges Bank basin, Baltimore Canyon trough, Carolina trough). The Blake Plateau basin is the most unusual, because the transition from continental crust to oceanic crust extends over nearly 400 km. Deep seismic data do not exist for the Blake Plateau basin, so the interpretation of crustal type is based primarily on poorly constrained gravity models. The basement and crustal structure in this southernmost basin are the least understood of any part of the margin.

The nature of the transitional crust also varies along the margin. For example, the southern part of the margin, towards Florida, is considered to be strongly volcanic, whereas the northern part, near Flemish Cap, is considered to be non-volcanic. The EDGE seismic experiment showed that a thick wedge of high-velocity presumably mafic material exists and coincides with rifting beneath the Carolina trough. Thus, this part of the margin is classified as a volcanic margin. Similar velocities have been interpreted from beneath the Baltimore Canyon trough. In contrast, a recent seismic experiment across Flemish Cap revealed that both serpentinized mantle and unusually thin oceanic crust lie adjacent to thinned continental crust. These anomalous features are interpreted as evidence of ultraslow seafloor spreading associated with a non-volcanic margin. The conjugate Iberian margin also has serpentinized rocks, which are thought to indicate non-volcanic processes. These have been drilled in the Ocean Drilling Program. The deeper structures of the Scotian and Georges Bank basins have not been well imaged using modern seismic techniques. Therefore, the nature of the deeper crust in these regions is uncertain, hindering our understanding of both the transition from continent to ocean and the transition from volcanic to non-volcanic parts of this margin.

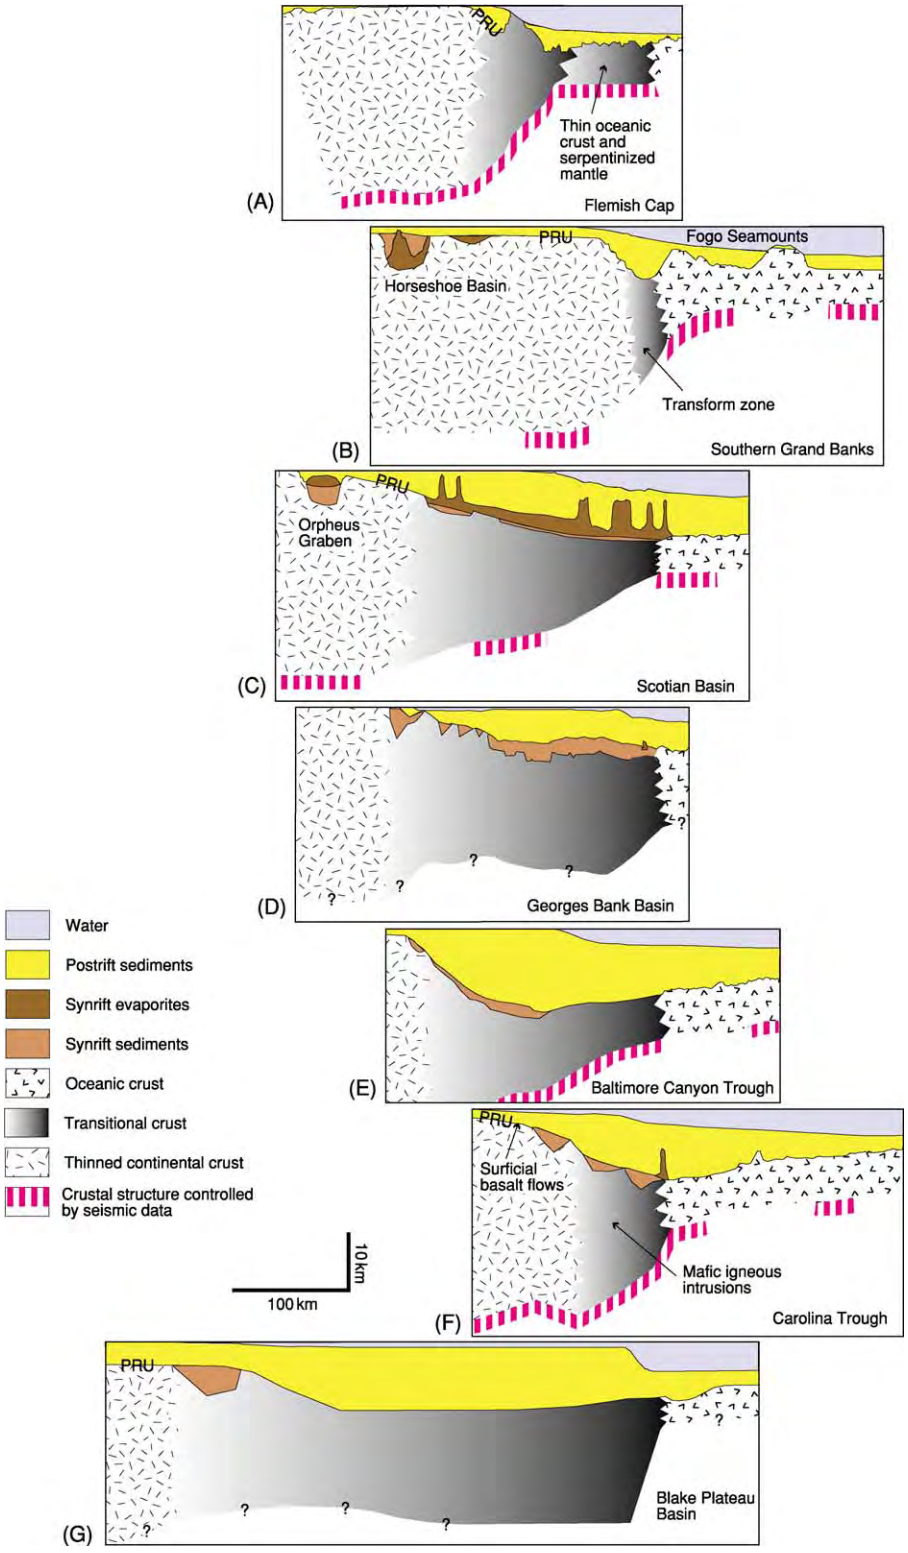

Figure 8 Simplified crustal cross sections through the major postrift basins of the North American Atlantic Continental Margin, aligned on the western edge of the oceanic crust. The transitional zone between continental crust and oceanic crust varies in thickness and width. PRU, postrift unconformity. (A) Flemish Cap, interpreted as a non volcanic transition (the two transitional crust patterns differentiate highly thinned continental crust on the landwards side from anomalous oceanic or serpentinized crust adjacent to the oceanic crust). (B) Southern Grand Banks, showing a narrow transition at the position of the fossil transform fault zone. (C) Scotian Basin. (D) Georges Bank Basin. (E) Baltimore Canyon Trough. (F) Carolina Trough, interpreted as a volcanic transition (the transition region is thought to contain magmatically emplaced crust). (G) Blake Plateau Basin.

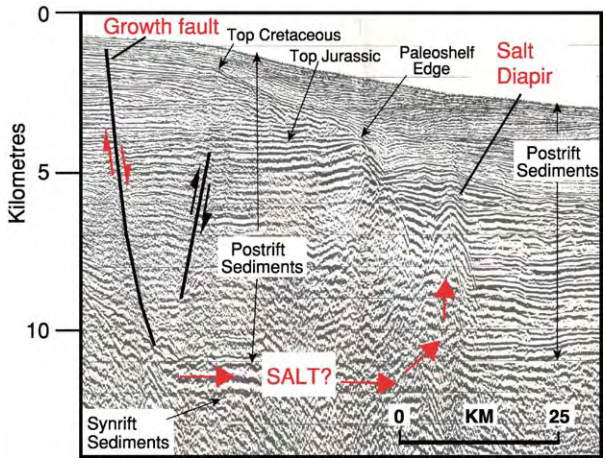

Figure 9 Seismic reflection profile and interpretation across the Carolina trough, showing the relationship between salt diapirism and faulting. Salt movement, shown by the arrows, is inferred to have caused growth faulting. PRU, postrift unconformity.

Numerous faults that offset postrift sediments are secondary structures on the continental margin. Beneath the Scotian basin and Carolina trough, faults are attributed to salt tectonism (Figure 9). Numerous small Cretaceous and younger north-east-trending reverse faults (e.g. the Block Island and New York Bight faults on the continental margin south of New England) are part of growing evidence for regional compression of the margin from Early Cretaceous through to at least Pleistocene times. The stress field east of the Rocky Mountains remains compressional today. Most of the faulting associated with the Chesapeake Bay bolide impact appears to be localized to the region surrounding the crater.

Sedimentary History and Palaeoenvironments

Interpretations of sedimentary history and palaeoenvironments are based on a combination of seismostratigraphic interpretation and direct samples from dredges, cores, drill cuttings, and submersible observations.

Triassic rifting began in central Pangaea (*see* **Pangaea**), where average elevations were probably more than 1 km above Mesozoic sea-level. Continental clastic redbed sequences filled large lakes that occupied subsiding rift basins, not unlike the large lakes of the modern East African Rift valley. The region from Florida to the Grand Banks spanned a latitudinal range from about 5° S to 20° N and encompassed equatorial rainforests to tropical savannahs. Evaporites (*see* **Sedimentary Rocks:** Evaporites) accumulated in shallower settings. Rift topography, and especially uplifted rift shoulders, exerted a local control on climatic processes (*see* **Tectonics:** Rift Valleys).

By the Late Triassic, shallow-marine conditions had developed around the site of the future continental margin. The initial marine incursion began in the north, when hypersaline waters transgressed the Grand Banks region, probably from across the Newfoundland–Gibraltar fracture zone. A 2000 m thick section of halite in the Osprey evaporites was deposited above redbeds of the Carson sub-basin. More extensive flooding proceeded southwards, and additional evaporites accumulated along the Nova Scotian margin (in a region now called the slope diapiric province). The youngest salt was deposited in the Carolina trough at the southern end of the future continental margin. The marine flooding marked a time when the sedimentary basins along the future margin became interconnected. Isolated rift basins still existed, however, on the distal edges of the zone of extension (i.e. exposed basins of the Newark Supergroup).

Evaporite deposition ended in the Early Jurassic when normal marine conditions became established. The ocean basin may have been as much as 350 km wide, 900 km long, and less than 1 km deep, although seafloor spreading did not become fully established until the Middle Jurassic. Carbonate platforms developed around the edges of the subsiding seaway, and calcareous mudstones were deposited in the deeper central portions. The developing North Atlantic Ocean was connected to the open ocean north of the Grand Banks (via Greenland and Europe) and to the developing Gulf of Mexico to the south. Uplift and basaltic volcanism interrupted and contributed to the Middle Mesozoic sedimentary record.

Between the Late Triassic and Middle Jurassic, the North American continent drifted northwards by about 10–15°, which created more arid conditions in the basins of the Grand Banks, while maintaining humid conditions in the south. The transition to more grey siliciclastic sequences during this interval indicates more humid palaeoenvironments.

The Middle Jurassic was a time of relative sealevel rise, which flooded the continental margins and started the transition from semi-closed to partially open circulation. Final plate separation occurred during the Middle Jurassic, and the ocean basin grew significantly wider (600 km) and deeper (2000 m, perhaps as much as 3000 m). All the large offshore sedimentary basins had formed by this time (Figure 10) and were accumulating enormous volumes of siliciclastics. This influx of siliceous material may have contributed to extensive radiolarian blooms. By the middle Middle Jurassic, local carbonate tracts were developing along the margins; these prograded rapidly seawards

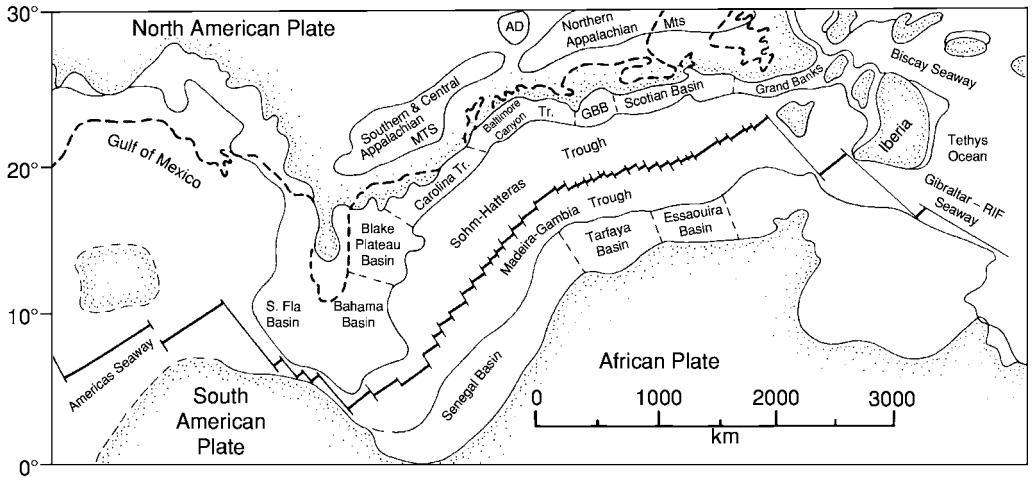

Figure 10 Structural, depositional, and physiographic features of the proto Atlantic seaway, reconstructed at the end of the Jurassic. Landmass boundaries and palaeolatitudes are approximate. GBB, Georges Bank Basin, AD, Adirondack Mountains. (Reproduced from Poag CW (1991) Rise and demise of the Bahama Grand Banks gigaplatform, northern margin of the Jurassic proto Atlantic seaway. *Marine Geology* 102: 63 130.)

in the latest Middle Jurassic and established carbonates as the dominant sediment type.

By the Late Jurassic, a giant carbonate platform extended for more than 5000 km from south of Florida to north of the Grand Banks (Figure 11). The Atlantic Ocean had opened to about 1400 km wide, and maximum seafloor depths reached nearly 4 km. The margin stretched from the equator to about 25° N. A very large carbonate bank formed across the entire Blake Plateau shelf. A more linear semicontinuous carbonate bank–reef system developed in the Baltimore Canyon trough. Farther north, in the Georges Bank and Scotian basins, the reef was more discontinuous. The morphology of the North American Atlantic Continental Margin at this time resembled that of the modern Great Barrier Reef of Australia, in which steep reef fronts mark the edge of the continental shelf and carbonate-rich aprons form on the continental rise seawards of the reef front. Gaps in the reef system channelled siliciclastics into large submarine fan complexes, which carried terrigenous material as far as 300–400 km from the shelf edge. A series of coalescing siliciclastic deltas also deposited terrigenous material shorewards of the carbonate platforms.

Except around the Blake Plateau, the giant carbonate platform ceased to exist in the Early Cretaceous because of rising sea-level, which stressed the carbonate-producing communities, and burial by siliciclastic sediments, which finally filled the back-reef basins and overflowed the bank–reef system. Overall, siliciclastic sedimentation slowed in the major basins, and the margins began to assume shapes similar to their present morphology. Globally, the Cretaceous was a period of poorly oxygenated marine waters,

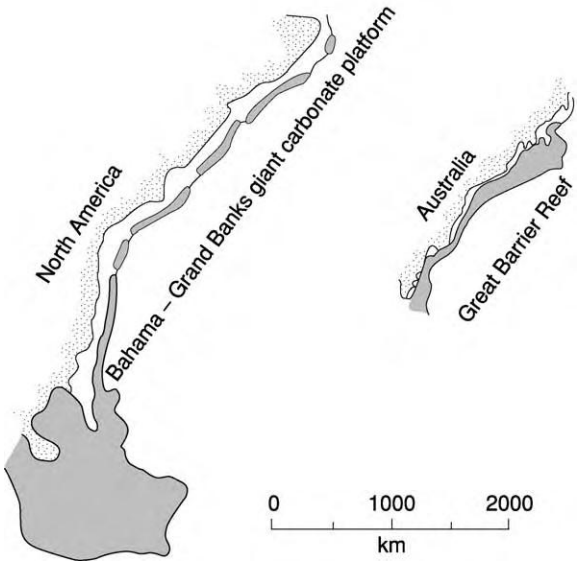

Figure 11 Carbonate tracts (stippled areas) associated with the Late Jurassic Bahama Grand Banks giant carbonate plat form along the North American Atlantic Continental Margin. The modern Great Barrier Reef system of Australia (rotated through 180°) is shown for comparison. (Reproduced from Poag CW (1991) Rise and demise of the Bahama Grand Banks gigaplat form, northern margin of the Jurassic proto Atlantic seaway. *Marine Geology* 102: 63 130.)

and studies of the dark carbon-rich Cretaceous deposits of the Hatteras Formation, on the rise and abyssal plain off the coast of North America, have contributed substantially to understanding black-shale sequences. The Cretaceous was also a time when the carbonate compensation depth cycled

between shallow (2000 m) and deep (more than 4000 m).

During the Cenozoic, continental-margin sedimentation was increasingly affected by currents, especially contour-parallel currents (*see* **Sedimentary Environments:** Contourites). Depocentres shifted seawards, causing the continental rise to be built up (Figure 12). The Paleocene and Eocene probably saw the onset of a current-dominated regime (e.g. the ancestral Gulf Stream) and the initiation of small canyons, but much of this early record is thin or missing because of subsequent erosion during the Oligocene. Global temperatures began falling as the Earth completed its transition from a 'greenhouse' in the Cretaceous and Paleocene to an 'icehouse' in the Oligocene. During the Middle Oligocene sea-level lowstand, the Baltimore Canyon shelf retreated by about 30 km. Cold water in the North Atlantic contributed to deep thermohaline circulation, and contour currents became more vigorous in the Early Miocene when cold Norwegian bottom waters overflowed the Norwegian–Greenland ridge and entered the Atlantic, initiating the formation of both the elongate Chesapeake and the Blake Outer Ridge drift deposits. Glaciation of North America in the Late Tertiary increased siliciclastic deposition, intensified down-slope sedimentary processes (e.g. turbidity currents, slumps, slides, and debris flows), and

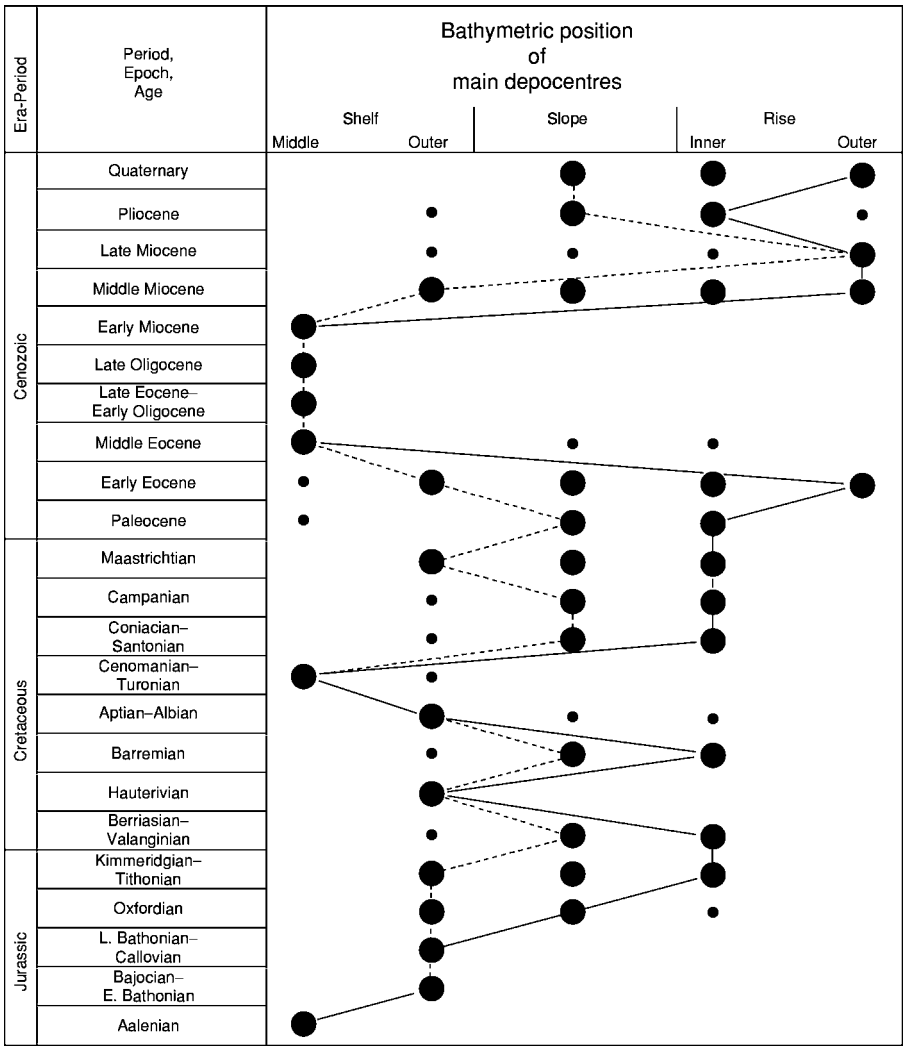

Figure 12 The bathymetric positions of the main depocentres in the Baltimore Canyon trough through the last 187 Ma. Large dots indicate major depocentres (i.e. thickest sediments). Small dots indicate secondary depocentres. Solid line shows the shift in the primary deep water depocentres through time. Dashed line shows the shift in the primary shallow water depocentres. This chart shows the migration of the trough seawards and landwards during the history of the margin. Note the marked period of limited shelf and slope deposition in the Late Miocene. shifted sedimentary depocentres to deeper water on the rise and abyssal plain. Many new canyons also developed.

Energy, Mineral, and Water Resources

The knowledge base about energy resources on the North American continental margin varies by country: drilling off the US East Coast in the late 1970s and early 1980s produced disappointing shows for both oil and gas in the Baltimore Canyon trough and Georges Bank basin. Neither the Carolina trough nor the Blake Plateau basin have been drilled or tested for petroleum maturation, although models suggest that maturation in the Carolina trough should have reached the oil window only in its deepest Early and Middle Jurassic rocks. The petroleum potential in the rift basins buried beneath the margin remains unknown. Currently the USA has a moratorium on leasing and drilling on its offshore Atlantic margin.

In contrast, Canada has had an active exploration and production programme on the Scotian Shelf and Grand Banks since the late 1970s. The Mesozoic Jeanne d'Arc rift basin contains the most significant discoveries on the Grand Banks (Hibernia, Terra Nova, Hebron-Ben Nevis, and White Rose fields). Both oil and gas have also been produced from Upper Jurassic and Lower Cretaceous sandstones on the Scotian Shelf in the vicinity of Sable Island. In the 25 years since exploration began, a robust offshore technology and infrastructure has grown to support the Canadian petroleum industry.

One of the best-known deposits of an unconventional hydrocarbon, gas hydrate, exists on the Blake Ridge off the coast of the south-eastern USA (Figure 13). Gas hydrate is an ice-like solid that holds high concentrations of methane in a crystalline water matrix, which forms under pressures, temperatures, and geochemical conditions that are often found in sediments near the seafloor deeper than about 500 m water depth (*see* **Petroleum Geology:** Gas Hydrates). The first dedicated gas-hydrate drilling leg of the Ocean Drilling Program occurred on the Blake Ridge in 1995 (Leg 164). Estimates of the total volume of methane in both hydrate and associated free-gas deposits on the Blake Ridge vary from 60 to 100 trillion cubic metres.

Occurrences of offshore minerals are known along the North American continental margin, but they have not been as extensively developed or exploited as their onshore equivalents, primarily because recovery and transportation are more expensive in an offshore environment. Phosphates, used in agricultural fertilizers, are successfully mined in coastal-plain (i.e. postrift) deposits in Florida and North Carolina, but phosphate deposits on the continental shelf between Georgia and North Carolina are largely unexploited. Manganese nodules and ferromanganese crusts, potential sources of manganese, nickel, cobalt, copper, and platinum, have been sampled on the Newfoundland and New England Seamounts, but their distributions are largely unmapped. More detailed studies of similar nodules and crusts have been carried out on samples from the Blake Plateau.

Placer deposits also exist offshore, the most famous being gold-bearing sands and alluvium along the Nova Scotian inner shelf, which are presumed to have a source in pre-Mesozoic basement rocks. Mining for these intriguing finds has been largely uneconomical. Placer deposits containing titanium and iron have been mapped off Florida and are inferred to exist on other parts of the margin. The most plentiful mineral deposits are quartz sands, which are dredged mainly from the inner shelf for beach nourishment (for example, off the coasts of most of the states between New Jersey and Florida). Other resources that have been identified but not developed offshore include high-purity silica sand in the Gulf of St Lawrence and on the Grand Banks (which could be used for glass making), calcium carbonate sand (which is a key ingredient of Portland cement), clay deposits (which supply material for bricks, sewer pipes, and other construction materials), and coarse sand and gravel (which could be used in road building and maintenance). Quaternary glaciation (*see* **Sedimentary Processes:** Glaciers) and modern depositional processes have controlled much of the distribution of unconsolidated sands and gravels on the margin from New England to Newfoundland.

One offshore resource that has received little attention is fresh groundwater within sediments of the continental margin. Freshwater springs are known along the Florida shelf. One of the most spectacular is the Crescent Beach spring, about 3 km off the coast of north-east Florida, in about 20 m water depth. This spring produces a boil with a hydrogen sulphide odour on the sea surface during times of high discharge. Within the fractured and porous limestone (*see* **Sedimentary Rocks:** Limestones) aquifer system of the south-eastern USA, this offshore fresh groundwater is derived from rainfall on land, and its pressure is considered to be in equilibrium with sea-level. In contrast, shallow wells drilled on the continental shelf off New Jersey show a thin wedge of almost-fresh water that extends more than 100 km across the margin at relatively shallow depths (less than 100 m beneath the seafloor, Figure 14). This fossil freshwater accumulated during the Pleistocene falls in sea-level and has been protected from saltwater contamination

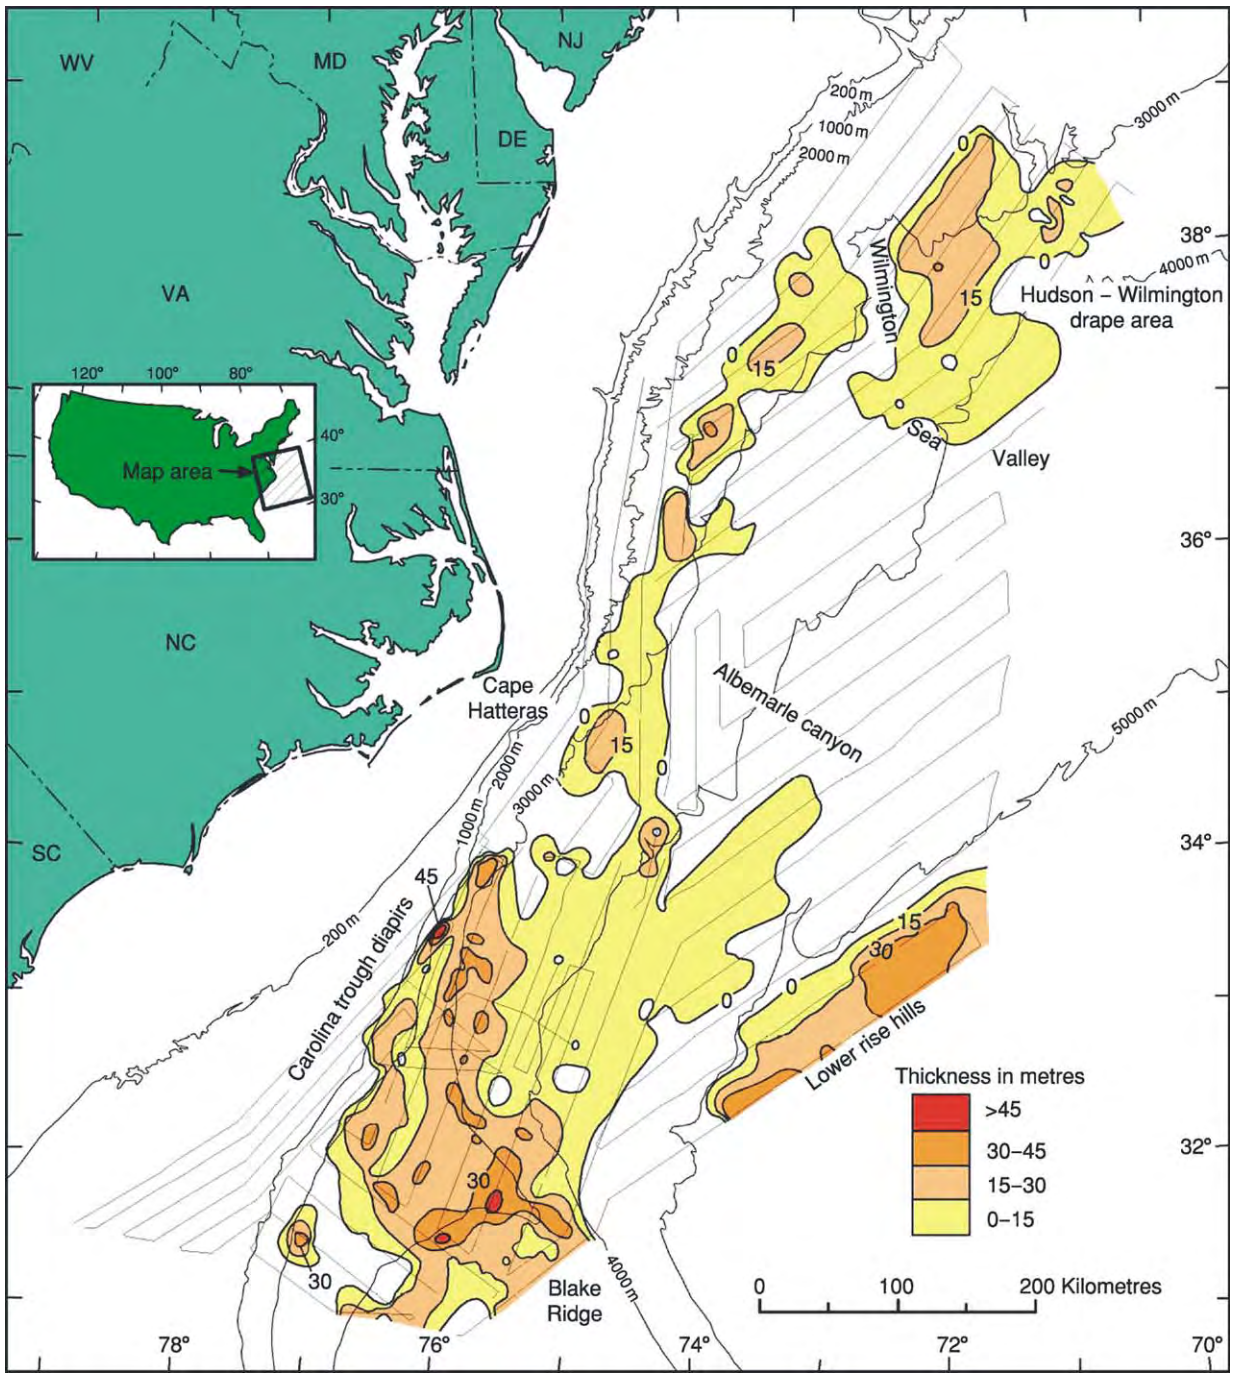

Figure 13 Distribution of gas hydrate inferred from seismic reflection data on the US Atlantic margin. Contours show the volume of pure gas hydrate in terms of thickness in metres. Volumes were estimated by mapping the extent of blanking in seismic profiles and then using a model to transform blanking to proportion of gas hydrate in the sediment. (Reproduced from Dillon WP, Fehlhaber K, Coleman DF, Lee MW, and Hutchinson DR (1995) *Maps Showing Gas Hydrate Distribution off the East Coast of the United States*. Miscellaneous Field Studies Map MF 2268, 1 : 1 000 000, 2 plates. US Geological Survey.)

by a low-permeability confining clay unit, which has prevented it from reaching equilibrium with the present saltwater hydrologic system. Freshwater is unknown in the continental-margin sediments off the coast of Canada.

Current and Future Societal Issues

As population growth has intensified in coastal regions, interactions between humans and nature have created an urgent need to understand surficial

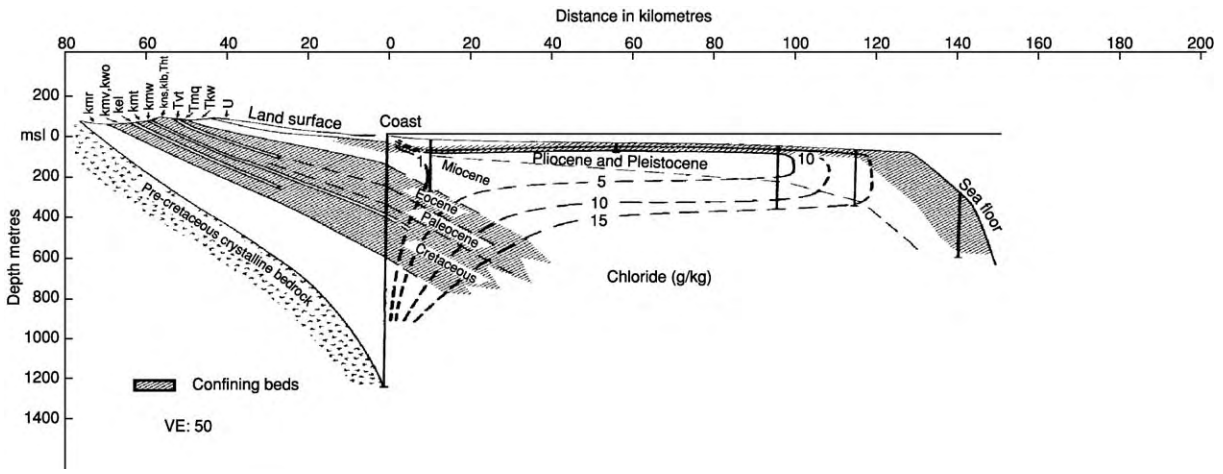

Figure 14 Schematic hydrological section through postrift sediments of the central Baltimore Canyon trough. Dashed contours show the chlorinity of the pore waters. The chlorinity of typical ocean water is about 19‰. (Modified from Kohout FA, Meisler H, Meyer FW, *et al.* (1988) Hydrogeology of the Atlantic continental margin. In: Sheridan RE and Grow JA (eds.) *The Geology of North America, Volume I 2: The Atlantic Continental Margin: U.S.*, pp. 463 480. Boulder, Colorado: Geological Society of America.)

geological processes that affect, for example, coastal erosion, sediment contamination, and habitat occurrence. Erosion from large storms results in loss of and damage to property and sometimes life. Beaches of the USA are among the most heavily artificially replenished of any country in the world: sand is often mined from the inner shelf. Three-dimensional bathymetric and geological mapping offshore has re-emphasized the importance of the geological framework of the shallow continental margin in understanding sediment transport, defining fragile habitats, and predicting the ultimate fate of industrial waste products in the oceans. Mapping techniques that integrate bathymetry, shallow subsurface profiles, video, and sampling have helped to determine which fishing grounds to open on Georges Bank and to manage other offshore fisheries. Many of these societal issues will increase in importance as population growth continues in coastal regions.

New technologies and high-speed computers are yielding new ways to view the continental margin and revealing new opportunities for fundamental scientific research. High-resolution bathymetric maps of the Hudson Shelf Valley reveal major bedforms and debris-flow deposits on the outer shelf, which appear to have been formed by a previously unrecognized enormous flood event. Sampling, dating, and interpretation of these deposits have not yet been achieved but are likely to modify interpretations of the late glacial and postglacial Quaternary history of the northern Atlantic region. Likewise, three-dimensional mapping of gas hydrates continues to challenge researchers to understand the importance of geology in controlling the occurrence of these highly dynamic potential resource reservoirs.

Recent ratification of the United Nations Convention on the Law of the Sea by Canada and the imminent ratification expected by the USA will create the need to identify geodetically accurate positions of the foot of the continental slope and to map accurately the sediment thickness in deep water. Such data can be used by nations to extend the legal boundary of their continental margin. These circumstances provide opportunities in which fundamental science can be integrated with practical needs.

Conclusions

The North American Atlantic Continental Margin is the type example of an Atlantic passive continental margin. For more than 200 million years, this margin has evolved from its initial equatorial rift configuration, accompanied by shallow oceanic flooding, to its present mature mid-latitude position bounding a deep ocean. The margin contains a rich record of diverse geological and tectonic processes and features, which include evaporite basins, extensive carbonate banks and reefs, and the modern sand-dominated partly glaciated sediment system. This margin provides sources of energy and minerals for human use and may hold a potential reserve of freshwater. The twentieth century was a time of great exploration, discovery, and characterization of the margin. At the start of the twenty-first century, new challenges confront researchers, in particular the need to understand how to balance human demands (e.g. for resources, stable coastlines, and waste disposal) with natural

processes (e.g. coastal erosion, habitat maintenance, and sediment and contaminant transport). Much of the continental margin remains an unexplored frontier area with regard to these new challenges.

Introduction

The islands of the south-west Pacific extend for 5000 km from New Guinea in the west to Fiji, Tonga, and Samoa in the east, and include the Solomon Islands, Vanuatu, and New Caledonia (Figure 1). The early European explorers called the area Melanesia because of the generally dark skin colour of the people. Subsequently, the parallel island chains have sometimes been referred to as the inner and outer Melanesian arcs. New Guinea was colonized from the west more than 40 000 years ago; New Britain, at least 35 000 years ago; New Ireland, at least 20 000 years ago; and the northern Solomon Islands, 28 000 years ago. The other Melanesian islands, New Caledonia, Vanuatu, and Fiji, were settled only 3000 years ago.

The islands have many similarities in their geology, in that, for the most part, they have been constructed on oceanic crust by one or more cycles of volcanic activity. Exceptions are the island of New Guinea, which is part of the Australian continent; the older rocks of New Caledonia, which first formed at the margin of the Australian continent; and the outermost Solomon Islands, which are elevated oceanic crust. There are deep-sea trenches on either side of the island chains. On the outer (north-eastern) side are the Manus, Kilinailau, Solomons, and Vitiaz trenches, which are only weakly active or are inactive, and the Tonga–Kermadec Trench east of Tonga (Figure 1), which is active. On the inner (south-western) side is an active system of trenches, the New Britain–Makira–Vanuatu–Hunter–Kadavu trenches. Other seafloor features include the massive Ontong Java submarine plateau of thickened oceanic crust (Figure 1), smaller oceanic plateaus of rifted continental lithosphere in the Coral Sea, and a number of small ocean basins, some of which are actively spreading.

The islands occupy the boundary zone between the north-moving Australian plate and the west–north-west-moving Pacific Plate, and for this reason are tectonically and volcanically active (Figure 2). The plate boundary is not a simple one but, rather comprises a number of smaller plates that exhibit a variety of plate interactions, from seafloor spreading to subduction, transform faulting, and rotation. The lines of earthquakes on the map (Figure 2) coincide with the plate boundaries, and give an idea of the high level of seismic activity in the region. The plot of depth-coded hypocentres shows the trace of a subducted slab dipping westward from the Tonga–Kermadec Trench, in the east, and of a subducted slab dipping northward from the New Britain Trench, in the north-west. The area has evolved since the Cretaceous by repeated episodes of crustal extension and crustal shortening. Extension produced small ocean basins, and shortening resulted in subduction and thrust faulting. The volcanic islands have grown through this time, initially (in the Eocene to Early Miocene) by volcanism related to subduction of the Pacific Plate on the outer trench system, and more recently (the past 10 million years) by volcanism related to subduction of the Australian Plate on the inner trench system.

Papua New Guinea

Papua New Guinea (PNG) comprises the eastern half of the island of New Guinea, the adjacent islands of the Bismarck Archipelago, and the northernmost of the Solomon Islands (Bougainville and Buka). The geology of PNG can be described in terms of four geological provinces (Figure 3): a stable platform in the south-west, where the Australian craton extends beneath the island of New Guinea; a collisional zone in the centre and north of the island, where terranes have been sutured to the Australian craton; a province built by volcanic arc activity in the north-east; and the Ontong Java submarine plateau.

Platform and Foldbelt

The stable platform comprises a continental basement of Palaeozoic and partly Precambrian metamorphic and igneous rocks overlain by a 4-km-thick paraconformable sequence of shelf facies Mesozoic siliciclastic, and Cenozoic carbonate and siliciclastic, sedimentary rocks (Figure 3). Rocks along the northern margin of the platform are buckled and faulted to form a basement-involved foreland fold-and-thrust belt. Northward of the fold-and-thrust belt, the Mesozoic sediments are transitional into a kilometres-thick sequence of black mudstones. These

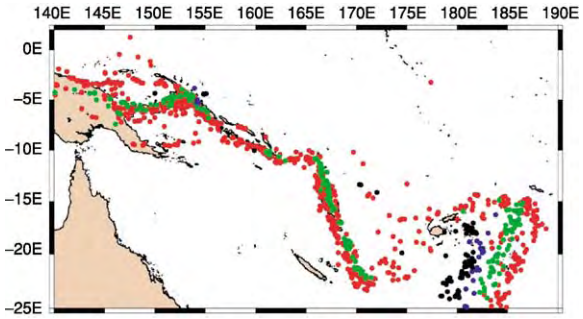

Figure 2 The map shows earthquakes with magnitude 6 or greater, recorded during 1963 2002. Red indicates hypocentre depth of 0 70 km, green 70 300 km, blue 300 500 km and black >500 km. Features of the map are the west dipping seismic zone beneath Tonga in the east, the north dipping seismic zone be neath New Britain in the north west, and the steeply dipping seismic zone beneath Vanuatu. Shallow seismic zones (red dots) mark the spreading ridges and transforms in the Bismarck and Solomon seas and the North Fiji Basin. Map prepared by Emile Okal.

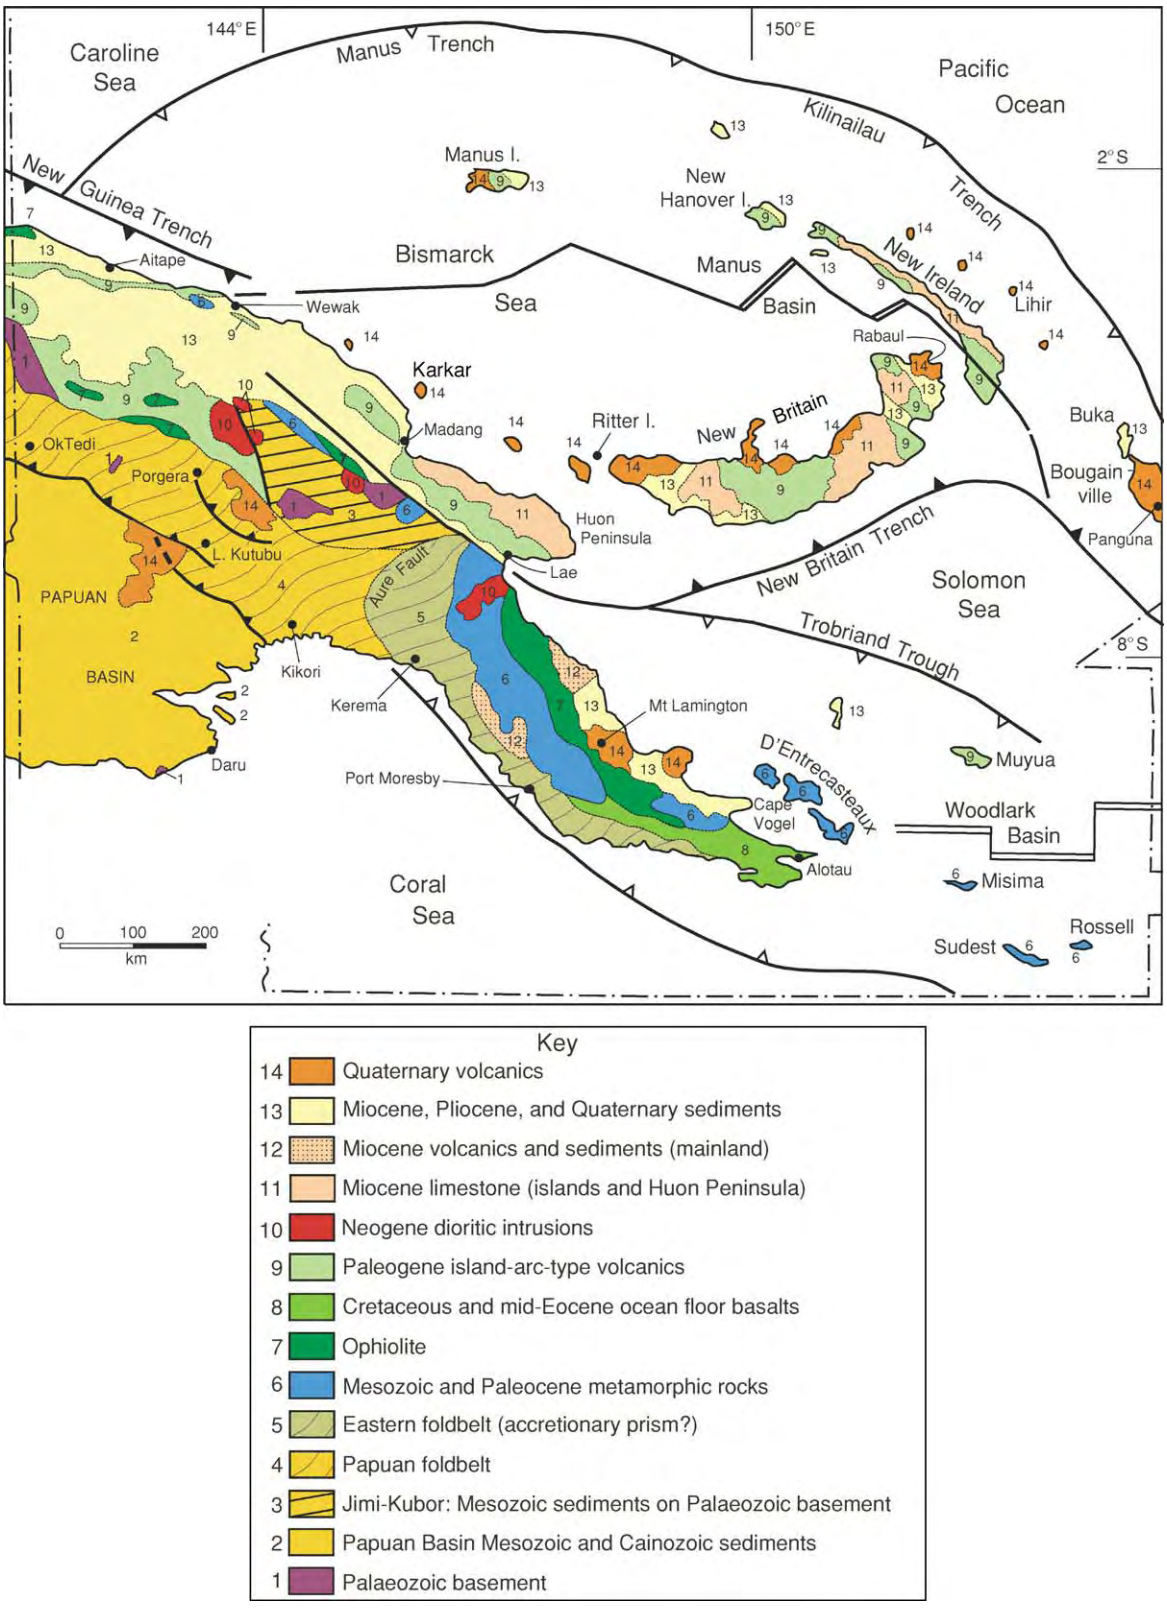
in turn are transitional northwards into greenschist facies graphitic schists. The sediments of the stable platform and foldbelt comprise the Papuan Basin.

The foldbelt changes character east of the Aure Fault (Figure 3). Beyond this point, the foldbelt comprises fault-bounded segments of Late Cretaceous, Paleocene, and Eocene fine siliceous siliciclastic and calcareous sedimentary rocks, associated with faulted slivers of ultramafic rock; Oligocene and younger coarser, partly volcanogenic, dominantly clastic sediments; and locally extensive Oligocene gabbro. There is no indication of a continental or cratonic basement, though such may exist. The Paleocene and much of the Eocene sediments were deposited in a deep marine environment and probably have been added to the mainland by accretion above a north-dipping subduction system.

Collisional Zone

The western part of the central collisional zone comprises fault-bounded terranes of Jurassic to Eocene sedimentary, igneous, metamorphic, and ultramafic rock, and younger (Eocene to Miocene) dioritic intrusive bodies. The association of ultramafic rocks with eclogite, blueschists, submarine volcanic rocks, and volcanogenic sediments indicates a former volcanic arc environment. Sediments associated with the volcanic rocks are of two ages, mid-Eocene and Oligocene. This suggests a history of successive development of volcanic arcs and successive collisions; the Oligocene volcanic rocks are found only on the north side of the northern ranges. Also included in the western part of the central collisional zone are two fault-bounded blocks of Palaeozoic basement. One of these lies on the border with Indonesian Papua and the other extends northward from the Kubor Range, to underlie the Jimi valley (Figure 3). These Palaeozoic terranes lie outward (northward) of younger accreted terranes and thus appear to be 'out of sequence'.



Key

14 Quaternary volcanics
13 Miocene, Pliocene, and Quaternary sediments
12 Miocene volcanics and sediments (mainland)
11 Miocene limestone (islands and Huon Peninsula)

Figure 3 Geological map of Papua New Guinea, showing active (solid triangles) and inactive or slow acting trenches (open triangles), transforms, and spreading ridges; major thrust faults on land (solid triangles) are also indicated. There are four geologic provinces: Platform in the south west, collisional in the centre, volcanic arcs in the north east, and Ontong Java Plateau. Map drawn by L Cotterall, Geology Department, Auckland University.

Possibly they are indications that the Palaeozoic craton extends northward as a substrate beneath the terranes of the collisional zone. Mesozoic amphibolite facies metamorphics near the north coast (Prince Alexander Range) and Oligocene metamorphics associated with ultramafic rocks just beyond the border on the north coast (near Jayapura) also are 'out of sequence' and may represent material ramped up from a subjacent older stratum.

The geology of the eastern part of the collisional zone, from Lae south-eastward, is much simpler and essentially comprises two rock units: an inner core of metamorphic rocks, flanked on the north-east side by a major ophiolite complex. The protolith of the metamorphics was felsic and psammitic sediments and some submarine basalts, partly of Cretaceous age, and these were metamorphosed in the Paleocene. The ophiolite comprises a 4- to 8-km thickness of tectonite harzburgite, overlain by lenses of cumulate-textured ultramafic rocks, which are in turn overlain by 4 km of gabbro and 4 km of basalt. Paleocene and Eocene volcanic rocks that overlie the ophiolite may be arc related. Ocean floor basalts that form the eastern end of the island are Late Cretaceous and Middle Eocene and may be related to the ophiolite. Miocene and younger, partly volcanogenic, dominantly siliciclastic sediments of the North New Guinea Basin unconformably overlie basement in the western part of the collision zone, and Miocene and younger volcanics and sediments of the Cape Vogel Basin unconformably overlie basement in the eastern part of the collision zone.

North-Eastern Province

The north-eastern province, constructed by volcanic arc activity, embraces the islands of the Bismarck Archipelago and the mainland mountain ranges of the Huon Peninsula. The oldest rocks are Eocene and Oligocene volcanics with some dioritic intrusions. These are partly overlain by Miocene limestone, which is in turn partly overlain by volcanic rocks of the present-day (Plio-Quaternary) volcanic cycle. Bougainville, in the Solomon Islands chain (see later), has similar geology. The land areas are separated by several small ocean basins: the Bismarck Sea, Solomon Sea, and Coral Sea (Figure 3). There are active spreading ridges and transforms in the eastern Bismarck Sea (Manus Basin) and southern Solomon Sea (Woodlark Basin) and active trenches on the inner side of New Britain and the Solomon Islands, on the outer side of the Solomon Islands and extending westward to Manus, and off the New Guinea coast west of Wewak. A trench on the south side of the Solomon Sea, at the Trobriand Trough, is masked by thick sediment. Volcanic activity is associated with the New Britain Trench but not with the trench west of Wewak (New Guinea Trench). The Coral Sea opened by seafloor spreading in the Paleocene (65–55 Ma), the Solomon Sea in the Oligocene (40–30 Ma), and the eastern Bismarck Sea and Woodlark Basin in the Plio-Quaternary (since 6 Ma).

Economic Minerals

The main mineral deposits of Papua New Guinea are porphyry copper–gold deposits, disseminated and vein gold deposits, and alluvial gold. Other less common deposits include lateritic nickel–cobalt ore over ultramafic rocks, minor manganese ore, and the small copper–gold massive sulphide orebodies that have been mined near Port Moresby. The Panguna mine (now closed) on Bougainville Island and the Ok Tedi mine in Western Province are classic porphyry copper–gold deposits. In both locations, copper and gold occur in Plio-Quaternary dioritic to granitic rocks and in the adjacent country rocks. Similar mineralization is known at Frieda River (West Sepik), Yandera (north-west of Goroka), and Wafi, 50 km south-west of Lae.

Disseminated and vein gold deposits are mined at Porgera; Ladolam on Lihir Island; Tolukuma, north of Port Moresby; and, until recently, Misima Island. Production is planned from Irumafimpa near Kainantu and from Hidden Valley, near Wau. Production from these mines, together with Ok Tedi, is sufficient to place Papua New Guinea in the top five of gold-producing nations, worldwide. The Panguna mine also was a major producer of gold. At Porgera, gold mineralization occurs in intrusive dioritic rocks and in the adjacent, baked sedimentary rocks. At Ladolam, the gold is in the floor of the caldera of an eroded volcano, with hot springs nearby. At Tolukuma, Irumafimpa, and Hidden Valley, the gold is in quartz veins. Alluvial gold is mined on a small scale in many parts of Papua New Guinea, notably near Amanab and Maprik in the Sepik, in the Western and Eastern Highlands, around Wau, and in Milne Bay Province.

From 1930 to 1965, with a break for the Second World War, alluvial gold was mined by dredges in the Bulolo valley. A total of about 65 tonnes of gold was produced. Within the last few years, a rich alluvial field was found at Mount Kare, south-west of Porgera. Where earlier gold rushes had been almost exclusively managed by overseas miners, Mount Kare was the first entirely Papua New Guinean gold rush. As many as 8000 miners were on the field at any one time and an estimated 15 tonnes of gold was taken out in 2 years. The only other fields to have produced more than a tonne of gold are the Lakekamu and Sepik alluvial fields, and Misima and Muyua (Woodlark), both of which were mixed alluvial and lode mining. Lateritic soils over ultramafic rocks south of

Madang contain economic concentrations of nickel and cobalt and await development.

Energy Resources

Oil currently is produced from several thrust-bounded anticlines containing the Kutubu, Gobe, and Moran oil fields, all of which are in the vicinity of Lake Kutubu in the Southern Highlands Province. Production from the South-east Mananda oil field within the giant Mananda structure between the Kutubu oil fields and the Hides gas field is planned. The oil was derived from Jurassic black shales and has accumulated in clean, shallow marine quartz sandstones of Late Jurassic and Early Cretaceous age. At the time of the initial discovery, in the Iagifu anticline, recoverable reserves were estimated at around 200 million barrels of oil. By the beginning of 2004, 354 million barrels had been produced from the various fields and remaining recoverable oil reserves stood at 222 million barrels. Production, which began in June 1992, has declined from a peak of almost 150 000 barrels day^{-1} in 1993 to around 50 000 barrels day^{-1} in 2004 as the fields have been depleted.

A small part of the large volume of gas in the Hides anticline, south-west of Tari, provides electrical power to the Porgera mine. The gas at Hides and in other structures in the foldbelt is sufficient to be developed commercially, provided that a market can be found. A pipeline to Queensland, Australia is planned, but the project awaits confirmed markets before detailed engineering and design work and construction can proceed. Large volumes of gas also have been discovered offshore in the Gulf of Papua at Pandora on the north-western corner of the Eastern Plateau, about 150 km south-west of Kerema. This gas occurs in a deeply buried cavernous Miocene limestone reef. Oil and gas seeps are known in the North New Guinea Basin and there are indications of petroleum in the Cape Vogel Basin. A pilot program to utilize geothermal energy at the Ladolam Mine on Lihir Island has proved successful and is being expanded. This is the first use of geothermal energy in PNG.

Natural Hazards

Papua New Guinea has 14 active and 22 dormant volcanoes and these pose a potential danger to 204 000 people. Ten of the fourteen active volcanoes and 12 of the 22 dormant volcanoes are in the Bismarck volcanic arc, from Bam, Manam, Karkar, and Long Island in the west to Langila, Garbuna, Makalia, Pago, Ulawun, and Rabaul in the east. Other groupings of active volcanoes are in the Admiralty Islands, on Bougainville Island, and in eastern Papua. The agency charged with monitoring the PNG volcanoes is the Rabaul Volcanological Observatory.

Rabaul volcano erupted in 1937, killing more than 500 people. When it erupted again in 1994, only five people were killed, but much of Rabaul town was devastated, leading to a decision to relocate government and most business activity to Kokopo. The worst volcanic disaster in historical time was the explosive eruption of Lamington volcano in Oro Province in 1951; 3000 people were killed. A major tsunami generated by the collapse of the west flank of Ritter Island volcano in 1888 caused untold loss of life on New Britain and adjacent islands. More recently, in 1998, the Aitape tsunami destroyed two villages, damaged other villages, and caused more than 1650 deaths.

Solomon Islands

The central and western Solomon Islands form a double chain on either side of a central trough and are bounded on both flanks by deep-sea trenches (Figure 4). The islands comprise three geological provinces: a north-eastern province of Cretaceous–Paleocene oceanic basalts and pelagic sediments, a central province of more complex geology that includes metamorphic and ultramafic rocks and Oligocene–Miocene arc-related volcanics, and a south-western province of Late Miocene to Quaternary volcanic activity. The islands of the north-eastern province are Malaita, the small island of Ulawa, and the north-eastern side of Santa Isabel. On these islands, Cretaceous and Paleocene submarine basalts with intercalated pelagic limestone and mudstone are overlain by younger Cenozoic marine sediments that contain terrigenous material. The Cretaceous and Paleocene rocks originated as part of the Ontong Java submarine volcanic plateau. On Malaita, an intrusion of alnoite, a silica-poor mafic rock, dating to 34 Ma, has attracted interest in the past because of the occurrence of unusual xenoliths, including garnet peridotite.

The islands of the central province are Choiseul, the south-western side of Santa Isabel, the Florida islands, Guadalcanal, and Makira (San Cristobal). Basement on these islands comprises Cretaceous basalt, greenschist and amphibolite facies, mafic schists, and ultramafic rocks; the metamorphic rocks have radiometric ages around 50 Ma, Early to mid-Eocene. Volcanic rocks of Late Eocene(?), Oligocene, and Early Miocene age unconformably overlie the basement rocks, and volcano-related dioritic stocks intrude basement. A thick sequence of Miocene to Pliocene clastic sediments covers much of Guadalcanal Island but is not strongly developed on the other islands.

The south-west province comprises Late Miocene to Holocene arc volcanic rocks and associated

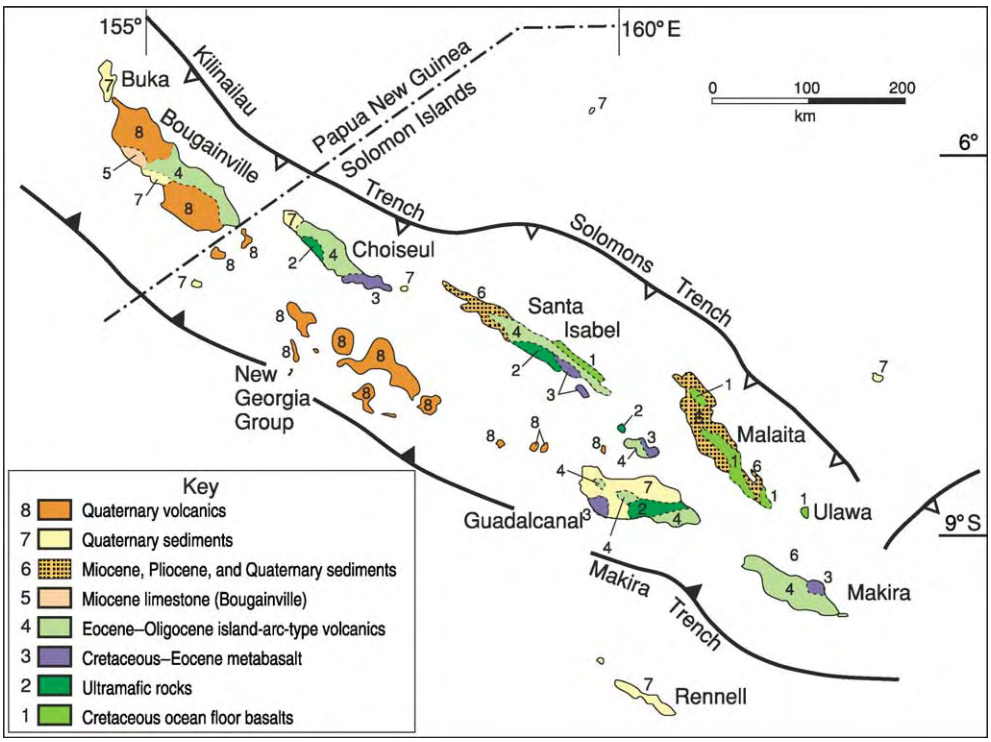

Figure 4 Geological map of the Solomon Islands, including Bougainville and Buka Islands (Papua New Guinea), showing the Makira (San Cristobal) active trench, the Kilinailau inactive trench, and the North Solomons slow acting trench. The dashed line marks the international border. Map drawn by L Cotterall, Geology Department, Auckland University.

sediments and intrusive rocks. These extend from Bougainville (PNG) and the Shortland Islands in the north-west, to the near end of Guadalcanal in the south-east. There is an outlier of Pliocene volcanics and intrusive rocks in central Guadalcanal, at Gold Ridge. Bougainville Island, politically a part of Papua New Guinea, is the north-westernmost of the Solomon Island chain and combines characteristics of both the central and south-western geological provinces. A basement of Eocene and Oligocene arc-related volcanic rocks is partly overlain by Miocene limestone and Plio-Quaternary volcanoes and is intruded by Pliocene dioritic stocks. The Solomon outer eastern islands are far removed from the central and western islands and are shown on the Vanuatu geological map (Figure 5). The islands of the Santa Cruz Group comprise Miocene to Holocene volcanic rocks and sediments. The Duff Islands, and the islands of Anuta, Fatutaka, and Tikopia (not shown on Figure 5) comprise Quaternary volcanic rocks and sediments. Tinakula in the Santa Cruz Group is the only active volcano.

Geological Evolution

The islands of the north-east province developed as a result of continued convergence across the line of the Kilinailau Trench (Figure 4), and resulting delamination and eastward overthrusting of an upper part of the Ontong Java volcanic plateau. The rocks of the lower part of the Ontong Java plateau continue to be subducted steeply beneath the Solomon Islands. The central province association of ultramafic rocks, Cretaceous basalt, and Eocene metamorphic rocks is thought to have developed as a result of subduction of Pacific plate at the Kilinailau Trench in the Eocene, but the apparently rapid exhumation of these rocks (exhumed before the Oligocene) is not readily explained. The same cycle of subduction yielded the Oligocene to Early Miocene arc-type volcanic rocks that overlie basement on the islands of the central province. The Late Miocene to Holocene volcanic rocks of the south-west province were generated by subduction of the Australian plate at the Makira (San Cristobal) Trench.

Economic Geology

Gold associated with Pliocene intrusives has been mined at Gold Ridge on Guadalcanal Island, and soils on ultramafic rocks on Santa Isabel Island have been tested for lateritic concentrations of nickel and cobalt.

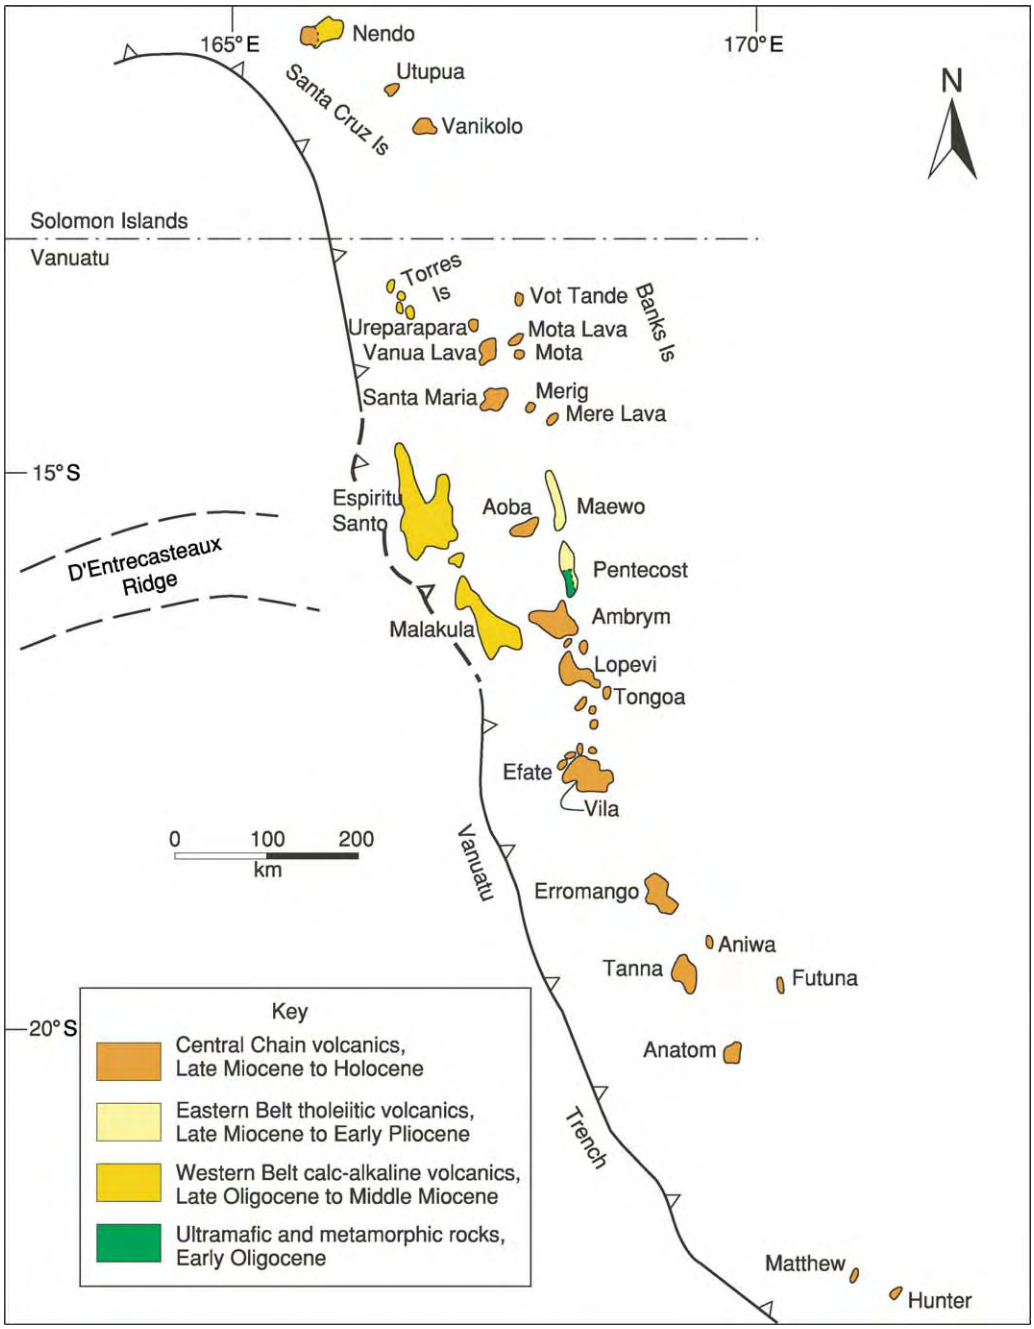

Figure 5 Geological map of Vanuatu, including the Santa Cruz Group in the Solomon Islands (the dashed line marks the international border). The map shows the active Vanuatu trench, the western belt Islands of Late Oligocene to Middle Miocene volcanics, the eastern belt (Maewo and Pentecost Islands) of Late Miocene to Early Miocene volcanic rocks, and the central chain of Late Miocene to Holocene volcanoes. Ultramafic and metamorphic rocks (dating to 35 Ma) are exposed on southern Pentecost Island. Map drawn by L Cotterall, Geology Department, Auckland University.

Vanuatu

The islands of the Vanuatu archipelago (Figure 5) form a narrow chain that extends for more than 1200 km, from the Torres Islands in the north to Matthew and Hunter islands in the south. The island chain is bounded eastward by the North Fiji Basin and westward by the Vanuatu Trench. The islands are, with one exception, entirely volcanic in origin, with associated sediments and intrusive rocks. The exception is on southern Pentecost Island, where ultramafic rocks associated with blocks of schistose amphibolite, metamorphosed pillow lava, and metagabbro are in

fault contact with Pliocene sediments. The metamorphic minerals have a radiometric age of around 35 Ma, and thus are older than any of the volcanic rocks.

The geology of Vanuatu has been described in terms of three volcanic provinces: a western province of Late Oligocene to Middle Miocene age (27–14 Ma; calc-alkaline volcanics), an eastern province of Late Miocene to Pliocene age (7–4 Ma; tholeiitic volcanics), and a central province of Miocene and Pliocene to Holocene volcanic rocks (6 Ma to the present day; Figure 5). The volcanic rocks of the western province developed in response to westward subduction of the Pacific plate at the Vitiaz Trench. The Vitiaz Trench, at that time, lay immediately east of Vanuatu. The trench moved away from Vanuatu (see Figure 1) with the opening of the North Fiji Basin in the past 6 million years.

The volcanic rocks of the eastern province developed in response to eastward subduction of Australian plate at the Vanuatu Trench. Magmatism in the central chain began at 6 Ma and was initially focused on Erromango, Tanna, and Anatom in the south. Volcanism subsequently developed along the entire length of the arc and shifted closer to the trench because of a steepening of the subduction zone to its present inclination of 70°.

The D'Entrecasteaux aseismic ridge, an Eocene–Oligocene island-arc complex, collided with central Vanuatu at 3–1.5 Ma, near Epi, and has migrated northwards as a result of the obliquity of the ridge relative to the trench. The collision has caused a slowing of subduction that may in turn have caused the development of back-arc thrust faults east of Maewo and Pentecost Islands, and the elevation of the ultramafic and metamorphic rocks on Pentecost. Five of the volcanoes of the central province are potentially dangerous. These are Ambae, Gaua, Ambrym, Tanna, and Lopevi. Only Yasur volcano on Tanna Island is monitored.

Economic Geology

Manganese oxide has been mined on Efate, where it typically is developed at contacts between tuff and overlying limestone. Occurrences of copper, zinc, molybdenum, and gold are known.

New Caledonia

The island of New Caledonia and the adjacent islands (Belep Islands to the north and Isle of Pines to the south) lie on the Norfolk Ridge. To the west, beyond the New Caledonia Basin, is Lord Howe Rise, and to the east are the Loyalty Ridge and Loyalty Islands (Figure 1). The rock units of New Caledonia (Figure 6) do not form a simple stratified sequence but, rather, comprise a series of terranes, juxtaposed during a complex history of convergent and extensional tectonic activity, and successor basin sediments. Four terranes make up a pre-Cretaceous basement. This is unconformably and tectonically overlain by Late Cretaceous and younger successor basin sediments and terranes.

Basement Terranes

The pre-Cretaceous basement is a complex amalgam of ophiolite, volcanics, and sediments that developed along the East Gondwana margin during the Permian to Jurassic. Four distinct terranes are recognized. The oldest, the Late Carboniferous Koh ophiolite, is a dismembered fore-arc ophiolite that is probably the basement on which two of the other three terranes, the Teremba and Central Chain terranes, were deposited. The Teremba Terrane, of mid-Permian to Late Jurassic age, has arc-related volcanics and volcaniclastics at its base, but is dominantly composed of a simply deformed thick sequence of diagenetically altered, fossiliferous shallow water sediments. The Central Chain Terrane, considered to be the distal equivalent of the Teremba Terrane, is composed of volcaniclastic sediments and minor arc-tholeiitic basalts that all have been weakly metamorphosed. The Boghen Terrane is a thick sequence of metagreywackes and schists, with sedimentary compositions ranging from pelitic to mafic, on a basal sequence of tholeiitic pillow lavas and red and green radiolarian cherts; detrital zircons in the sedimentary rocks indicate the sediments are of Jurassic age and derived from a south-east-Gondwana arc system and the Antarctic continent. The Boghen Terrane is considered to be a Jurassic accretionary complex, metamorphosed in the Late Jurassic.

Successor Basin Sediments

A transgressive sequence of Late Cretaceous coal measures and conglomerates rests unconformably on all of the older terranes, and forms thick sequences in the Nouméa–Bourail region and in the northern part of New Caledonia. Coarse carbonaceous sediments at the base of this sequence become finer upsection and are overlain by Paleocene to mid-Eocene siliceous shales and a pelagic chert and micrite sequence (pthanites). The coarser grained lower parts of the Late Cretaceous–Paleocene sequence locally contain shoshonitic basic volcanics, and there are also felsic horizons of rhyolitic flows and pyroclastics that appear to be younger than the basic volcanics. Later Eocene sequences, unconformably overlying the pelagic sediments, are carbonates. In the Bourail region, these are overlain by an alternating sandstone and siltstone flysch sequence. These are topped by an

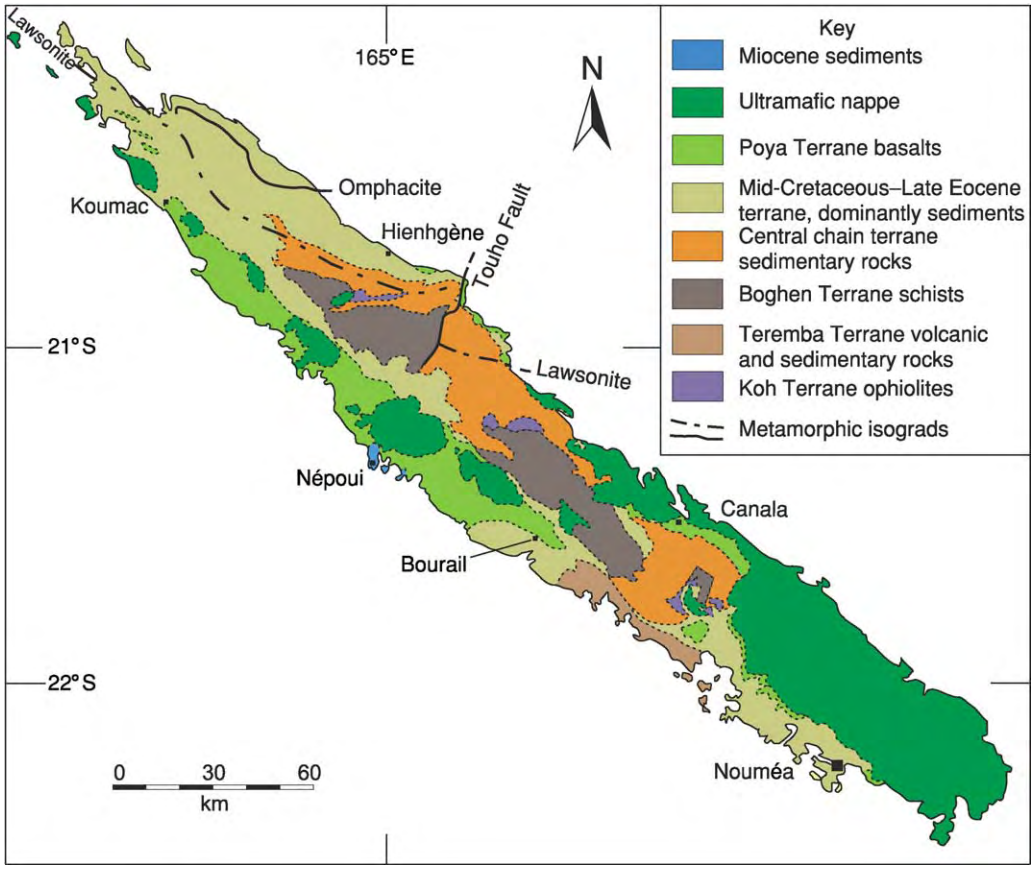

Figure 6 Geological map of New Caledonia (excluding the Loyalty Islands, Belep Islands, and Isle de Pines). The pre Cretaceous basement comprises the Koh ophiolite and the Teremba, Boghen, and Central Chain terranes. These are unconformably overlain by mid Cretaceous sediments forming a mid Cretaceous to Late Eocene terrane or successor basin sequence. Great thrust sheets of Poya Terrane basalts and ultramafic rocks (the ultramafic nappe), emplaced in the Late Eocene, overlie the older terranes. Miocene marine sediments are preserved on the south west coast. Map drawn by L Cotterall, Geology Department, Auckland University.

olistostrome that contains reworked components of the successor basin sediments, including upper Eocene bioclastic limestone and the flysch.

The Younger Terranes

The New Caledonian ophiolite, emplaced in the Late Eocene, overlies all the older rocks on the island. It consists of two units that appear to be geochemically unrelated: an overlying mainly harzburgitic ultramafic sheet (the ultramafic nappe) and the dominantly basic volcanic Poya terrane. The Poya terrane is composed of slices of geochemically variable submarine mafic volcanic rocks, mainly pillow lavas, together with dolerites and minor gabbros, and associated abyssal sediments. The ophiolite was emplaced as a result of Eocene convergence along the eastern margin of New Caledonia. Convergence was driven by the opening of the North Loyalty and South Fiji basins. Eastward-dipping subduction associated with the convergence consumed most of the South Loyalty Basin and caused high-pressure metamorphism of the Cretaceous–Eocene sediments of northern New Caledonia. The Eocene Loyalty Island volcanic arc formed above the subduction zone.

Miocene

Early Miocene coral reef and shallow-water marine sediments containing material derived from the ultramafic sheet are exposed at Nepoui. Small intrusions of granodiorite of Miocene age intrude the ultramafic sheet east of Nouméa, and north-east of Canala. Buoyancy-driven uplift in the Miocene has exhumed and exposed the high-pressure metamorphosed Cretaceous–Eocene sediments on the north-eastern coast of New Caledonia.

Economic Minerals

Since the Miocene, New Caledonia has been emergent and subjected to intensive tropical weathering, with the result that thick lateritic soils developed on the ultramafic rocks. The laterites have been mined for nickel, cobalt, and iron since the late nineteenth

century and still comprise the largest single reserve of nickel worldwide. Chromite has been mined directly from the ultramafic rock. Manganese deposits are associated with the Poya terrane basalts. Copper, lead, and zinc deposits have been mined from volcano-sedimentary horizons in the metamorphic rocks of the Diahot valley in northern New Caledonia. Gold-bearing quartz veins have been mined in the Diahot valley and gold and molybdenum deposits are associated with the Miocene granodiorite intrusions.

Fiji

The Fiji archipelago (Figure 7) comprises 800 islands, most of which lie between 16° and 19° south, 177° east, and 178° west. The Lau Group of islands in the east extends to 21° south (Figure 1). The largest islands are Viti Levu and Vanua Levu. The island of Rotuma, 650 km north of Viti Levu, is also a part of the Republic of Fiji. The islands are mainly volcanic and of island-arc origin, of basaltic, basaltic andesite, andesitic, and dacitic composition, and tholeiitic, calc-alkaline, or shoshonitic affinities. The younger volcanic rocks are mostly more alkaline and mainly belong to the alkali–basalt suite, and are intraplate rather than subduction related.

Viti Levu

The oldest rocks in the Fiji archipelago are exposed on Viti Levu. These are the volcanic and plutonic rocks of the Late Eocene to Early Oligocene Yavuna arc, and of the Late Oligocene to Middle Miocene (and possibly Late Miocene) Wainimala arc. The two volcanic suites are separated by an unconformity. The Yavuna arc rocks are exposed in western Viti Levu and include basaltic pillow lavas and volcaniclastic rocks, dacite, tonalite, and limestones of both Eocene and Oligocene ages. The basalts are geochemically primitive to arc like.

The Wainimala arc rocks are exposed throughout southern and central Viti Levu and on the islands of Malolo and Waya, immediately to the west. The rocks include mainly dacites in the centre of the island and basalts overlain by pelagic limestone and dacitic and andesitic lavas and volcaniclastics in the south-west. On Malolo and Waya, there are basaltic pillow lavas and breccia, and swarms of basalt dykes, indicating the local arc axis. Gabbro and tonalite of the Colo Plutonic Suite are thought to be part of the Wainimala arc activity and have mid- to Late Miocene radiometric ages (12–7 Ma). They were exposed to erosion in the Late Miocene. The Colo, Yavuna and Wainimala rocks show the effects of some deformation and weak metamorphism. They are unconformably overlain by latest Miocene to Early Pliocene basaltic and andesitic volcanic rocks and associated sediments (radiometric ages, 5.6–4 Ma). These cover much of the northern half of the island. The centre of the island was elevated at about 4 Ma. In the south-east, sediments were deposited in relatively deep water during the latest Miocene and through the Early Pliocene, the Messinian sea-level low being represented by a subaerially eroded coral reef. Shallow-water sediments were laid down in the latest Pliocene. In the south-west, sandstone and siltstone, overlain by limestone, were deposited in the Early Pliocene.

Vanua Levu

Vanua Levu comprises Late Miocene to Pliocene volcanic rocks (7–2.8 Ma). Volcanic activity appears to have progressed with time from east–north-east to west–south-west. The volcanic rocks are generally tholeiitic to calc-alkaline and include basalt, andesite, and some dacite, including a strong development of dacite and rhyolite in the north-east. Boninitic basalts were erupted on Cikobia to the north-east. Vanua Levu was elevated at about 3.5 Ma and Seatura Volcano began to form in western Vanua Levu not later than 3.3 Ma. Clastic sediments were deposited along the south-east coast.

Yasawa Group

The Yasawa and other islands north-west of Viti Levu, other than those of the Wainimala arc, were formed by volcanic arc activity (Yasawa arc) in the Late Miocene, from around 8 Ma. Early submarine dacites and basalts were succeeded by subaerial basalts in the central Yasawa islands, and by varied andesites. Strata generally dip towards Viti Levu, but at the north-eastern and southern ends of the chain have been strongly deformed with the development of overturned folds and thrust faults.

Islands Immediately South of Viti Levu

Vatulele, Beqa, and Yanuca (Serua) are Early Pliocene volcanoes south of Viti Levu. On Vatulele, shoshonitic rocks were erupted through limestone.

Islands of the Koro Sea

The islands of the Koro Sea (Lomaiviti and the Moala Group) mostly formed by volcanic activity in the Early Pliocene. Exceptions are the island of Koro, which formed in the Late Pliocene, and a Late Pleistocene cone on Nairai. The rock types range from tholeiitic through calc-alkaline to alkali basaltic and shoshonitic, and are mostly basaltic, with some hornblende andesite, monzonite, olivine monzonite, and tonalite. Olivine nodules occur in basalts on southern Moala and the western Koro islands.

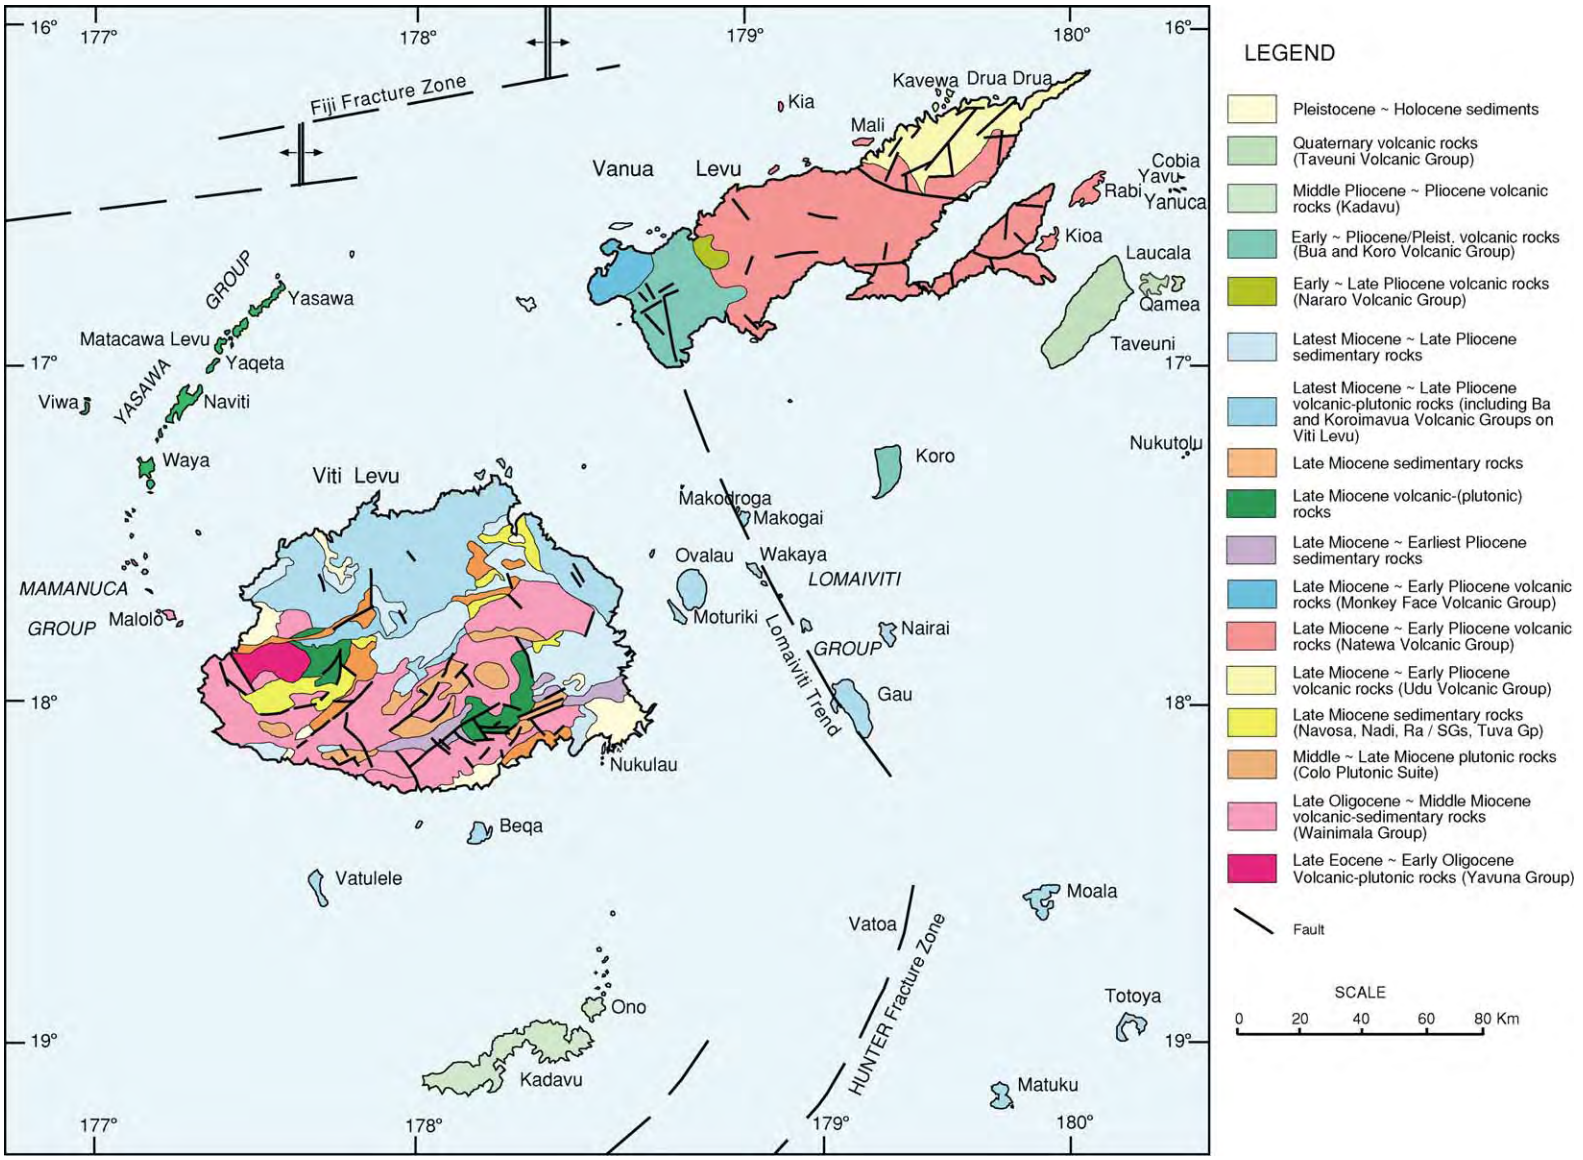

Figure 7 Geological map of Fiji, excluding Lau Islands and smaller Islands. On Viti Levu, the main rock units are Late Eocene Early Oligocene Yavuna volcanic and plutonic rocks, Late Oligocene Middle Miocene Wainimala volcanic rocks, Middle to Late Miocene Colo plutonic rocks, Late Miocene sediments, and Late Miocene to Pliocene volcanics and sediments. On Vanua Levu, the main rock units are Late Miocene Early Pliocene Udu volcanics, Late Miocene Early Pliocene Natewa volcanics, Early to Late Pliocene Nararo volcanic rocks, and Early Pliocene Pleistocene volcanics. On Koro Island are Early Pliocene Pleistocene volcanics; and on the Kadavu Islands are Middle Pliocene volcanic rocks. Map reproduced with permission from Mineral Resources Department, Fiji.

Kadavu Islands

The Kadavu islands, south of Viti Levu, are a volcanic island arc related to subduction at the Kadavu Trench. Ages range from 3.2 Ma to Holocene. Compositions range from basaltic to dacitic and are generally potassic.

Lau Islands

The islands on the Lau Ridge (Figure 1) formed in several periods of volcanic activity, probably beginning in the Eocene. The oldest exposed rocks, on Yacata island, are Middle Miocene (14 Ma). Further south, Late Oligocene rocks have been recovered by dredging. The exposed volcanic rocks are of three ages: Middle and Late Miocene, Middle Pliocene, and Late Pliocene to Pleistocene. Eruptive rocks in the two earlier episodes were tholeiitic to calc-alkaline, and in the third episode were alkali basalt. Limestone was deposited in the Middle to Late Miocene, Late Miocene to Early Pliocene, and Late Pliocene to Quaternary.

Quaternary Volcanic Activity

Quaternary volcanic activity of mainly alkali basalt composition formed the island of Taveuni immediately south-east of Vanua Levu (where the most recent dated eruption was at 340 ± 70 years), and the island of Rotuma, 650 km north of Viti Levu. Many small centres of Quaternary alkali-basalt volcanism are scattered around the archipelago in the north-east, the north-west, in Lomaiviti, adjoining Kadavu and in the Lau Group, but none is known on the Viti Levu platform. High-K andesite to dacite erupted at the western end of Kadavu island.

Economic Geology

Gold has been mined at Vatukoula on Viti Levu since 1933 and has been mined at other locations on Viti Levu and at Mt Kasi on Vanua Levu at different times. Manganese ore was mined from 1950 to 1971, most production being from Viti Levu in the 1950s. Magnetite was mined at Tuveriki in south-west Viti Levu from 1957 to 1963. Deposits of gold, polymetallic sulphides, and disseminated deposits are being explored, notably the Waisoi and other porphyry–copper deposits at Namosi on Viti Levu. Bauxite deposits occur in western Vanua Levu, mainly around Wainunu, and some islands of the Lau Group have deposits of phosphatic clay.

Plate Tectonic Setting

The early volcanic arcs that now form the basement of the Fiji platform developed above subducted Pacific plate in the Eocene, Oligocene, and Miocene. Initially the Yavuna arc and Lau–Tonga Ridge probably were parallel to, and close to, New Caledonia, but were moved to the north-east by the opening of the South Fiji Basin (36–25 Ma). By the Middle Miocene, the Lau–Tonga arc, Fiji, and Vanuatu arcs formed a single east-facing arc above subducted Pacific plate. This simple arc, sometimes referred to as the Vitiaz Arc, was disrupted in the Late Miocene with the onset of back-arc extension in the North Fiji Basin. This extension caused the clockwise rotation of Vanuatu and the anticlockwise rotation of the Fiji platform. In the Pliocene, spreading extended east and then south, causing separation of the Lau and Tonga ridges and the oblique subduction of South Fiji Basin lithosphere at the Kadavu Trench. Rotation of the Fiji platform caused local compression and extension. As Fiji moved away from sites of active subduction, volcanism became mainly alkali basalt in composition.

Tonga

The Tongan archipelago is a north–north-east-trending double-island chain that straddles the northern end of the active convergent plate boundary that separates the Pacific and Australian plates. A well-defined Benioff zone dips westward at 43–45° beneath Tonga and extends to a depth of 700 km. The larger islands of the archipelago form the eastern chain, 130–150 km west of the Tonga–Kermadec Trench. These are low-lying islands made up mainly of coraline limestone. On Eua, the southernmost of this eastern chain, the stratigraphic sequence has been described as consisting of coraline limestone, Miocene tuffs and tuffaceous limestones, Late Eocene tuffaceous marlstone (thickness, 60–80 m), Late Eocene foraminiferal and algal limestone, and Middle Eocene (46 Ma) basaltic and intermediate lava, volcanic breccia, and tuffs cut by dykes. Although the Eocene and Miocene rocks are not exposed elsewhere in Tonga, seismic profiles indicate that they form the basement of the Tonga Ridge. The crust beneath the ridge is 12–18 km thick. Development of the Tonga Trench and uplift of the frontal arc occurred in Middle to Late Oligocene. The Miocene tuffs are thought to represent the initial stages of arc volcanism. The islands of the western chain, which lie 150–200 km west of the trench, comprise the Tonga or Tofua volcanic arc. The volcanoes have a history of intense modern activity, with more than 35 eruptions occurring during the past 200 years, including both subaerial and submarine events. The volcanic products are mainly basalt and basaltic andesite with subordinate dacite, as is to be expected from an intra-oceanic arc system. West of the Tonga or Tofua arc is

the Lau basin, an area of attenuated crust and high heat flow that is interpreted as an extensional back-arc basin.

Samoa

The Samoan archipelago lies between latitudes 13° and 15° S and longitudes 169° and 173° W and extends for 500 km on azimuth 288°, from Rose Island in the east–south-east to Savaii Island in the west–north-west. The archipelago comprises a chain of hotspot-related intraplate volcanoes made up of the alkaline and tholeiitic basalts that are typical of Pacific island chains. The two largest islands are Savaii (1700 km^2) and Upolu (1115 km^2). These, together with the small islands of Manono and Apolima, comprise Western Samoa.

Savaii is the summit of a large basaltic volcano. Many small parasitic cones occur about its flanks and the lavas of the historical eruptions of 1760 and 1905–11 are widely distributed across the northern part of the island. On Upolo Island, young cones and lava flows overlie older, deeply eroded volcanic sequences that form spectacular topography on the eastern end of the island. Similar geology is seen on Tutuila, the third largest island, where post-erosional lavas overlie an older group of volcanics. Further east, the volcano chain is reduced to subaerial remnants in the Manu'a islands and the easternmost Rose Atoll.

Pacific island chains typically increase in age westward. Dating of Samoan lavas and dredged tholeiitic samples from seamounts west of Savaii confirm that this is the case in the older volcanic rocks of the Samoan chain. For example, shield volcanics on Upolu range in age from 2.8 Ma to 1.7 Ma and on Tutuila, to the east, range from 1.54 to 1.28 Ma. The post-erosional volcanic activity on Savaii, Upolu, and Tutuila, from 700 000 years ago to the present, does not fit the 'older westward' pattern. Possibly this is a side effect of the sharp change in the orientation of the Tonga–Kermadec Trench which, at a point about 100 km south of the Samoan islands, swings from a near north–south azimuth to near east–west (Figure 1). Flexural bending of the Pacific plate at this point presumably could cause rifting in the Samoan archipelago and thus provide a conduit for renewed volcanic activity.

ORIGIN OF LIFE

J Bailey, Anglo-Australian Observatory and Australian Centre for Astrobiology, Sydney, Australia

Introduction

Establishing the nature of the processes by which life originated is one of the most fundamental unsolved scientific problems. Fifty years of study have enabled us to assemble many pieces of the puzzle but have also left a number of critical gaps in our understanding. Even the issues of when and where life originated are still poorly constrained, but life probably appeared on Earth between about 4.2 Ga and 3.5 Ga ago. There is good evidence that the current DNA–RNA–protein basis for life developed from a stage known as the 'RNA world' in which RNA performed the information-storage and catalytic roles currently performed by DNA and proteins. Direct formation of the RNA world from prebiotic chemistry seems unlikely, so much current research focuses on possible precursors to the RNA world. Various suggestions for pre-RNA worlds have been made, but none has yet proved entirely satisfactory. A number of terrestrial and extraterrestrial processes can produce prebiotic organic molecules, but there are still problems in obtaining the right molecules in sufficient quantities.

Development of Ideas on the Origin of Life

The idea that all life on Earth has a common origin became well established only in the twentieth century. Early ideas on the evolution of life were most clearly expressed by Lamarck, who described the process as one of progression from simpler to more complex and advanced forms (*see* **Evolution**). The observation that both simple and complex organisms are currently present therefore required that simple organisms are appearing even today from inorganic matter by a process of 'spontaneous generation' (a concept that has its origins in antiquity). Thus, the ideas of transformism (evolution) and spontaneous generation were closely linked in the early nineteenth century and put Lamarck and his followers in conflict with the religious and scientific establishment, who argued for the immutability of species, which were divinely created in their current forms. Lamarck's ideas were criticized by scientists such as Cuvier (*see* **Famous Geologists:** Cuvier) (in a celebrated debate with Geoffroy Saint-Hilaire in 1830) and later by Pasteur, who carried out his famous 'swan-necked flask' experiments to discredit the idea of spontaneous generation.

Darwin's theory of evolution by natural selection opened the way for the modern view of the origin of life (*see* **Famous Geologists:** Darwin). In Darwin's theory there is not necessarily a ladder of progress from simple to more complex forms. Simple organisms can be as evolutionarily successful as complex ones. This allowed the idea that all life, simple and complex, had a single origin in the distant past. While the subject of the origin of life is hardly mentioned in Darwin's published writings, the following quote (from a letter to his botanist friend Joseph Hooker) gives us an inkling of his thoughts on the subject at that time:

> If (and oh! what a big if!) we could conceive in some warm little pond, with all sorts of ammonia and phos phoric salts, light, heat, electricity present, that a protein compound was chemically formed, ready to undergo still more complex changes... .

Oparin and Haldane in the early twentieth century developed the idea that chemical reactions on the early Earth could have led to the production of a range of organic compounds, forming a 'primordial soup' in which the required building blocks for life would have been present.

But it was not until 1953 that these ideas received experimental support. Stanley Miller, then a graduate student working in the laboratory of Harold Urey, set up his famous experiment in which electrical discharges were passed through a mixture of gases (methane, ammonia, hydrogen, and water vapour) simulating a thunderstorm on the primitive Earth. The experiment produced a mixture of several amino acids, the building blocks of proteins. Miller speculated that this was how organic compounds had been made on the early Earth. In the same year, Crick and Watson published their structure for DNA, the first step in elucidating the fundamental molecular basis of life. These two discoveries meant that we had both a plausible way of generating simple organic building blocks and an understanding of the macromolecules on which

life depends. A detailed experimental and theoretical study of the origin of life was now possible.

The Earliest Life

Sedimentary rocks of about 3.5 Ga old are found in the Pilbara region of Western Australia and in the Barberton Mountain Land in South Africa; these are the oldest such rocks that are sufficiently well preserved to contain fossils. These rocks contain structures that are interpreted as fossil stromatolites (layered structures built by colonies of micro-organisms) as well as filamentous microstructures interpreted to be microfossils of bacteria (*see* **Biosediments and Biofilms**). The biogenicity of many of these early fossils is controversial, but, if accepted, their presence indicates that life was well established on Earth at 3.5 Ga. It is even more difficult to say much about the nature of this early life. Some of the Pilbara microfossils have been suggested to resemble present-day cyanobacteria, but recent reinterpretation of the stratigraphy of the region suggests that the rocks originated in a hydrothermal environment.

Evidence for life has also been claimed in rocks of about 3.8 Ga from Greenland. These rocks are too metamorphosed to preserve physical fossils, but they contain carbon depleted in ^{13}C, which is consistent with the occurrence of biochemical reactions. These claims are also controversial.

The Tree of Life

The early history of life can also be studied through the techniques of molecular biology. It has been found that all life on Earth shares the same fundamental chemical processes. All life uses DNA as its basic genetic material. The DNA message is read by copying it onto RNA (transcription), and this RNA message is used to synthesize proteins (translation) by means of an RNA–protein complex called the ribosome (Figure 1). The resulting proteins are most frequently used as catalysts (enzymes) to drive the many chemical processes in the cell. The genetic code – which translates three-'letter' sequences of the four DNA bases (A, C, G, and T) into the corresponding amino acid to be added to a protein – is almost universal (with a few minor variations).

The common chemical basis for life strongly supports the idea that all life on Earth is related and descended from a single universal ancestor, sometimes known as LUCA (last universal common ancestor). Moreover, by comparing the sequences of genes involved in these fundamental processes common to all life, we can construct a 'family tree' showing the relatedness of all groups of life. Such molecular phylogenetic analysis has led to the 'three domain' taxonomy, in which life is divided into the domains Bacteria, Archaea, and Eucarya (Figure 2).

	U	C	A	G	
U	Phe Phe Leu Leu	Ser Ser Ser Ser	Tyr Tyr STOP STOP	Cys Cys STOP Trp	U C A G
C	Leu Leu Leu Leu	Pro Pro Pro Pro	His His Gln Gln	Arg Arg Arg Arg	U C A G
A	Ile Ile Ile Met	Thr Thr Thr Thr	Asn Asn Lys Lys	Ser Ser Arg Arg	U C A G
G	Val Val Val Val	Ala Ala Ala Ala	Asp Asp Glu Glu	Gly Gly Gly Gly	U C A G

Figure 1 Summary of the key molecular processes common to all life. Genetic information is carried by DNA and can be copied (replication) onto new DNA molecules. The genetic message is read by first copying onto RNA (transcription) and then using the RNA message to synthesize a protein (translation). Three letter sequences of the RNA bases (uracil (U), cytosine (C), adenine (A), and guanine (G)) are translated into a corresponding amino acid to include in a protein according to the genetic code shown on the right.

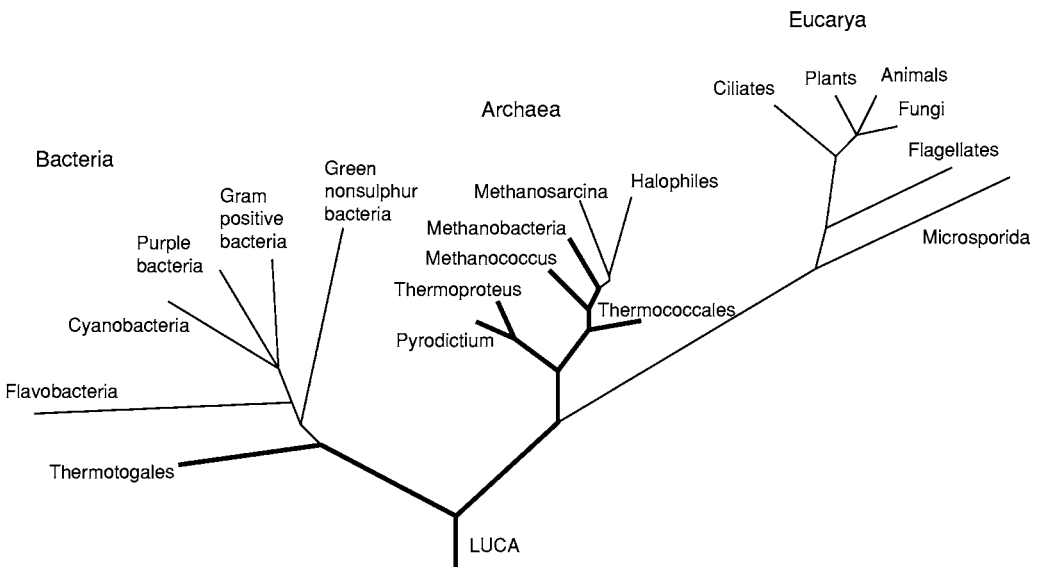

Figure 2 The tree of life derived from analysis of the small subunit ribosomal RNA gene, showing the division of life into the three domains Bacteria, Archaea, and Eucarya. Heavy lines indicate the branches containing hyperthermophilic organisms and illustrate the hypothesis that LUCA (the last universal common ancestor) was a hyperthermophile.

One feature of this phylogenetic tree is that many of the deepest branches closest to the 'root' of the tree are found to contain the hyperthermophiles (organisms adapted to very high temperatures). This has led to the suggestions that LUCA itself was probably a hyperthermophile and that perhaps life originated in a high-temperature environment. However, the interpretation of the tree is complicated by the likely occurrence of horizontal gene transfer (transfer of genes between different species), and there are possible interpretations of the tree that do not require LUCA to be hyperthermophilic.

Even if LUCA was a hyperthermophile, this does not necessarily tell us much about the environment in which life originated, since we do not know how much evolution occurred before LUCA. For example, one scenario is that life had already adapted to a wide range of environments before LUCA, but a catastrophic event such as a major impact wiped out everything except the hyperthermophiles.

LUCA is likely to have been similar to present-day bacteria. While these are usually regarded as simple organisms, even the simplest bacteria still contain substantial complexity, having genome sequences of several hundred thousand base pairs and using several hundred enzymes to catalyse a wide range of metabolic processes. The basic problem of the origin of life is to understand how such complexity could arise from a system simple enough to have assembled by chance in a prebiotic environment.

The key process is likely to be evolution by Darwinian natural selection. This process is capable of developing increased complexity. We therefore need to identify simpler systems that preceded the current DNA–RNA–protein basis for life but retain the basic requirements for natural selection to operate. While we have no fossil record to guide us in studying this stage of life's history, there are clues in the molecular mechanisms of modern organisms.

The RNA World

The DNA–RNA–protein basis for life presents a chicken-and-egg problem. DNA requires protein enzymes to catalyse its replication and transcription. However, these proteins can be made only by using the DNA genes that code for them. Hence, DNA is dependent on proteins and vice versa. A possible solution to the problem of how such a system originated was provided by the discovery by Cech and Altman that RNA can exhibit catalytic activity. This means that RNA can perform the roles of both a replicating information store (like DNA) and a catalyst (like protein enzymes).

This discovery led to the concept known as the RNA world – the idea that there was a stage in the development of life in which RNA acted as both the genome and the catalyst. These roles were subsequently taken over by DNA and proteins, leaving RNA in its modern role as an intermediary between DNA and proteins. The RNA-world concept is supported by a number of features of the molecular structure and chemistry of modern cells.

First, the structure of the ribosome, which catalyses protein synthesis, has recently been determined in detail. Although the ribosome contains both RNA and protein components, it has been found that the important catalytic activity comes from the RNA components, with the protein playing a peripheral role. This shows that protein synthesis (translation) is carried out almost exclusively by RNA and therefore probably originated at a time when only RNA catalysts were available. By contrast, the replication and transcription of DNA is carried out mostly by enzymes. Second, the synthesis of the nucleotides of DNA is carried out by building the corresponding RNA nucleotides first and then converting them to DNA nucleotides. Third, there are a number of important biochemical processes that use RNA (but not DNA) nucleotides or closely related molecules. These include the use of ATP (adenosine triphosphate) as the main energy carrier, and the cofactors used to assist a number of enzymes.

All these lines of evidence point to RNA being more ancient than either DNA or proteins and suggest that a pure RNA world 'invented' protein synthesis, giving rise to an RNA–protein world; subsequently, DNA was adopted as the primary genetic material.

For a pure RNA world (i.e. one in which proteins play no role) there must have been an RNA catalyst (or ribozyme) capable of catalysing the replication of RNA. No such molecule exists in modern organisms (although there are protein enzymes, known as RNA-dependent RNA polymerases, that do this). However, attempts have been made to synthesize such an RNA polymerase ribozyme. This is done by a process of 'in-vitro evolution', in which many copies of an RNA strand are made with random variations and then selected for appropriate catalytic activity. After many cycles of selection, ribozymes have been made that are capable of copying short sections of RNA (up to 14 bases) but are too inefficient to copy larger molecules.

The Origin of the RNA World

An RNA world is now widely accepted as being a stage in the development of life. The RNA world was either the first stage of life or preceded by an earlier stage of life, the pre-RNA world.

If the RNA world was the first stage of life then there must be a way of making a viable RNA world through the random processes of prebiotic chemistry. However, there are a number of difficulties with such a process. RNA consists of a sugar–phosphate backbone carrying four possible bases – guanine, adenine, cytosine, and uracil. Prebiotic syntheses have been suggested for the bases, but some require contrived conditions. The ribose sugar can be produced by the formose reaction but only in small quantities as part of a complex mixture of other sugars. The assembly of a complete ribonucleotide from these components presents further difficulties.

The nucleotides would then need to be assembled into RNA strands of sufficient length to show useful catalytic activity. Experiments using montmorillonite clay as a catalyst have led to RNA molecules of up to about 40 nucleotides. However, for this to be possible the nucleotides must be provided in their activated, or energy-rich, triphosphate form.

A further difficulty with an RNA world is imposed by the chirality of RNA. RNA replication (like many processes in biological chemistry) depends on the RNA nucleotides being based on the right-handed version of the two mirror-image structures for the sugar (i.e. D-ribose rather than L-ribose). However, any prebiotic process would be expected to make the sugar as a racemic mixture (i.e. equal quantities of D-ribose and L-ribose).

Pre-RNA Worlds

The difficulties with the prebiotic synthesis of RNA lead many researchers to conclude that direct production of an RNA world is highly improbable, and there must have been a preceding stage, or pre-RNA world, that used some other genetic material. Many different suggestions have been made.

The most obvious precursor to RNA is some other organic polymer that carries information in the same way as DNA and RNA. One suggestion is the peptide nucleic acids (PNA) (**Figure 3**). These molecules use the same set of bases as DNA and RNA but have a much simpler backbone linked by peptide bonds. The prebiotic synthesis of PNA seems to be more straightforward than that of RNA. Furthermore, PNA is achiral, thereby avoiding the chirality problems associated with RNA.

Another possible RNA precursor is TNA. This is a nucleic acid in which the four-carbon sugar threose replaces the five-carbon sugar ribose used in RNA. TNA can base pair with RNA or DNA and is the structurally simplest member of the RNA family. The four-carbon sugar should be easier to make than ribose in prebiotic conditions.

Some other suggestions for pre-RNA worlds involve very different ideas. For example, it has been suggested that inorganic clay crystals, rather than organic polymers, provided the first genetic material. Another suggestion is the 'compositional genome', in which the genetic information is carried by a set of molecules

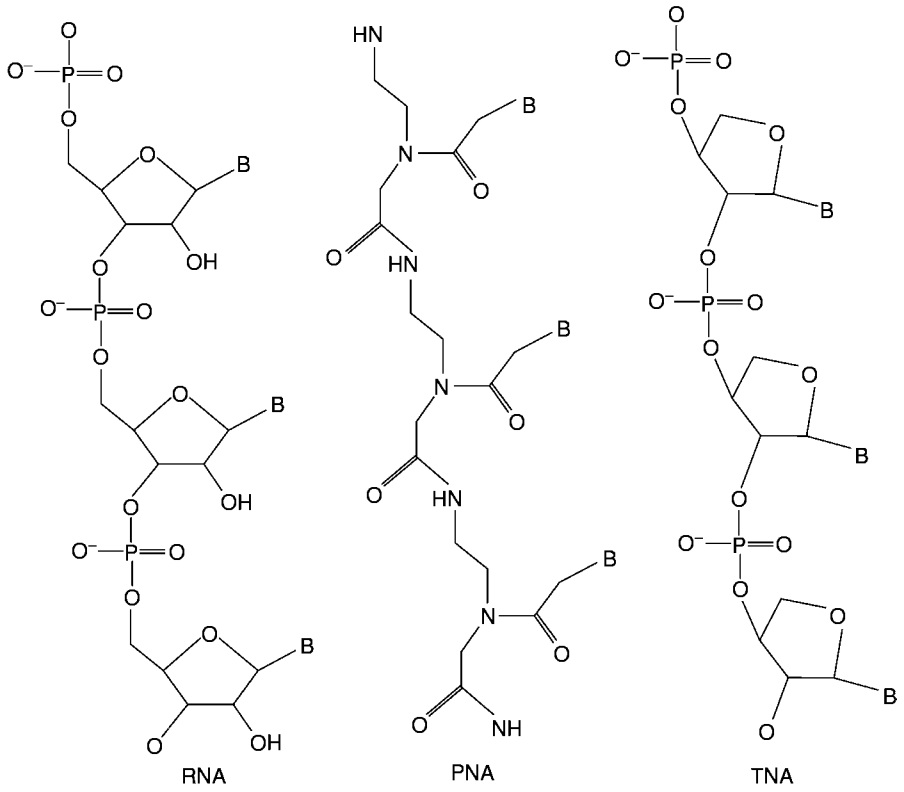

Figure 3 The molecular structures of RNA and two molecules that have been suggested as possible precursors of RNA. PNA (peptide nucleic acid) uses a simpler backbone based on peptide bonds, and TNA replaces the five carbon sugar ribose with the four carbon sugar threose. All three molecules can use the same set of four bases (attached at the positions marked B) and can base pair with RNA or DNA.

enclosed by a membrane. Other models propose that networks of reactions that are the forerunners of modern metabolic processes preceded the development of genes. All such models present a number of problems, not least in explaining how the transition to an RNA world could occur (Figure 4).

Suffice it to say that no model of a pre-RNA world has yet achieved any degree of consensus, and the problem of how to build an RNA world out of the available prebiotic material remains unsolved.

Sources of Prebiotic Organic Molecules

The Miller experiment, described above, provided the first demonstration of how organic molecules of biological relevance might be produced in the atmosphere of the primitive Earth. Similar experiments have produced a wide range of organic molecules in this way. However, to achieve a substantial yield, a strongly reducing atmosphere (i.e. one containing gases such as hydrogen, methane, and ammonia) is required. Current ideas suggest that the atmosphere of the early Earth was instead composed mostly of carbon dioxide and nitrogen (*see* **Atmosphere Evolu-**

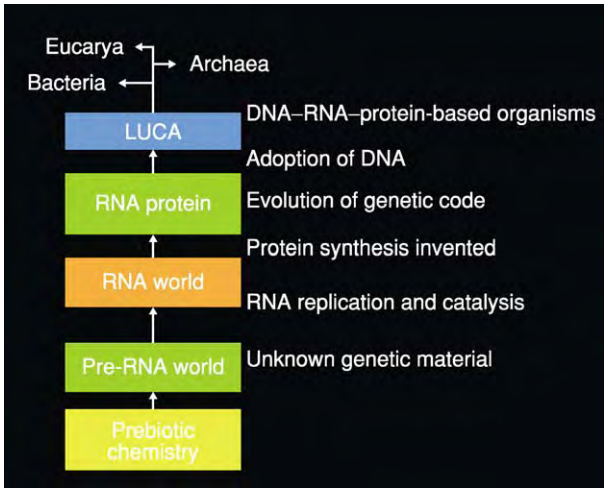

Figure 4 Outline of a possible series of steps in the development of life from prebiotic molecules up to the modern DNA RNA protein basis for biological chemistry.

tion). There may have been a small amount of methane (up to about 100 ppm), making the atmosphere, at best, weakly reducing and allowing the production of small amounts of organic material in this way.

A possible alternative source of organic molecules is extraterrestrial delivery. We know from astronomical observations that interstellar clouds contain at least 100 species of simple organic molecule, while experiments simulating interstellar conditions have shown that more complex molecules, including amino acids, might be produced by photochemistry in ice-coated dust grains. The Murchison meteorite, which fell in Murchison, Australia in 1969, has been found to contain a huge range of organic compounds including more than 70 different amino acids. During the phase of heavy bombardment in the first few hundred million years after the solar system was formed, the Earth would have been subject to frequent impacts of comets and asteroids (*see* **Earth Structure and Origins**). While the heat produced by the impacts of these large bodies may destroy much of the organic material, recent experiments and simulations suggest that at least some organic material may be able to survive these major impacts. Organic material can also be delivered to the Earth's surface by interplanetary dust particles. However, current estimates of the amount of organic material that might have been delivered to the early Earth vary widely.

One intriguing discovery is that at least some of the amino acids in the Murchison meteorite show a small excess of the L or left-handed form. This excess is found in amino acids not known to be present in the biosphere, so it cannot be due to contamination, and suggests that a chiral imbalance existed in the organic material of the early Solar System. This could be relevant to the origin of biological chirality. A possible cause of the original excess of L-amino acids is photolysis by circularly polarized light, which could have occurred in the star-formation region in which the Sun originated.

Another source that has been suggested for organic compounds is reactions occurring in the superheated water around deep-sea hydrothermal vents (*see* **Tectonics:** Hydrothermal Vents At Mid-Ocean Ridges). Reactions involving mineral catalysts could build organic molecules from simple molecules such as carbon dioxide. However, some workers argue that the high temperatures in hydrothermal vents are more likely to destroy organic molecules than create them. It has been calculated that virtually all the water in the oceans circulates through hydrothermal vents on a timescale of about 10^7 years, and the temperatures would be high enough to destroy molecules such as amino acids. This limits the amount of organic material that can build up in the oceans from any of the above sources.

Thus, while there are a number of possible sources of prebiotic organic compounds, we are still left with two significant problems. First, the total amount of organic material produced by any of these mechanisms seems to be enough to lead to only very weak concentrations in the ocean. Second, the molecules that are most easily made do not necessarily appear to be the most relevant. For example, amino acids are readily produced and are certainly important in modern biology, but the adoption of proteins seems to be a relatively late step in the development of life. The building blocks needed for RNA (such as ribose) are more difficult to make, although RNA appears to be essential for early life.

Where did Life Originate?

Given that we do not yet understand the chemical processes required for the early stages of life, it is hard to say much about the likely location. However, there are some general considerations that can be applied. The early Earth would have been subject to bombardment by asteroids at a high but rapidly reducing rate, and some of the largest impacts would have been 'sterilizing impacts' capable of vaporizing the oceans and destroying any life. Clearly life must have appeared after the last sterilizing impact, which might have been around 4–4.2 Ga ago. (There could, of course, have been one or more earlier origins of life that were wiped out in the impacts.) However, somewhat smaller impacts might have destroyed life near the surface while allowing it to be preserved deep in the oceans or within the Earth's crust. This suggests that life might have originated in a deep-ocean location or even deep within the crust. Another important consideration is that life requires an energy source (for modern life this is normally solar energy via photosynthesis). For a deep location the likely energy source is geothermal energy. A location on or near the surface would make available other energy sources such as ultraviolet radiation and lightning. A surface origin would, however, be much more exposed to impacts, and life would therefore have to have arisen somewhat later, towards the end of the heavy bombardment. This leaves a rather small time window between the end of the bombardment and the first evidence of life on Earth. However, the timings of both these events are somewhat uncertain.

Finally, the possibility must be considered that life did not originate on Earth at all. More than 20 meteorites have been identified as coming from Mars. The most famous is ALH84001, which has been sug-

gested to contain fossil evidence of Martian life. While many are unconvinced by these claims, the meteorite does provide evidence that material can be transferred from Mars to Earth with relatively good preservation, and suggests that something like a bacterial spore could seed life from one planet to another. There is evidence that early Mars had liquid water and may have been at least as favourable as Earth as a site for the origin of life. During the heavy-bombardment phase transfer of material from Mars to Earth would have been much more frequent than it is today.

Glossary

ALH84001 Martian meteorite discovered in the Allan Hills ice-field in Antarctica in 1984. It has been suggested that this meteorite contains evidence of Martian microbial life.

Amino acid Simple organic molecule containing an amino group (NH_2) and a carboxyl group (COOH). Amino acids link together in chains to form proteins.

Archaea One of three domains of life, the other two being the Bacteria and the Eucarya. The archaea are prokaryotic organisms, which were shown to be distinct from the bacteria by molecular phylogeny using 16S ribosomal RNA. The archaeal domain includes many extremophilic organisms.

Bacteria One of three domains of life, the other two being the Archaea and the Eucarya. The bacterial domain includes all prokaryotic organisms not classified as archaea.

Base pairing (Watson–Crick base pairing) The pairing of the DNA and RNA bases through chemical bonds, which link the double-helix structure of DNA and allow the copying of information. Adenine always pairs with thymine (or uracil), and cytosine pairs with guanine.

Bases The components of DNA and RNA that carry the genetic information in their sequence. DNA uses adenine, guanine, cytosine, and thymine. In RNA, thymine is replaced by uracil.

Chirality A chiral molecule is a molecule with an asymmetric structure that can exist in two mirror-image forms (or enantiomers). In living organisms such molecules are usually found in only one of the two possible enantiomers (homochirality). Thus, amino acids are normally in the left-handed or L-enantiomer, while sugars are in the right-handed or D-enantiomer.

Cyanobacteria A class of bacteria that make use of oxygen-producing photosynthesis; commonly referred to as blue-green algae.

DNA Deoxyribonucleic acid; the molecule that constitutes the genome of living cells. DNA molecules have a double-stranded helical structure built from a sugar–phosphate backbone and a set of four bases (adenine, guanine, cytosine, and thymine). The sequence of bases specifies the genetic information.

Domain The highest taxonomic division in the classification of living organisms. The three domains are the Archaea, the Bacteria, and the Eucarya. Domains are subdivided into kingdoms. While the three-domain model is widely used in astrobiology, some biologists prefer other schemes, such as the five-kingdom system.

Enzyme A protein that acts as a catalyst. Most chemical processes in living cells are enzyme catalysed.

Genetic code The set of rules by which three-letter 'words' in a DNA or RNA sequence describe an amino acid to be incorporated in a protein.

Genome The complete set of genetic information for a particular organism.

Heavy bombardment During the first few hundred million years after the formation of the solar system, the Earth and the other planets were subject to an intense bombardment by the debris left over from the formation of the solar system. It is during this phase of heavy bombardment that most of the craters on the Moon were formed. The emergence of life on Earth appears to coincide roughly with the end of the heavy bombardment.

Hyperthermophile An organism adapted to life at very high temperatures. Hyperthermophiles have optimum growth temperatures above 80°C, and a number can grow at temperatures above 100°C.

Interstellar molecule Molecules in interstellar space are most commonly detected by means of radio-frequency emission lines coming from the gas in molecular clouds. Molecules can also be detected from the infrared spectra emitted from dust. Well over a hundred molecular species have been detected by these methods. Some of the more complex molecules found include acetic acid, acetone, and ethanol.

Lateral gene transfer The transfer of genes between different species. Lateral gene transfer may have been widespread in the early stages of life on Earth, and this complicates the interpretation of the tree of life.

LUCA Last universal common ancestor; the last common ancestor of all living organisms.

Martian meteorites Meteorites that originate from Mars, also known as SNC meteorites. Their Martian origin is demonstrated by bubbles of gas trapped within them, which have identical composition to the atmosphere of Mars.

Miller–Urey experiment (or Miller experiment) An experiment carried out by Stanley Miller and Harold Urey in 1952, which demonstrated the synthesis of amino acids in conditions simulating a thunderstorm on the early Earth. The experiment can be seen as marking the beginning of the experimental study of the chemistry of life's origins.

Nucleic acid The molecules that carry genetic information – DNA and RNA.

Phylogeny The evolutionary relationships between different species of organism, represented in the form of a phylogenetic tree. In molecular phylogeny these relationships are determined by analysing the differences in the sequences of genes common to the various species.

Pre-RNA world A hypothetical early stage in the development of life, which preceded the RNA world and used some other genetic material in place of RNA or DNA.

Ribosomal RNA The RNA components of a ribosome. One of these components, the small subunit ribosomal RNA (also known as 16S ribosomal RNA in prokaryotes or 18S ribosomal RNA in eukaryotes), has been widely used to determine the tree of life.

Ribosome A structure composed of protein and RNA molecules that reads genetic information from messenger RNA and synthesizes the corresponding protein.

Ribozyme An RNA molecule that acts as a catalyst. The discovery of RNA catalysis led to a Nobel prize for Sidney Altman and Thomas Cech, and to the concept of the RNA world.

RNA Ribonucleic acid; a molecule that can carry genetic information in a similar way to DNA. In modern cells, RNA molecules are important in the process of protein synthesis, in the form of messenger RNA, ribosomal RNA, and transfer RNA.

RNA world A hypothetical early stage in the development of life, in which RNA molecules provided both the genome and the catalysts, roles that were subsequently taken over by DNA and proteins.

Stromatolites Layered structures built by colonies of micro-organisms that are commonly found in the Archaean and Proterozoic fossil records. Modern examples can be found in sites such as Shark Bay in Western Australia.

Tree of life A phylogenetic tree covering all groups of life on Earth. The term is commonly used for the tree derived by molecular phylogeny using small subunit ribosomal RNA, as pioneered by Carl Woese in the 1970s.

PALAEOCLIMATES

B W Sellwood, University of Reading, Reading, UK
P J Valdes, University of Bristol, Bristol, UK

Introduction

An evaluation of the climatic regime under which sedimentary successions accumulated has often been integral to their overall interpretation. It is an essentially uniformitarian approach. Palaeoclimatology, the understanding of past climatic regimes (palaeoclimates), has only relatively recently become a subject in its own right and is currently undergoing a major phase of expansion. One reason for this is the light thrown by palaeoclimatic studies on the natural variability that exists in the Earth's climate in the context of future, anthropogenically influenced, climate changes. Another is the realization that many of the Earth's sedimentary resources (e.g. coal, hydrocarbons, and other extractable minerals) formed under particular types of climatic regime.

Through time, the climate of the Earth has undergone many changes – the most recent ice age ended a mere 500 human generations ago. Astronomical data suggest that the Sun is of a type that steadily increases its heat output as it ages, increasing by about 1% per 100 Ma (*see* **Solar System:** The Sun). This presents a problem (the 'faint young sun paradox'). Simply stated, in its early days the Sun would have emitted about 45% less than its current heat output, so Earth should have been frozen, but there is ample evidence from Earth's most ancient rocks (e.g. in Greenland, South Africa, and Australia) to suggest that aqueous processes were operating. This paradox can be overcome if it is accepted that Earth's atmosphere was much denser and much richer in greenhouse gases (such as carbon dioxide and methane) during its early history. The rock record makes it clear that the Earth was periodically affected by major freezes during its early history, and controversy exists over the possibility that the Earth periodically froze from the poles to the equator (the 'snowball Earth hypothesis') during Proterozoic and older times (*see* **Atmosphere Evolution**).

Despite the possibility that the Sun was significantly cooler 500 Ma ago, abundant and widespread geological evidence suggests that through much of the subsequent time the Earth has been significantly warmer than at present. Since the Cambrian there appear to have been only three episodes that were cooler than now. One was in the Ordovician, when glaciation was centred on the present Sahara (*see* **Palaeozoic:** Ordovician), and one was in the Late Carboniferous (*see* **Palaeozoic:** Carboniferous) and Early Permian, with glaciation centred on southern Gondwana (*see* **Gondwanaland and Gondwana**). The latest 'ice ages' took place during the Quaternary (*see* **Tertiary To Present:** Pleistocene and The Ice Age), from about 1.67 Ma, but a growing body of evidence suggests that this latest phase had its origins at around the Eocene–Oligocene boundary (36 Ma), when ice began to accumulate over eastern Antarctica. For around 250 Ma, since the Late Permian, there appears to have been a period of extreme warmth, often referred to as the 'greenhouse world'. The Earth's past climate regimes can now be simulated using general circulation models (GCMs) similar to those used in long-term weather forecasting.

Orbital Forcing of Climate

In 1875, James Croll was the first to describe the cyclic way in which the Earth's orbit behaves. The eccentricity varies from near-circular to elliptical over a cycle of about 110 Ka and affects the total amount of solar radiation reaching the Earth. Changes in the tilt of the Earth's axis of rotation (obliquity; currently about 23.4° but varying between 21.8° and 24.4°), which affect the latitudinal distribution of received solar radiation, take around 40 Ka. In addition, a rotational wobble in the Earth's axis of rotation (as if the poles describe a circle against the background of the stars) causes the precession of the equinoxes and takes around 22 Ka to complete a cycle. In the 1930s and 1940s, Milutin Milankovitch, improving on Croll's work, realized that each of these cycles interacts with the others to cause changes in the amount of insolation received by the Earth that are sufficient to promote climate changes (*see* **Earth:** Orbital Variation (Including Milankovitch Cycles)). These cycles are now named after Milankovitch and have been used to predict the time-frame of glacial cycles in the Quaternary. Changes in palaeoclimate have been recognized in Neogene oceanic sediments, which provide a metronomic time signal, synchronized with the Milankovitch time-frame, and hence a means of short-term correlation that was unavailable until recently.

Geological Proxies of Palaeoclimate (Figures 1A and 1B)

Sedimentary facies and palaeontological data generally provide qualitative evidence of palaeoclimates

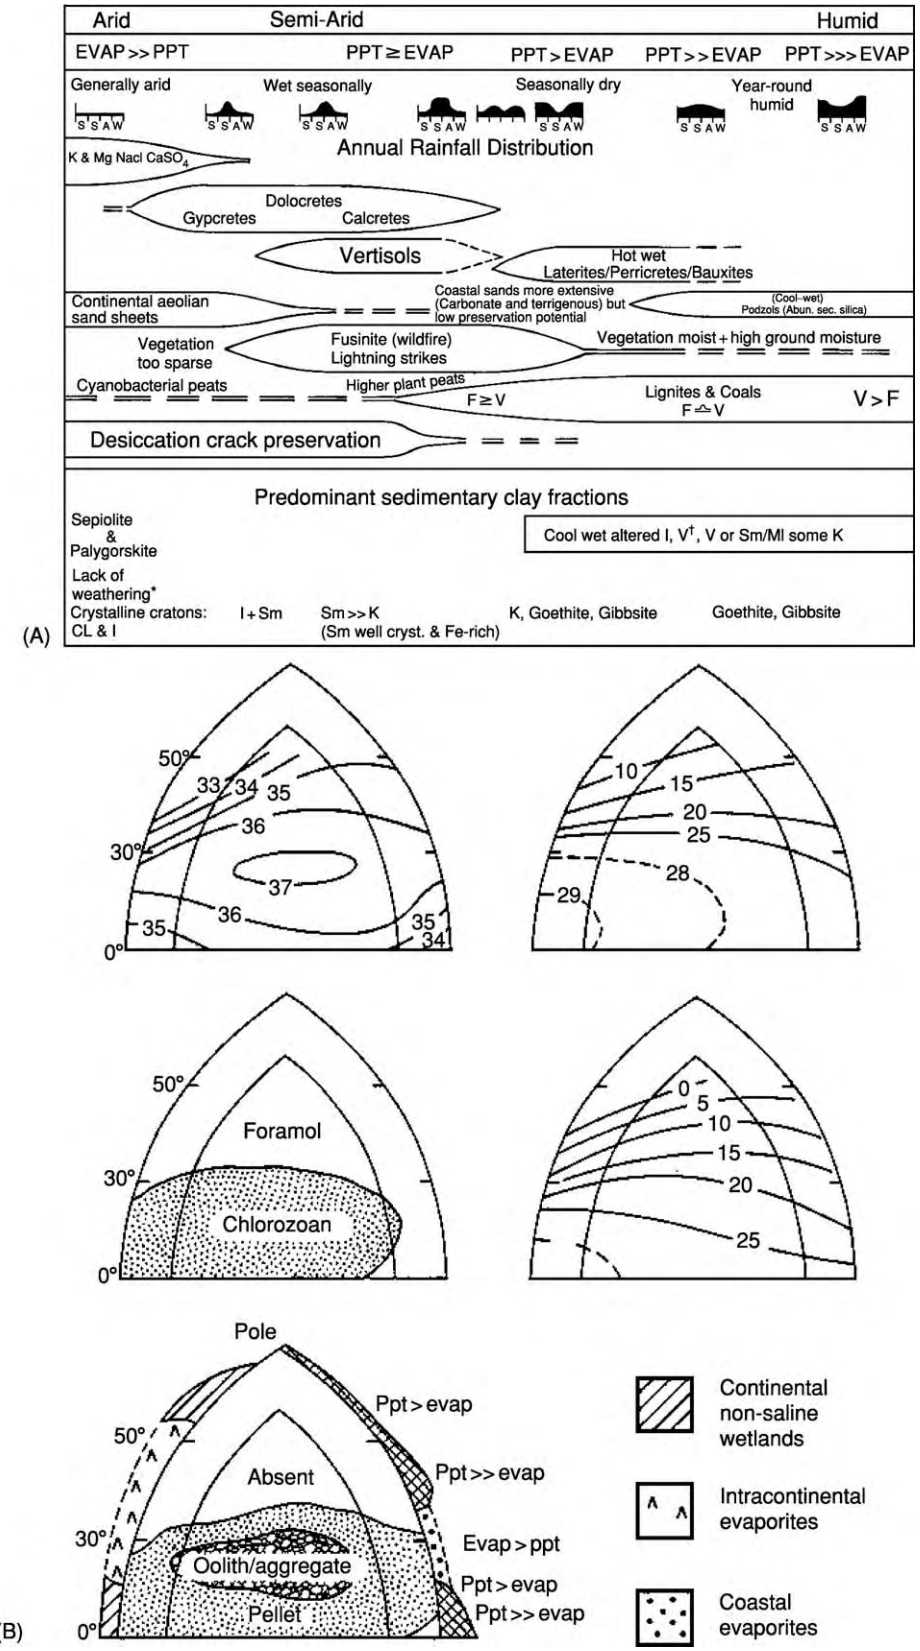

Figure 1 Geological palaeoclimate proxies for (A) terrestrial environments and (B) marine carbonates and evaporites (top left, salinity (‰); top right, maximum temperature (°C); middle left, skeletal associations; middle right, minimum temperature (°C) Lower left, predicted modern carbonate and evaporite distributions. Cross hatching shows maritime latitudes where precipitation exceeds

and climate changes. These are palaeoclimate proxies. The most climatically informative structures are glaciogenic features (striated pavements, tills, and tillites), distinctive soil types (e.g. laterites and bauxites), and indicators of aridity (e.g. evaporites and aeolianites). Supplementary evidence of climate is provided by a range of other features, such as other types of palaeosol (e.g. calcretes, gypcretes, and vertisols), clay mineralogy (reflecting weathering regime), storm deposits, reefs and oolites, glendonites, and fusain (from wildfires). Coals, often considered to require moist tropical climates, are now known to accumulate equally well in temperate mires. Critical information on past climates (particularly quantitative information on palaeotemperature) comes from oxygen isotopic ($\delta^{18}O$) data derived from carbonate fossils, but such data have to be treated with care because of problems associated with diagenetic resetting. Palaeobotanical data, particularly regarding plant appearance (physiognomy), are generally qualitative, and have also been claimed to provide quantitative information. The density of leaf stomata may be related to the concentration of atmospheric carbon dioxide, and there is, today, a striking relationship between mean annual temperature and leaf shape (percentage of entire-margined, as opposed to toothed-margined, species) in a biome. Entire-margined leaves dominate warm biomes.

Fossil reptiles such as crocodilians, like their modern descendants, have global distributions that are principally controlled by temperature. A coldest-month mean temperature of 5.5°C marks the minimum thermal limit for the group (corresponding to a modern mean annual temperature of *ca*. 14.2°C). Such evaluations of temperature have been successfully applied globally for the Mesozoic and Cenozoic and compared with GCM output on climate for those times.

Marine Carbonates

Modern shelf seas are dominated by carbonate facies in areas where organic productivity is high, generally in low latitudes (between about 30°N and 30°S) with strong insolation and warm normal-salinity seawaters (>20°C and 35‰ salinity). Carbonate shelves also occur in temperate waters, particularly where rates of terrigenous run-off are low. However, rates of productivity in these areas are much lower than in warmer waters, and the biota is dominated by different species. Nonetheless, dominance of carbonates in a particular rock succession may not necessarily indicate warm waters, particularly for more ancient rocks in which the biota have only tenuous links with modern forms (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves).

Present-day warm-water shelves unpolluted by fine-grained terrigenous run-off have diverse communities with hermatypic (reef-building) corals and codiacian calcareous algae and may include ooids, aggregates, and pellets; these latter grain types reflect carbonate precipitation and early cementation. This is known as the chlorozoan skeletal grain association and can be recognized as far back as the Triassic. Modern temperate-water carbonate factories are dominated by benthic foraminiferans, molluscs, bryozoans, barnacles, and calcareous red algae. This is termed the foramol skeletal grain association and can be recognized, albeit equivocally, into the Mesozoic Era. The polewards expansion of reef and carbonate facies (by about 10° latitude) in the Mesozoic and Early Cenozoic, relative to today (30° today, *ca*. 40° in the Mesozoic and Palaeogene), suggests that the Earth was more equable during these times.

The principles of palaeotemperature determination from carbonates using oxygen isotope ratios are well established, and for many years oxygen isotopic ratios have been used to quantify sea-surface temperatures and bottom-water temperatures. The technique has most successfully been applied using the fossil shells of organisms considered to be robust to diagenetic changes (e.g. planktonic forams, coccolithic oozes). Such data have shown that ocean waters have changed their isotopic ratios in concert with the waxing and waning of the ice-caps during Quaternary glacial cycles, the oceans becoming relatively depleted in ^{16}O during glacial episodes (shells therefore showing ^{18}O enrichment) by comparison with interglacials. In the longer term the $\delta^{18}O$ trend for ocean waters suggests that seawater has become progressively depleted in ^{16}O (leading to positive $\delta^{18}O$ values) since about 55 Ma. This has occurred in a series of steps, probably reflecting, first, the cooling of deep waters, followed by the onset of permanent ice on Antarctica at around the Eocene–Oligocene boundary. Then followed a series of significant more positive excursions, through the Oligocene and Miocene, before a major and permanent swing in the Miocene (15 Ma), which is taken to reflect the formation of the Antarctic ice-sheet. The growth of the northern hemisphere ice-sheets is

evaporation). Under lignites and coals V, vitrinite; F, fusinite; I, illite; V, vermiculite; Sm, smectite; K, kaolinite; CL, chlorite; ppt, precipitation; evap, evaporation; *, unaltered parent rock with fines under both arid and frigid terrains; †, vermiculite can form under a wide variety of conditions.

marked by a further more positive excursion in the Quaternary.

Evaporites

Evaporite salts may form anywhere on Earth where evaporation exceeds rainfall (*see* **Sedimentary Rocks:** Evaporites). Their preservation is controlled by the nature of the post-depositional climate, the ingress of groundwaters, and subsequent burial history. Modern coastal evaporites accumulate between 15° and 35° latitude, but intracontinental evaporites may occur beyond 50°, sometimes being frozen for several months in the year. So salts do not necessarily imply permanent warmth. The formation and preservation of the more soluble salts of potassium require low atmospheric humidity (less than 50%). Salts may form very rapidly under ideal conditions (100 m in 1 Ka), so short-lived episodes of evaporation may lead to great thickness of salts.

Glaciogenic and Cold Water Sediments

About 10% of the Earth is covered by ice today, but this increased to 30% during the Quaternary glacials. Ice and permafrost provide a series of erosional and depositional fingerprints (e.g. striated pavements and boulders, dropstones, ice wedges, and glacial tills (diamicton)) (*see* **Sedimentary Processes:** Glaciers) as well as a range of geomorphological features, such as eskers, kames, etc., some of which have been recognized in association with ancient glacial systems (e.g. in the Lower Palaeozoic of the Sahara and the Late Palaeozoic of Gondwana). However, boulders may be dropped into deep water through mechanisms other than ice rafting (e.g. from the roots of floating trees). More cryptic evidence of cold-water precipitation comes from glendonites – carbonate nodules pseudomorphing the mineral ikaite, the low-temperature polymorph of calcium carbonate ($CaCO_3 \cdot 6H_2O$). It is today associated with clathrates in cold deep waters and in shallow polar waters. Glendonites are reported from Cretaceous localities in Australia and Canada and from the Jurassic of Siberia.

Coals and Lignites

Coals and lignites are indicative of an excess of precipitation over evaporation: vegetation accumulates in wetland mires, which, if rain occurs on most days of the year, will grow upwards above the general level of the regional water table. Preservation of peat requires rapid burial and/or anoxic conditions. Frigid conditions favour preservation, as do environments in which rainfall is evenly spread throughout the year. Today such conditions occur in equatorial zones and in high mid-latitudes. In the Mesozoic equatorial zones appear to have been more arid than they are today.

Wildfires and Palaeosols

Fusain, almost pure carbon in sedimentary rocks, is a product of wildfires. Natural fires, mostly triggered by lightning strikes, are favoured in strongly seasonal climates where vigorous plant growth is promoted by a distinct wet season, followed by a dry season creating tinder that becomes fire-prone during thunder storms at the onset of the next wet season. Fusain-rich sediments are frequently associated with other evidence of strong seasonality (distinct wet–dry seasons) such as vertisols (and associated smectite-rich clay mineralogies) and calcretes.

Laterites (or ferricretes) reflect the relative accumulation of haematite, goethite, aluminium hydroxides (e.g. gibbsite), and kaolinite within soil profiles (*see* **Soils:** Palaeosols). Pedogenic and groundwater laterites form best in humid tropical climates with a distinct dry season. Bauxites (aluminium-rich laterites) often occur in association with laterites. Some, like those of the Cretaceous of the Tethyan region, occur on karstic surfaces cut into carbonate platforms (*see* **Sedimentary Processes:** Karst and Palaeokarst). In such cases the detrital materials are likely to have been brought into the system, probably by aeolian activity.

Clay minerals in oceanic sediments reflect the weathering processes in the adjacent continental areas and the climatically controlled distribution of soils. Differential settling causes some depositional segregation of clay species (e.g. near-shore accumulation of kaolinite); nonetheless, recognizable patterns in the ancient can be preserved (*see* **Clay Minerals**).

Aeolianites

Although coastal dune complexes may form across a range of latitudes, major sand seas occur predominantly in arid environments. Such aeolianites provide both local and regional palaeowind data, which may be used to test palaeoclimate models generated by GCMs (see below). (*see* **Sedimentary Processes:** Aeolian Processes)

Palaeoclimate Models

A recent approach to understanding past climate regimes on Earth has been through the application of complex computer models, specifically atmospheric general circulation models (AGCMs), ocean general circulation models (OGCMs), and recently even more complex coupled ocean–atmosphere general circulation models (OAGCMs). There are now many contributions in this field, the palaeoclimatic

approach having been pioneered by John Kutzbach and Eric Barron.

General Circulation Models

GCMs use the laws of physics and an understanding of past geography to simulate climatic responses. They are objective in character. They require powerful computers to handle vast numbers of calculations. Nevertheless, it is now possible to compare the results of different GCMs for a range of times and over a wide range of parameterizations for the past, present, and future (e.g. in terms of predictions of surface air temperature, surface moisture, precipitation, etc.). GCMs are currently producing simulated climate predictions for the Mesozoic and Cenozoic that compare favourably with the distributions of the geological climate proxies discussed above. They can be used effectively to predict sites of oceanic upwelling and the distribution of petroleum source rocks and phosphorites. Models also produce evaluations of parameters that do not leave a geological record (e.g. cloud cover, snow cover) and quasi-parametric phenomena such as storminess. Parameterization is the main weakness of GCMs (e.g. palaeogeography, palaeobathymetry, sea-surface temperature, orography, cloud behaviour), and model output for continental interiors is still colder in winter than indicated by palaeontological data. The sedimentary and palaeontological record provides an important way of evaluating GCMs, and this is important because the same GCMs are currently being used to predict possible changes in future climate.

The outputs discussed below were generated by an AGCM (HadAM3) and an OAGCM (HadCM3L), which is currently state-of-the-art. The model was developed at the Hadley Centre for Climate Prediction and Research, which is part of the UK Meteorological Office. The GCM consists of a linked atmospheric model, ocean model, and sea-ice model. The horizontal resolution of the atmospheric model is 2.5° latitude and 3.75° longitude. This provides a grid spacing at the equator of 278 km north–south and 417 km east–west. The atmospheric model consists of 19 layers. It also includes a radiation scheme that can represent the effects of minor trace gases. Its land-surface scheme includes a representation of the freezing and melting of soil moisture. The representation of evaporation includes the dependence of stomatal resistance on temperature, vapour pressure, and carbon dioxide concentration. There is an adiabatic diffusion scheme, to simulate the horizontal mixing of tracers.

The ocean model has the same spatial resolution as the atmosphere model and 20 vertical layers, with a time step of 30 min. This contrasts with HadCM3 (the standard version of the Hadley centre OAGCM), which uses a horizontal resolution of $1.25° \times 1.25°$.

Palaeoclimate of the Mesozoic – Model Output and Geological Data

The Mesozoic Earth was an alien world, as illustrated here by reference to a Triassic GCM simulation and geological data. Throughout the Mesozoic dense forests grew close to both poles, experiencing months of continual daylight in warm summers and months of continual darkness in cold snowy winters. Neither Triassic nor Jurassic oceanic sediments provide good evidence, but in the Late Cretaceous, from ODP (Ocean Drilling Program)/DSDP (Deep Sea Drilling Program) data, the ocean depths appear to have been warm (8°C or more at the ocean floor), and reefs grew 10° further north and south than at the present time. During the era the whole Earth was warmer than now by at least 6 °C, giving more atmospheric humidity and a greatly enhanced hydrological cycle. However, from modelling studies, it seems that much of the rainfall could have been predominantly convective in character, often focused over the oceans. The model output might help to explain geological data suggesting that major desert expanses extended across the continents in low latitudes. From the model, polar ice sheets are unlikely to have been present because of the high summer temperatures. The model suggests the possibility of extensive sea ice in the nearly enclosed Arctic seaway through parts of the year, but there is as yet no proxy data against which such predictions may be tested. The Triassic world was a predominantly warm world; the model outputs for evaporation and precipitation conform well to the known distributions of evaporites, calcretes, and other climatically sensitive facies.

Triassic: Comparison of Model and Proxy Data – A Case Study

Modelled temperatures (Figure 2) A significant feature of the Triassic Earth is that the landmasses were almost symmetrically distributed in a broad arc about the equator (*see* **Mesozoic:** Triassic). A major aspect of the modelled Earth is its overall warmth. Despite temperatures plunging to −20°C and below over Siberia in the northern-hemisphere winter and to similarly low values over southernmost Gondwana in the southern-hemisphere winter, the annual average temperature is subdued in these high-latitude areas because of the high summer values achieved there (*ca.* 24°C). These high summer values preclude the possibility of year-round ice and snow.

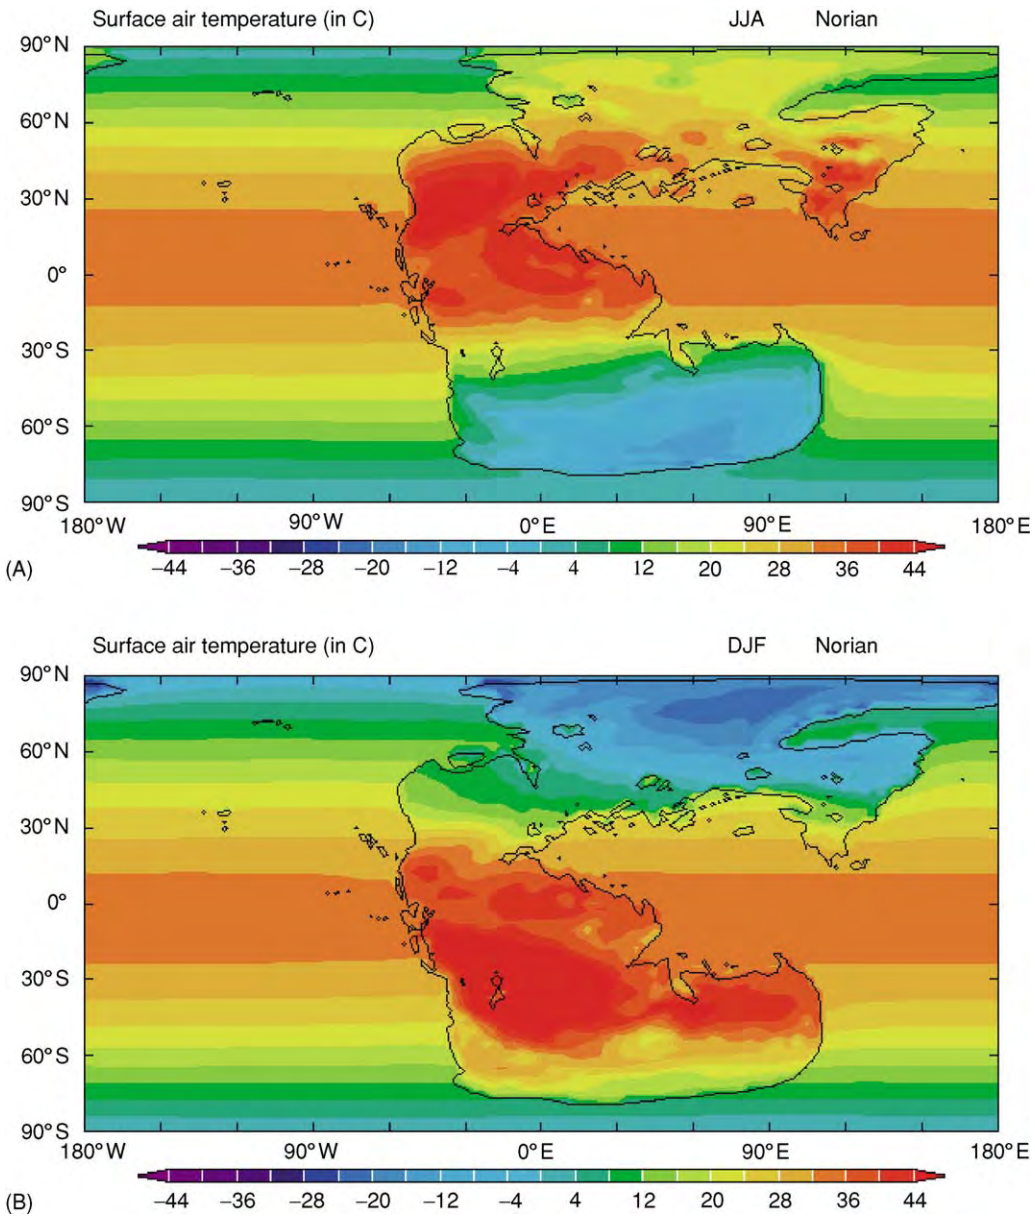

Figure 2 Model simulated mean seasonal temperatures for the Norian for (A) December February and (B) June August. Units are °C and the contour interval is every 4°C. The ocean sea surface temperatures were prescribed. JJA, June, July, August; DJF, December, January, February.

Temperature-limited facies According to the model, low temperatures would not have been a significant barrier to coral reef development around the Tethys. Reef systems developed and diversified through the Triassic, extending their range from between 2°S and 25°N in the mid-Triassic to a maximum range of 35°S to 33°N in the Late Triassic. Range limits are very close to the 20°C isotherm in the model.

Precipitation (Figure 3) Large tracts of Pangaea between about 40°N and 40°S are modelled to receive very little rainfall. Much of the rainfall is over the oceans, being convective in character, with the main zone of rainfall migrating north and south through the year with the movement of Intertropical convergence zone (ITCZ). The equatorial lands surrounding eastern and southern Tethys are modelled to receive relatively little rainfall during December–April. North-eastern Gondwana is modelled to have a monsoonal climate (winter wet). Northern and eastern Siberia have some rainfall throughout the year, the wettest period generally being through June and the

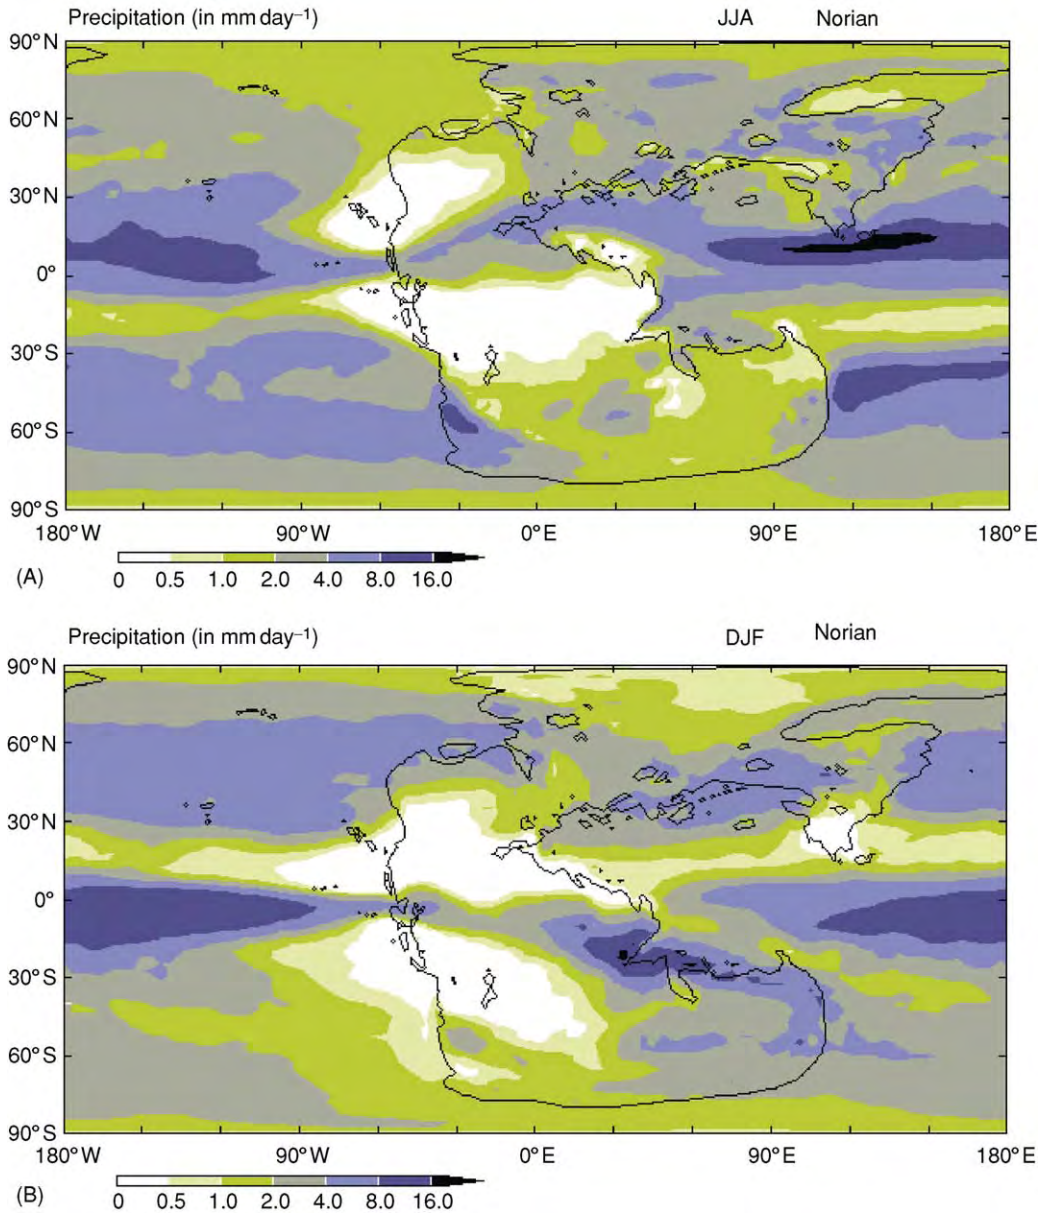

Figure 3 Model simulated mean seasonal precipitation for the Norian for (A) December February and (B) June August. Units are in mm day ^{1} and the contour interval is not regular. JJA, June, July, August; DJF, December, January, February.

driest during the summer months of July and August (also equivalent to a winter-wet biome). South-western Gondwana is also modelled to be winter wet; the eastern parts of Gondwana are moister than the western parts. Nonetheless, large tracts of Pangaea, particularly in the tropics but extending to nearly 50°N and 50°S, have a large excess of evaporation throughout much of the year, as does a large part of western Tethys. Southernmost Gondwana is also winter wet, including the southern polar area during its months of darkness.

In the Triassic (Figure 4), the following climate zones have yet to be recognized from geological data: ice; polar; cold temperate; and cold temperate arid (steppe/desert). Tillites have not been reported. An absence of both ice caps and several of these biomes would be expected from the model simulations, but with some caveats as the biomes are modelled by reference to modern equivalents (e.g. cold temperate).

In the Triassic the highest-latitude floras contain a lycopod that has a worldwide distribution, reflecting a global climate largely devoid of frost. From

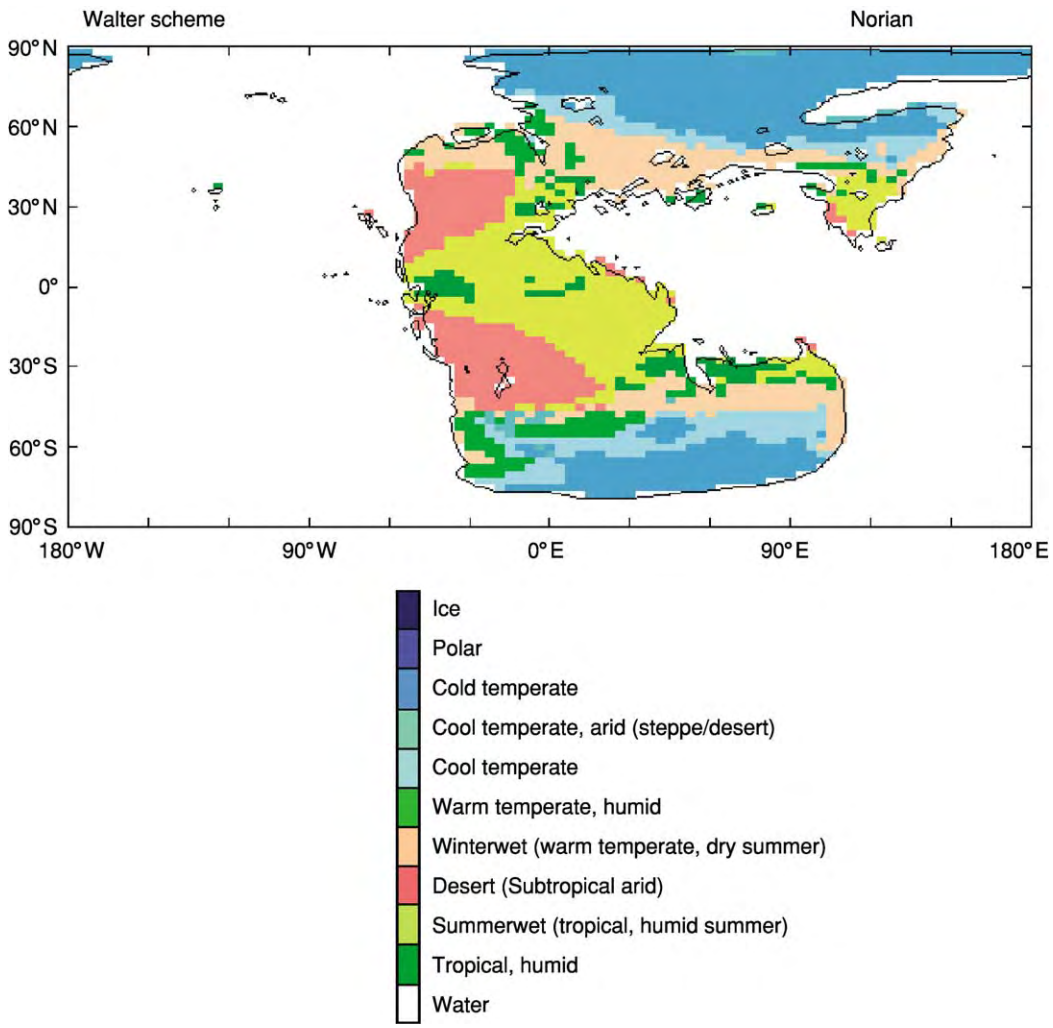

Figure 4 The Walter biome zones for the Triassic based on the model predicted temperatures and precipitation.

geological proxy data the interior of Pangaea was hot and dry, with warm temperate climates extending to the poles. In Siberia the flora was deciduous and displays well-defined annual growth bands; the climate is interpreted to be cool temperate, with cool winters and warm summers and a growing season of four to eight months. For this biome to extend to 75° in both hemispheres, as is observed, the poles must have been far warmer than at present. This is consistent with modelled output. The distribution of extensive calcretes throughout Europe and the western Tethyan margin is in agreement with the modelled climate: hot and predominantly arid but with a short wet season.

Relatively low-diversity communities of conifers were confined to lower latitudes and are often found in the proximity of evaporites (usually found in both hemispheres between about 10° and 40° latitude). They thus represent the subtropical dry environment, and their distributions are closely in line with model predictions in terms of the ratio between precipitation and evaporation.

On the basis of facies and palaeobotanical data, warm temperate climates existed between 5° and the equator, with high-diversity floras of ferns, cycads, and seed ferns, as well as conifers and ginkgoes. The cool temperate zone extended to central Siberia and is associated with the postulated uplands of the Central Siberian Volcanic Traps.

During the Middle Triassic, abundant evaporites and calcretes were deposited in Europe, whereas in northern and southern China warm temperate and cool temperate floras predominated. These observations are fully in agreement with model output. Warm temperate floras extended to about 70° N in north-eastern Siberia, and the first northern-hemisphere coal swamps since the end-Permian appear in this area. Southern-hemisphere coal swamps are found in

South America and Antarctica, again compatible with modelled zones where precipitation exceeded evaporation for much of the year. Biomes and facies suggest that the equatorial zone is a predominantly arid belt, again lending support to the validity of the model. Exquisitely preserved fossil wood from the Middle Triassic of Antarctica (70–75° S in the Triassic) indicates forests with growth rates that were one to two orders of magnitude greater than those seen at such latitudes today.

In the Late Triassic the warm temperate biome was dominant between 30° and 50° of latitude in both hemispheres. The model generally supports this scenario, but lack of precipitation typifies many regions between these latitudes, especially away from the coastal zones.

Thus, the model output shows a good correlation with globally derived data, particularly for terrestrial plant biomes, terrigenous proxy facies, and the distribution of reefs. Terrestrial reptile distributions are difficult to relate directly to palaeoclimate, but can be interpreted to be broadly in line with model output. This illustrates the sort of model–proxy correlation that is currently possible.

Conclusions

Model simulations for the Mesozoic throw important light on climatic processes and the behaviour of Earth systems under greenhouse conditions. Model output generally compares favourably with climate proxy data, but discrepancies between data and models reveal some serious modelling problems (or possibly incorrect interpretation of the proxies). In continental interiors, model simulations generate winter conditions that are considered to be too cold (by 15°C or more) according to the interpretation of some palaeontological data.

Ocean temperatures could have been much warmer than today, not only at the surface but also at great depths. Such temperatures would have greatly reduced the oceanic storage capacity of both carbon dioxide (in ocean waters) and methane hydrates (in ocean-floor sediments) relative to the present day. Model output is in close agreement with proxy climate data in coastal and open-sea areas.

In its 'greenhouse' mode the Earth's palaeoclimate has greatly enhanced evaporation and precipitation, by comparison with the present, but much of the rainfall is convective in character, falling over the oceans. To replicate climatic conditions similar to those indicated by proxy facies throughout the Mesozoic a very large increase in atmospheric carbon dioxide is required (at least four times the present-day values).

Through the Phanerozoic, the Earth's climate has changed significantly, both on a variety of time-scales and over a range of climatic states, usually baldly referred to as 'greenhouse' and 'icehouse', although these terms disguise more subtle states between these extremes.

PALAEOECOLOGY

E M Harper, University of Cambridge, Cambridge, UK
S Rigby, University of Edinburgh, Edinburgh, UK

Introduction

Ecology is the scientific study of the way in which modern organisms interact with their environment. In practice, ecologists study a very wide range of questions, but there are two main branches of study, autecology and synecology. Autecology is concerned with the ecology of an individual taxon, such as a cheetah, blue mussel, or vestimentiferan worm. Questions tackled might concern mode of life, feeding and breeding habits, and physical and chemical factors that limit distribution. Synecology examines the complex interactions between populations of a single species or between communities of organisms; examples of synecological studies might concern the relationships between a variety of big cats and their prey on the plains of Africa, the organisms associated with a mussel patch on a rocky shore, or the chemosymbiotic relationships within deep-sea vent communities, examining topics such as trophic structure and diversity. Palaeoecologists seek to gain similar understandings about fossilized organisms and ancient communities.

Palaeoecological studies may have relevance outside the sphere of palaeobiology. Organisms are not randomly distributed and are adapted to particular sets of environmental conditions (e.g., salinity, light levels, substrate consistency, and temperature). Once it has been established that a particular fossil taxon had a particular set of habitat requirements, the presence or absence of that taxon may be used in a broader geological context as a palaeoenvironmental indicator. For example, stenohaline organisms such as echinoderms and brachiopods, which have no ability to excrete water gained by osmosis, are limited to normal marine salinity, thus the presence of the body fossils of these higher taxa has been widely used as an indicator of prevailing normal salinity. For other groups, a detailed knowledge of the palaeoecologies of their component genera or species has been invaluable in finely subdividing palaeoenvironments. For example, the relative proportions of milioline, rotaliine, and textularine foraminifera in sediments give important information concerning the salinity of a depositional environment from brackish to hypersalinity. Brackish waters are dominated by rotaliinids and textularinids, whereas miliolinids and rotaliinids make up the dominant species in areas of normal or elevated salinity.

In terrestrial sediments, details of the palaeoecology of plants, such as the relationship between leaf shape and temperature and between concentration of stomata and atmospheric carbon dioxide levels, may be used in palaeoenvironmental reconstruction. Most recently, there has been an added interest in palaeoecology because the study of how the ecologies of different organismal groups and communities have altered during periods of dramatic environmental change (for example, during glacial periods or after mass extinctions) may give useful clues to how life on Earth may react to future climatic perturbations linked to human activities.

Palaeoautecology

The palaeoautecology of an extinct organism may be taken broadly to equate to its mode of life. Of course, there are aspects of fossil palaeoautecologies for which there is very little hope of being able to reconstruct; for example, it is difficult to imagine that anything will ever be known of mating dances in extinct flies, but a remarkable amount can be gleaned. Arguments made from homology with living relatives and analogy from organisms with apparently similar adaptations, from trace fossils or from models of fossils, can be used. It is almost invariably preferable to use a combination of approaches in order to allow cross-referencing.

When fossil organisms belong to taxonomic groups that still have extant representatives, much can be learned by applying knowledge about living taxa, using principles of homology. Clearly this is likely to

be most successful in groups which are most closely related, and as this relationship is stretched, any conclusions that extant and fossil groups may have lived in the same way are tenuous. Interpretation of the modes of life of most fossil bivalve molluscs is relatively straightforward. Several features of bivalves make these organisms ideal for palaeoecological reconstruction. First, modern bivalves are more diverse, both in terms of taxonomic units and in life habits, than ever before in their 500-million-year evolutionary history, meaning that interpretations can be based on a wide range of possible models. Second, a wide variety (for example, oysters, scallops, mussels, and clams) are of great commercial interest and consequently their biologies have been studied intensively. Third, it is well demonstrated that bivalve shell morphology and life habit are intimately related (*see* **Fossil Invertebrates:** Bivalves).

An example of this methodology is illustrated in Figure 1, which shows the right valve of *Eopecten*, a large bivalve known from Middle and Upper Jurassic hardground faunas of Normandy (France) and Portugal. Several aspects of its morphology can be used to interpret the palaeoecology of this animal, based on comparison with a living bivalve of the same family. The oldest part of the shell, close to the umbo, is a regular scallop shape and shows the morphological features associated with attachment to a hard substrate by byssal threads spun by the foot. The surrounding section (later growth) of the shell is highly irregular and its form varies among individuals, because at this size the bivalve began to cement to the seafloor and modified its shape to suit the substrate. Experimental evidence has shown that cementation in bivalves is a good defence against predators.

Clearly some caution is required in using modern organisms to interpret the palaeoecology of extinct fossils, even when they are closely related. Some organisms have undergone a major shift in aspects of their life habits over their evolutionary history. For

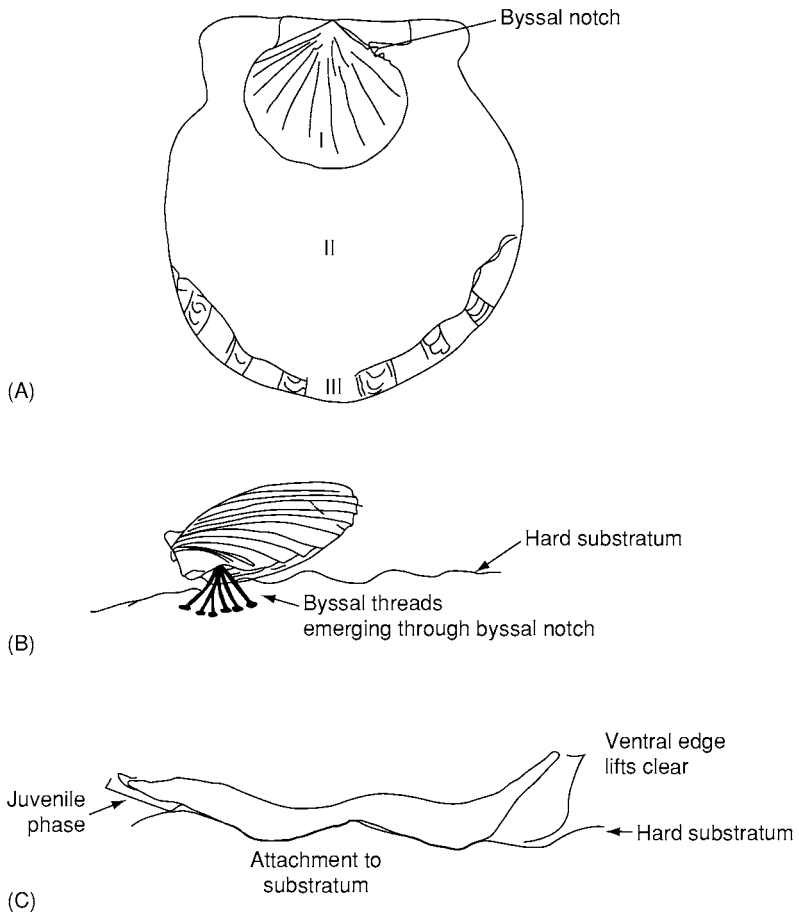

Figure 1 Reconstruction of life habits of Jurassic *Eopecten*. (A) External view of the right valve. I, Juvenile phase (the byssal notch is later filled with shell material); II, later growth (attachment scar, no ribbed ornament); III, valve lifts clear of substrate, coarse ribbed ornament. (B) Juvenile stage byssally attached to hard substrate. (C) Cross section through a mature animal, showing extensive cementation scar and raising of ventral margins above substrate.

example, monoplacophorans, a primitive caplike molluscan class (*see* **Fossil Invertebrates:** Molluscs Overview), are known from a variety of shallow marine sediments from the Lower Palaeozoic, apparently living in communities alongside brachiopods and trilobites. They then apparently disappear from the fossil record during the Devonian and were presumed extinct until the celebrated rediscovery of *Neopilina* during dredging of deep water (>3500 m) off the coast of Mexico during the Danish-led Galathea expedition in 1952. However, it would clearly be inappropriate to reconstruct the palaeoecology of the Palaeozoic forms based solely on our understanding of the biology of *Neopilina*. Presumably during the Upper Palaeozoic, monoplacophorans were forced, perhaps by competition or predation pressure, into deep-water refuges that are not represented in the sedimentary record. Other Palaeozoic taxa that were important and widespread in shelf communities, such as brachiopods and stalked crinoids, are postulated by some also to have been driven into refugia. These examples clearly demonstrate the need to use several lines of evidence when reconstructing palaeoecology and, most importantly, not to divorce the study of fossils from their lithological context.

What happens when there are no convenient living homologues? In such cases, the palaeoecologists must use more imaginative approaches. Trilobites (*see* **Fossil Invertebrates:** Trilobites) became extinct by the close of Palaeozoic, although much may be gleaned of their palaeobiology by homology and by analogy with other arthropod groups (such as understanding their moulting and likely internal anatomy). It is believed that trilobites exploited a wide range of life habits; although most were benthic, others were pelagic or nektonic. Some (e.g., *Calymene*) are interpreted as having been voracious predators, whereas others were thought to have been filter feeders or deposit feeders. The lines of evidence used to elucidate these different palaeoecological details are varied. Much is reliant on detailed studies of functional morphology, but evidence from trace fossils (including some that show evidence of trilobites tracking worms) and experimental modelling have also played a role. An interesting example is the interpretation of the Lower Palaeozoic olenellids as possible chemosymbionts in an elegant study by Richard Fortey. Using a combination of evidence based on the functional morphology of the family, principally the large number and wide nature of the thoracic segments and degenerate hypostome, the lithological evidence that olenellids tended to inhabit sulphur-rich unbioturbated black shales, and by analogy with totally unrelated modern chemosymbiotic organisms such as lucinid bivalves, Fortey suggested that these trilobites might well have harboured sulphate-reducing bacteria on their gills, which allowed them to live in 'difficult' oxygen-poor environments.

When living relatives and even good analogues are absent, more unconventional approaches can be taken in the study of the fossil mode of life. Graptoloids (*see* **Fossil Invertebrates:** Graptolites) were a significant group of macrozooplankton living in the Ordovician to mid-Devonian open seas. They have very remote living relatives, the pterobranchs, but their benthic, encrusting mode of life makes direct comparisons unrealistic. Instead, work has concentrated on the response of graptoloid shapes to seawater, which had the same properties in the Lower Palaeozoic as it does now. Physical and computer-derived models show that both the overall colony shape and its detailed morphology would have had important consequences for the behaviour of the species in water. Colonies were designed to rotate during movement, thereby increasing the volume of water that could be sampled. Flow of water was directed into the thecal apertures where the zooids lived by an arrangement of spines, hoods, or hooks in many species. A standard orientation relative to the dominant direction of water flow was maintained by structures such as the virgella and virgula, arrayed at the proximal and distal ends of the colony (**Figure 2**). Understanding the physical effects of adaptations shown by fossils allows inferences about life habits to be made (for example, concerning the likely feeding position of the zooids and the sampling requirements that conditioned their fitness and hence evolution).

Palaeosynecology

Ecologists define a community as a recurring group of taxa (in fixed proportions) that live together in a particular habitat. The focus of interest is in the way in which populations of single species or different taxa interact and the manner in which resources within that habitat are shared between the different groups. Ecological studies can be well founded on quantitative analyses based on direct observations. Palaeoecologists, however, are faced with a number of problems and must use less direct methods. First, a high proportion of any community may be soft-bodied or weakly skeletonized such that they are unlikely to be preserved in the fossil record. It is estimated that more 70% of modern taxa fall into this category and the Middle Cambrian Burgess Shale lagerstätte (*see* **Lagerstätten**) provides a salutary lesson, showing the wealth of poorly or unskeletonized organisms (such as worms and arthropods) not usually preserved in contemporary deposits. Second, relatively few organisms are preserved in life position and many may have been

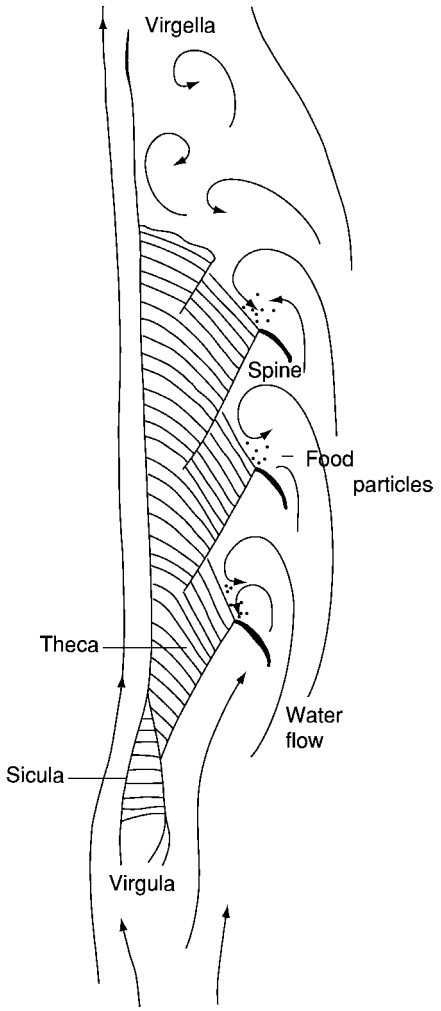

Figure 2 Sketch of flow patterns of water over a monograptid graptoloid model. The virgula and virgella maintain the colony in a stable orientation relative to the main current. Spines at the thecal openings produce local turbulence and direct flow over the apertures, concentrating food particles conveniently for animals living in the thecae.

transported far from their original habitats. As a result, the palaeoecologist must consider whether the group of fossils being studied is autochthonous (i.e., preserved in life position), parautochthonous (i.e., elements are disturbed and disarticulated, but the fossils are not necessarily far removed from their origins), or allochthonous (i.e., organisms from different habitats have been swept together) before drawing any conclusions. Third, even if a group of fossils is considered autochthonous, it has to be recognized that any bed, or even bedding plane assemblage, is going to be time averaged, and it will thus contain a sample of individuals that lived on that site over many centuries or even thousands of years. In this way, individuals of the same species but of very different generations may be found next to one another, or taxa that lived in successive communities on that site may appear to have co-existed. As a result of these complications, palaeoecologists prefer to use the term 'assemblage' rather than 'community'. In addition, the soft-bodied components of the original communities are seldom found fossilized. If similar assemblages are found to occur widely, either geographically or temporally, this provides a good indication that they are a real ecological phenomenon, and these are given the name 'associations'.

Investigating Fossil Populations

Populations of organisms are sensitive to characteristics of the environment and can be studied in two main ways, by the examination of life strategy and through survivorship analysis (Figure 3). Two extreme life strategies, commonly termed *r* and *K*, are derived from the logistic equation that states that the number of individuals (N) in a population will be a function of reproductive rate (r) modified by closeness of the number of individuals to the total number that can be supported by an environment (the carrying capacity, or K):

$$dN/dt = rN[(K - N)/K]$$

The *r*-strategist species depend heavily on high rates of reproduction, often breed early (at small size), and may die after breeding. They generally invest little in the care of their offspring, but have many offspring at once. The strategy is characteristic of unstable environments in which the carrying capacity varies significantly over short time-scales. The *K*-strategist species breed late, often bearing single young over whom care is expended. Individuals often live for a considerable time, even after breeding has ceased. This strategy is typical of stable environments in which the carrying capacity is highly predictable. Although these two descriptions are extremes, and most organisms show a mixture of *r* and *K* features, the generalizations have great use in making first-level interpretations of population dynamics.

Survivorship analysis is a complementary tool for use in the examination of fossil populations. The number of survivors of each age group of a population is plotted on a logarithmic scale as a function of age. In fossil populations, the number of survivors can be inferred if the bedding plane is time averaged, or can be observed if mass mortality of a single group produced the association. Most survivorship curves fall into three distinct categories, though variations exist, and organisms with very different life habits at different stages of their lives may show composite patterns. In cases in which high infant mortality occurs, as might be seen, for example, in fish stocks,

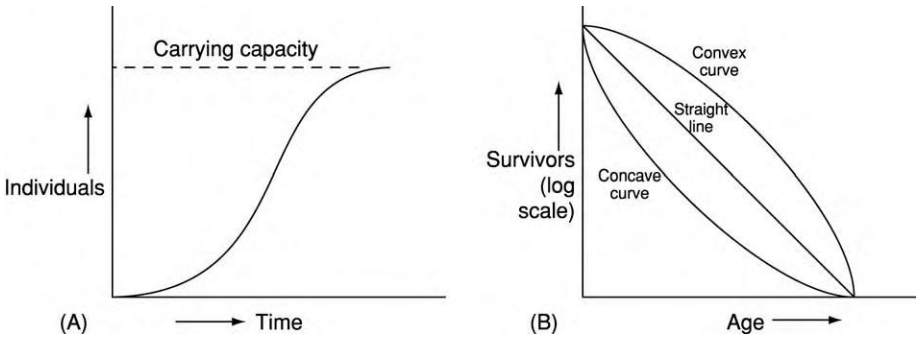

Figure 3 Key graphs for the interpretation of fossil populations. (A) A plot of the logistic equation, showing the rate of population increase slowing as the population size approaches the carrying capacity of the local environment. (B) Survivorship curves for populations with a high juvenile mortality (concave curve), an equal chance of mortality at any age (straight line), and a high gerontic mortality (convex curve).

the survivorship curve will be concave. In environments in which there is an equal risk of mortality at any age, the survivorship curve will be straight. The classic example of this type of curve is that of garden birds. Palaeontological examples are found, especially in extreme environments in which mortality is generated by frequent, unpredictable, and unselective events. In more stable environments, mortality rate is low initially but increases with age after a certain point, producing a convex survivorship curve. In these cases, organisms can be fit enough to survive the variation seen in their environment, but this characteristic is reduced later in life through illness or gerontic effects.

Investigating Interactions between Organisms

Organisms may interact in a number of different ways. Most important among these are competition for resources (e.g., for nutrients, space, light, or mates), either intra- or interspecifically; predator–prey interactions; and symbiosis, which runs through a spectrum, from being beneficial to both partners (commensalism) to parasitism, in which one partner's advantage is deleterious to the other. Ecologists have found that these interactions play an important role in controlling the fitness of modern organisms, and competition and predation in particular are thought to be extremely important driving forces in evolution. At first sight it might seem that the fossil record is likely to be virtually mute on the interactions between organisms; however, this is not the case. Clearly, individual cases must be carefully assessed, but it is possible to generate quantitative data on interactions between organisms from the fossil record.

Competition

The competitive exclusion principle suggests that two species that have exactly the same requirements cannot exist together within a habitat. Where two species do appear to have the same requirements, one will be prevented from maintaining a viable population by the success of the other, or one will be forced to adapt in order to use slightly different resources. The latter strategy may involve character displacement (e.g., modification of filter-feeding apparatus to cope with particles of a different size).

Competition has often been invoked as a cause of macroevolutionary change, although it is difficult to demonstrate. For example, some have suggested that the post-Palaeozoic decline in articulated brachiopods was at least in part influenced by the superior competitive advantages of bivalves that may occupy the same niche, and a similar argument has been made to link the success of dinosaurs with the decline of synapsids towards the end of the Triassic. One situation in which it has been possible to collect high-quality data concerns interactions between borers and skeletonized encrusters (e.g., bryozoans, oyster-like bivalves, and serpulid worms). These organisms have the advantage of having been preserved *in situ* and thus the fossils maintain their spatial relationships to one another and to the substratum. It must be remembered that soft-bodied encrusters (e.g., anemones, sponges) that may also have co-existed will be unrepresented, although evidence of their existence may be revealed by bioimmuration (preservation by the overgrowth of a skeletonized organism). In these cases, it is also possible to examine competitive overgrowth. It is known that space on hard substrates is at a premium in modern marine habitats, from which it may be inferred that taxa that are able rapidly to colonize space will be at an advantage over those that do so less aggressively. Much of this type of research has been centred on two clades of extant bryozoans, the cyclostomes and cheilostomes (*see* **Fossil Invertebrates:** Bryozoans). Both evolved independently from soft-bodied ctenostome ancestors, the cyclostomes in

the Ordovician and the cheilostomes in the Cretaceous. The cheilostomes replaced the cyclostomes as the dominant bryozoan clade and it has been argued that the former were more successful competitors. An analysis of competitive overgrowths between the two groups from a range of localities (Cretaceous to Recent) by McKinney has revealed that cheilostomes consistently 'won' around 66% of all interactions between the two clades, although interestingly this figure appears to have remained constant over geological time.

Predation

All organisms die, and a great many deaths are the result of being eaten by predators, becoming part of the food chain. The need to avoid predation is a very important selection pressure, hence the battery of defensive morphologies (e.g., spines and thick shells), behaviours (such as leaping by cockles or swimming by scallops), and life habits (such as deep burrowing) that may be demonstrated in modern organisms. Very rarely, predators may be fossilized in the act of predation, with prey remains preserved in their guts, for example. But predator–prey interactions may be interpreted from the fossil record in a number of other ways, such that palaeoecologists are not limited to exceptional preservation to chart the evolution of different predatory groups and methods. Various aspects of an organism's functional morphology, such as possession of teeth or claws, may suggest that it was a predator. For example, the large, toothed chelicerae of Palaeozoic eurypterids (large aquatic scorpions) have been used to suggest that they may have been powerful predators of the early fish. Most theropod dinosaurs (*see* **Fossil Vertebrates:** Dinosaurs), including the well-known *Tyrannosaurus rex*, have narrow, sharp-pointed curved teeth, many with serrated edges, which suggests that they were carnivores. The most useful evidence, however, has come from the study of prey remains. Although some predatory groups eat their prey without leaving any evidence of damage (for example, starfish that prise apart bivalve shells, or fish that simply swallow their prey whole), there are two important and widely used predatory methods on shelled prey, crushing and drilling, that can be recognized in the fossil record. A whole variety of arthropod and vertebrate predatory groups feed by crushing open the shells of their victims, many leaving very diagnostic breakage patterns. Similarly, a number of worms, gastropods, and octopods drill neat holes in their victims, for either the extraction of tissue or the injection of toxins (Figure 4). Where such damage is evident, it is possible to undertake quantitative surveys of the frequency of attack by a particular predatory group and the frequency of prey repair (which provides a measure of the effectiveness of their defences), and also some aspects of behaviour, such as prey preference or stereotypic (predictable and so diagnostic of the predator) attack strategy.

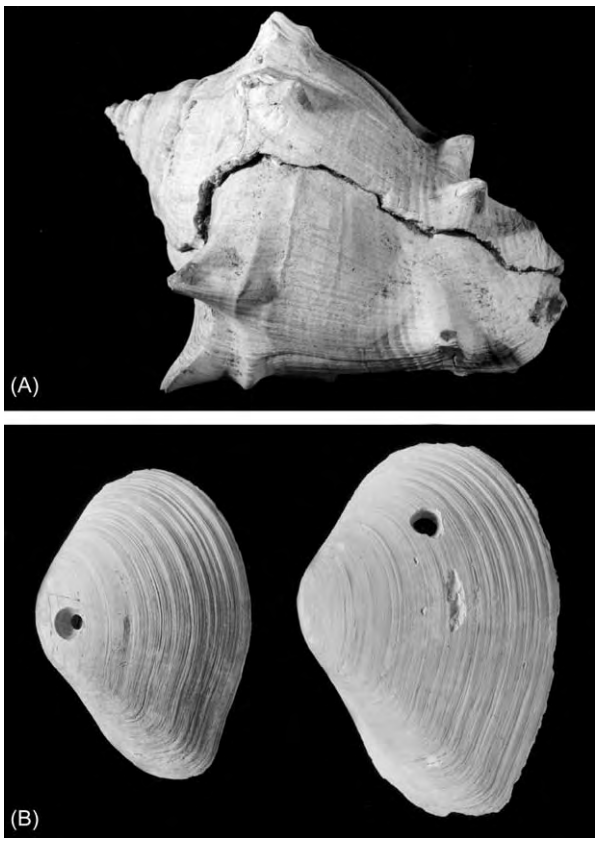

Figure 4 (A) Repaired predator induced breakage to gastropod prey. Miocene, France (×1). (B) Predatory drill holes produced by naticid gastropods in bivalve prey. Pliocene, United States (×1.5).

There is now a strong body of evidence to suggest that levels of predation pressure have increased during the Phanerozoic. In particular, it is evident that there have been marked increases in the past 270 million years, especially during the Cretaceous and Early Tertiary, during which time the numbers of predator taxa increased and more specialized feeding techniques evolved. This is part of the so-called Mesozoic Marine Revolution, a major restructuring of marine communities following the Permian–Triassic extinctions and leading to ecosystems taking on their 'modern' aspect. It can be argued that this increase in predation pressure had a profound effect on the evolution of individual taxa and changed the ecological properties of communities. It has been effectively shown that post-Palaeozoic gastropods have become better armoured (thickening their shells,

more taxa with slit-like apertures, and fewer taxa with loose coiling) and therefore better able to resist crushing predators, such as crabs. Many bivalve taxa adopted 'new' life habits such as cementation and deep burrowing, which can be shown to have decreased the threat from predators, and stalked crinoids moved away from shallow water communities into deeper habitats where there would have been fewer predators.

Symbioses

If two different fossil taxa are frequently found together, this may be evidence of a symbiotic relationship, but it may not be easy to demonstrate where the benefits and the costs of the relationships lay. Upper Palaeozoic platyceratid gastropods are frequently preserved in close association with the calyces of a variety of crinoids, in particular in a position close to or over the anus. The margins of these snails mirror closely the morphology of the calyx, implying that the animals were in close proximity long-term and that the gastropod literally grew to fit its location. The relationship appears to have been detrimental to the crinoid (i.e., a case of parasitism), because those with platyceratids are usually smaller than those without.

Hermatypic scleractinian corals (*see* **Fossil Invertebrates:** Corals and Other Cnidaria) are involved in an intimate symbiotic relationship with zooxanthellae that live within their soft tissue. Theirs is a commensal relationship of mutual benefit to both partners: the photosynthetic zooxanthellae gain a living site free from sediment cover, held aloft in the water and protected from the stinging nematocysts of the host, and the coral uses carbon fixed by the zooxanthellae to augment dramatically their own calcification processes. It is a strong relationship and many corals cannot survive without their zooxanthellae, which explains the very stringent requirements of scleractinian corals to inhabit clear water within the photic zone.

Examples of Palaeosynecological Studies

The Middle Cambrian Burgess Shale is one of the most important lagerstätten to have been discovered. The vast collection of material from the site has allowed a detailed examination of the palaeosynecology of the deposit. In a survey of more than 65 000 specimens collected from the Phyllopod Bed of the Burgess Shale, Conway Morris was able to examine the life habits of each of the taxonomic groups represented and to make calculations of biomass. It was also possible to undertake a trophic analysis (i.e., examining the feeding methodologies of different elements of the fauna). Largely using evidence from functional morphology, as well as some instances of preserved gut contents, Morris demonstrated the presence of deposit and suspension feeders, predators, and scavengers and allowed the tentative reconstruction of a trophic web.

In another study, Fürsich, Palmer, and Goodyear examined the palaeosynecology of bivalve-dominated patch reefs from the Upper Jurassic of the southern UK. Their studies recognized a number of 'guilds', or species that exploit a particular way of life or resource. Primary framebuilders (mostly bivalves, solenoporacean algae, and bryozoans) accounted for 55–70% of the volume of the reef, but there were also accessory encrusters (other bivalves, bryozoans, serpulids, and forams); a crevice-dwelling fauna (including byssate bivalves, small terebratulid brachiopods, and worms) that occupied cavities within the reef and borings made by endoliths; borers on a variety of scales, from large borings of bivalves to microscopic borings made by a variety of taxa (including phoronids,

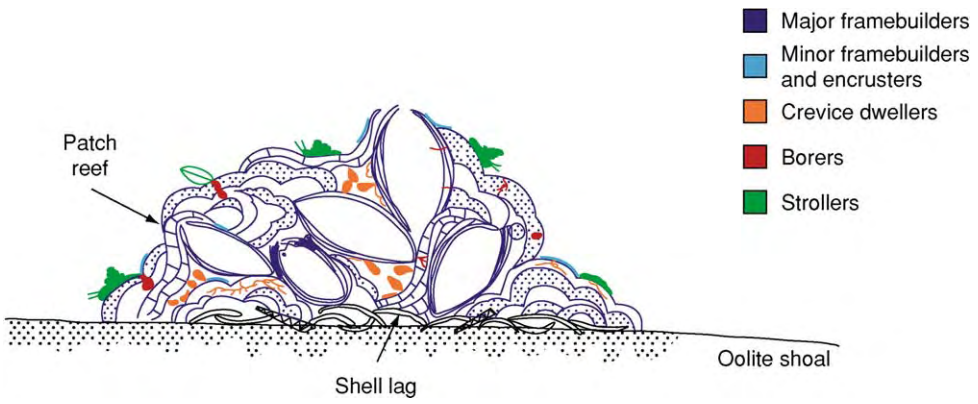

Figure 5 A reconstruction of a patch reef from the Upper Jurassic Portland Beds of South England. The key shows the different guilds of organisms, linking taxa by function within the reef, rather than by family tree.

crustaceans, and bryozoans); and a small number of vagile taxa, or strollers, largely gastropods, that roamed the surfaces of the reefs. It is likely that this latter guild is under-represented. These studies suggest that the reefs built up after initially unstable oolitic shoals had been stabilized by both infaunal and epifaunal bivalves, the shells of which then provided the firm seafloor onto which the reef-forming organisms were recruited (**Figure 5**).

PALAEOMAGNETISM

T H Torsvik, Geological Survey of Norway, Trondheim, Norway

Introduction

Palaeomagnetism is the study of the Earth's magnetic field preserved in rocks. The discovery that some minerals, at the time of their formation, can become magnetized parallel to the Earth's magnetic field was made in the nineteenth century. Early in the twentieth century, Bernard Brunhes made the startling discovery that some rocks are magnetized in the opposite orientation to the Earth's present-day magnetic field. This led him to propose that the Earth's magnetic field had reversed its polarity in the past. These reversals have subsequently been shown to be non-periodic and the Earth's magnetic field reversal history is now well known for the past 175 million years and more sketchingly understood to the beginning of the Palaeozoic (*ca*. 545 Ma).

Palaeomagnetism has a range of application potential (*see* **Magnetostratigraphy, Analytical Methods:** Geochronological Techniques), and the focus here is on understanding the importance of palaeomagnetism as an investigative tool in assembling palaeogeographical reconstructions.

Fundamentals

The Earth's magnetic field is believed to originate from the outer fluid core and, at the surface, the field is described by its inclination (angle with respect to the local horizontal plane), declination (angle with respect to the Greenwich meridian), and field strength (**Figure 1**). The inclination of the Earth's field varies systematically with latitude, which is of prime importance for palaeomagnetic reconstructions. At the north magnetic pole, the inclination of the field is $+90^\circ$ (straight down), at the equator the field inclination is zero (horizontal) pointing north, and at the south magnetic pole the inclination is -90° (straight up; **Figure 2**). The magnetic north and south poles currently differ from the geographical north and south poles by 11.5° because the magnetic axis is inclined from the geographical (=rotation) axis. The

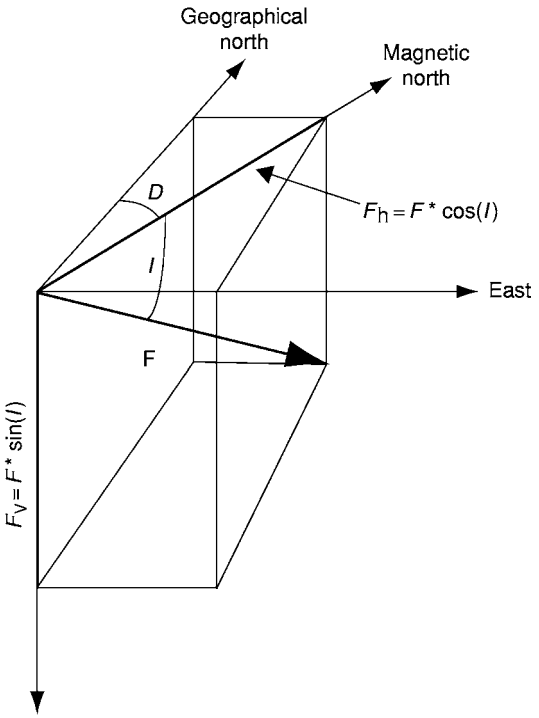

Figure 1 The direction and intensity of the total field vector (**F**) decomposed into declination from geographical north (D) and inclination from the horizontal (I). The equations relate the horizontal (F_h) and vertical (F_v) components of the total field (**F**) with I and D.

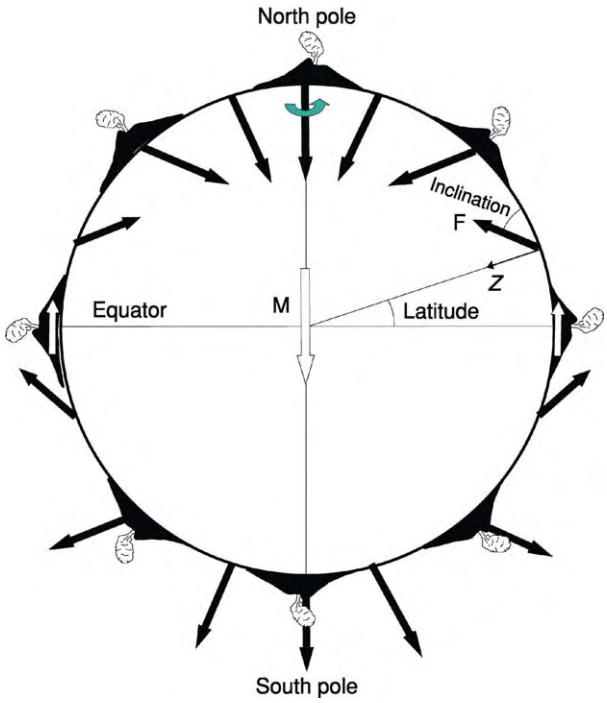

Figure 2 Field lines at the Earth's surface for a geocentric axial dipole. At the equator, the inclination is flat (zero) and, at the north and south poles, the inclination is vertical (+90° and −90°, respectively). The inclination recorded in volcanoes formed on the Earth's surface is dependent on the latitude (see also **Figure 3**). Declinations in a normal polarity field, such as today's, should point to the north.

magnetic axis, however, is slowly rotating/precessing around the geographical axis (known as secular variation) and, over a period of a few thousand years, it is hypothesized that the averaged magnetic poles correspond reasonably well with the geographical poles. This is known as the geocentric axial dipole (GAD) hypothesis. We can therefore imagine that a magnetic dipole is placed at the centre of the Earth and aligned with the Earth's rotation axis (**Figure 2**). In palaeomagnetic studies, it is therefore important to sample rocks whose ages range over more than a few thousand years; a study of a single dyke or basalt flow, for example, represents an instantaneous reading of the Earth's magnetic field (cools within a scale of days to weeks) and will not accurately record the position of the Earth's rotation axis.

When rocks form on an ideal planet, they acquire a remanent (permanent) magnetization parallel to the Earth's magnetic field at that location (**Figures 2 and 3**). There are a number of ways in which a rock can acquire a remanent magnetization, but most rocks are magnetized by one of the following processes: (1) as magma solidifies and cools below the Curie temperature (T_C, i.e., temperature above which a magnetic material loses its magnetism because of thermal agitation), magnetic minerals acquire a thermoremanent magnetization aligned with the Earth's magnetic field at the time of cooling; (2) during the deposition of sediments, magnetic mineral grains settle statistically in the direction of the Earth's magnetic field and a detrital remanent magnetization is acquired; and (3) when magnetic minerals are formed during chemical processes (diagenesis or metamorphism), the magnetic minerals grow as magnetized crystals with their magnetization in the direction of the external magnetic field; this creates a chemical remanent magnetization. Most magnetic minerals are iron–titanium oxides that belong to two solid solution series (**Figure 4**): the titanomagnetites (e.g., the end-member magnetite) and the titanohaematites (e.g., haematite). In the titanomagnetite series ($Fe_{3-x}Ti_xO_4$), there is an approximately linear variation of spontaneous magnetization ($\mathbf{M}_s$) and T_C with composition (x). Other common magnetic minerals include goethite and pyrrhotite (**Table 1**).

As an example, we can consider the remanence acquisition of a basaltic lava flow during cooling. The most important magnetic mineral in basaltic rocks is titanomagnetite. Low-titanium phases (e.g., pure

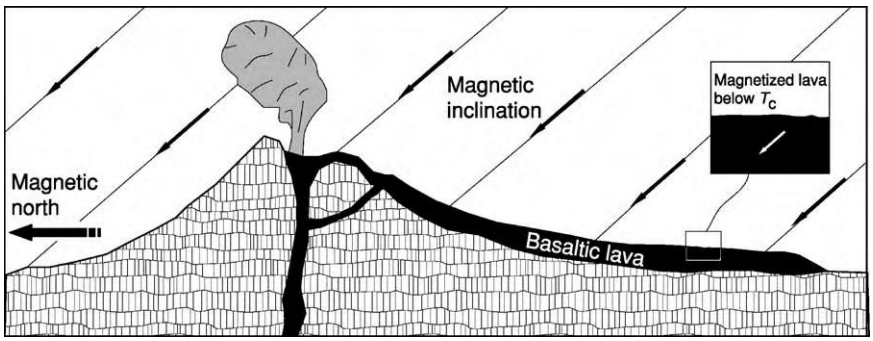

Figure 3 Example of acquisition of a thermoremanent magnetization (TRM) at intermediate northerly latitudes (acquired in a normal polarity field similar to today's). A lava will acquire a TRM upon cooling below the Curie temperature (see text), and the inclination will parallel the inclination of the external field and have declinations due north.

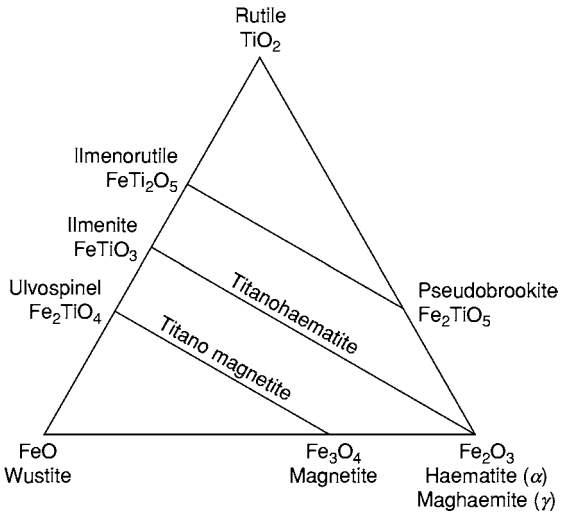

Figure 4 Ternary diagram showing the magnetically important iron oxide minerals in the titanomagnetite and titanohaematite solid solution series.

Table 1 Magnetic properties of some common minerals in rocks

Mineral (composition)	M_s(kA m ^{1})	T_C (°C)
Titanomagnetite ($Fe_{2\,4}Ti_{0\,6}O_4$)	125	150
Magnetite (Fe_3O_4)	480	580
Maghaemite (γ Fe_2O_3)	380	590 675
Haematite (α Fe_2O_3)	~2.5	675
Goethite (α FeOOH)	~2	120
Pyrrhotite (Fe_7S_8)	~80	320

magnetite; Table 1) have T_C values close to 580°C, whereas the presence of titanium lowers the T_C value. During a basaltic volcanic eruption, the temperature of a lava is approximately 1200°C; when a lava flow cools below T_C, the Earth's magnetic field is recorded within the lava flow (Figure 3). The declination, inclination, and magnetization intensity, which are proportional to the strength of the field, can today be measured in the laboratory. The magnetization intensity can vary by several orders of magnitude between different rock types, and thus different laboratory instruments are required to measure the magnetization precisely. Volcanic rocks normally have high intensities and the magnetization can be measured on standard spinner magnetometers. Conversely, sedimentary rocks can be extremely weakly magnetized, and highly sensitive superconducting magnetometers (superconducting quantum interference devices, SQUIDs) are required to measure and unravel their magnetization history.

Palaeomagnetic Analysis

In the early days of palaeomagnetic studies, it was common to measure the magnetization in a rock and assume that this magnetization, referred to as the natural remanent magnetization (NRM), represented a primary magnetization that had survived magnetic resetting from subsequent thermal or chemical activity. However, during the 1970s, it became more and more evident that rocks can undergo magnetic resetting, and it is therefore now standard procedure to test the stability of the NRM by thermal, alternating field, or chemical (rare) demagnetization. With the former method, a sample is measured following heating to higher and higher temperatures in a 'zero' field oven. From the 1980s, it became standard procedure to display the demagnetization data in orthogonal vector plots, also referred to as Zijderveld diagrams (Figure 5). These diagrams portray directional and intensity changes on a single diagram – magnetization components are identified as linear segments in both the horizontal ('declination') and vertical ('inclination') planes. Components and the degree of linearity can be computed using least-squares algorithms. A single-component

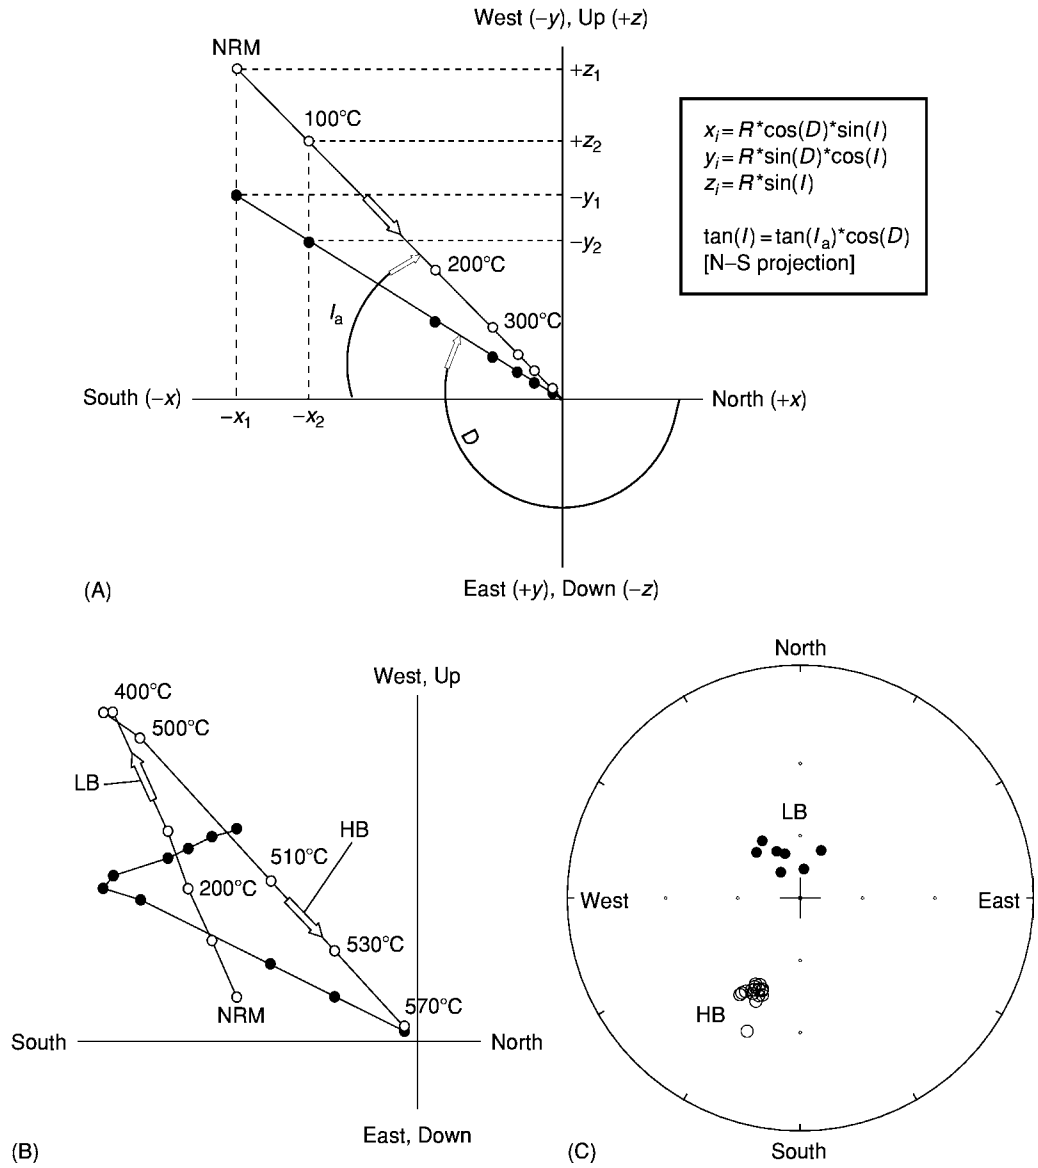

Figure 5 A Zijderveld plot illustrating vector components of magnetization during progressive thermal demagnetization, projected onto orthogonal horizontal (declination; filled symbols) and vertical (inclination; open symbols) planes. For each demagnetization step, the measured declination (D), inclination (I), and magnetization intensity (R) are decomposed to cartesian coordinates, x_i, y_i, and z_i, using the formulae in the box in (a). N S (+x, x) is selected as the projection plane as the declination is closer to N S than E W. The horizontal component is plotted as x_i,y_i, whereas the vertical plane is plotted as x_i,z_i. This procedure is repeated for each demagnetization step (in the example, natural remanent magnetization (NRM): 100°C, 200°C, etc.). Using this procedure, a magnetic component is recognized as a linear vector segment. The declination for a component can be read directly from the diagram, normally numerically computed by least squares analysis, whereas the inclination is apparent (I_a) and always larger than the real I; the 'distortion' of I_a depends on the projection plane. (A) Single component magnetization decaying towards the centre of the diagram. (B) Two component magnetization with a low unblocking component (LB) identified below 400°C and a high unblocking component (HB) decaying towards the centre of the diagram; the stability up to 570°C suggests pure magnetite as the remanence carrier. (C) Mean site compilation of HB and LB components shown in a stereoplot. LB is a recent overprint, whereas HB should be considered to be a Late Permian magnetization from the Oslo area (Baltica). The mean declination/inclination in this hypothetical study is 205°/ 41° (95% confidence circle around the mean, α_{95}, is 2.3°). The calculated palaeomagnetic pole for the site (60° N, 10° E) is 49.3° N and 152.3° E. In the stereoplot, open (filled) symbols denote negative (positive) inclinations.

magnetization is identified by single vector decay towards the origin of the diagram as the sample is progressively demagnetized (Figure 5A). Multi-component magnetizations, in which a primary component has been partly overprinted by younger components, can be recognized by the presence of two or more linear segments (Figure 5B). In the latter example, a hypothetical Permian dyke magnetization

from the Oslo region (Norway), with SSW declinations and negative (upward-pointing) inclinations (high unblocking component), is partially overprinted by a younger magnetization of Holocene origin, with NNW declinations and positive (downward-pointing) inclinations (low unblocking component). When the blocking temperatures overlap, curved segments are observed.

In a typical palaeomagnetic study, 5–10 samples are analysed from each site. Magnetization components are computed by least-squares analysis, a mean direction is computed for each site using Fisher statistics, and, finally, a mean direction is calculated from all the sites. In our example, we can imagine that the stereoplot in Figure 5C represents the mean directions from numerous individual dykes in the Oslo region.

Palaeomagnetic Stability Tests

Magnetic overprinting or resetting presents a problem. However, there are four fundamental tests used to check the stability and the potentially primary character of magnetizations: (1) the fold test; (2) the reversal test; (3) the conglomerate test; and (4) the contact test (Figure 6). The fold test determines whether a magnetization was formed prior to or after folding of a rock, and is therefore a relative test that does not prove a primary origin of the remanence. If a remanence is pre-fold, the site vectors should be dispersed after folding (Figure 6A); conversely, if a magnetization is post-fold, the site vectors should be similar throughout the fold structure (Figure 6B). The presence of antipodal stratigraphically linked reversals in a sedimentary or basaltic sequence is the best evidence for primary remanence (Figure 6A). The conglomerate test is also a powerful test. If magnetizations are random between individual boulders (Figure 6A), this is an indication for a primary magnetization in the host rock. Conversely, if boulder magnetizations concur with those in the surrounding rocks, magnetic overprinting is indicated (Figure 6B). A contact test is employed to check whether an intrusion or a dyke carries a primary magnetization. A dyke and its baked margin should coincide, whilst non-baked samples should differ if significantly older

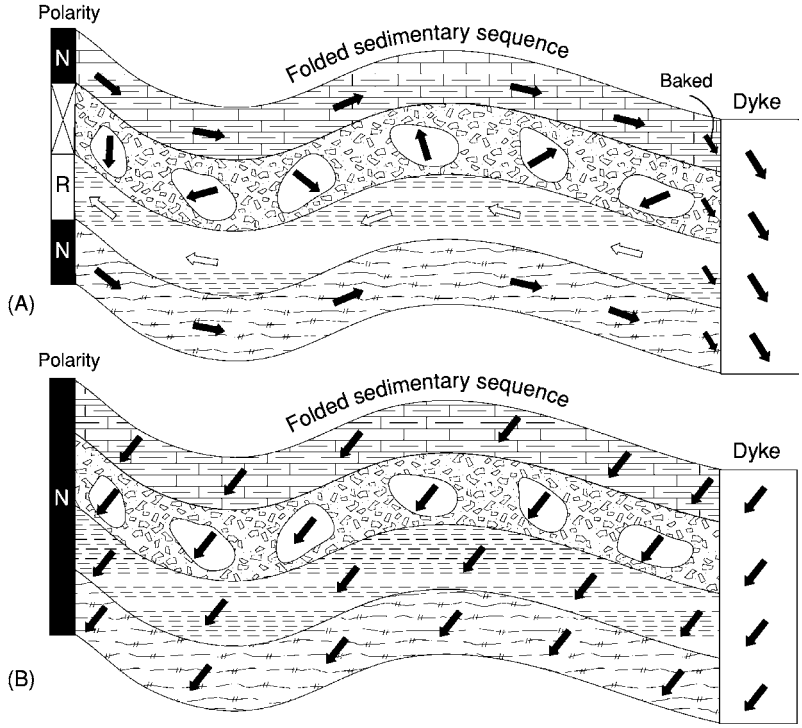

Figure 6 (A) Positive field tests. We assume that a sedimentary sequence was deposited at the equator (flat inclinations) and later folded. Polarity is indicated by the arrows. As the inclinations follow the bedding (except in the conglomerate), this is a pre fold magnetization. Evidence for a primary magnetization is witnessed by layers with antipodal polarity, and we can therefore establish a magnetostratigraphy (alternating normal and reversed magnetic fields). Further evidence for a primary magnetization is observed from a layer with boulders that show random magnetization vectors. A dyke intruded the folded sequence later, and steeper inclinations (indicating that the continent must have moved to higher latitudes) from the dyke and its baked/chilled margin indicate a primary dyke magnetization. (B) Negative field tests. All layers, conglomerate boulders, and the dyke have similar magnetizations and no reversals are observed. This indicates a regional secondary overprint after the folding and dyke intrusion.

than the dyke (Figure 6A). Conversely, if the dyke and all the surrounding rocks have a similar magnetization, the dyke records a younger overprint (Figure 6B).

Palaeomagnetic Poles and Reconstruction of a Continent

Based on the measurement of the remanent inclination, we can calculate the ancient latitude for a continent when the rock formed from the formula: $\tan(I) = 2 \times \tan(\text{latitude})$. In addition, the remanent declination, which deviates from 0° or 180° (depending on the polarity of the Earth's magnetic field), provides information about the rotation of a continent.

The inclination and declination change with the position of the sampled rock on the globe (Figure 2), but the position of the magnetic pole of a geocentric axial dipole is independent of the locality at which the rock acquired its magnetization. Thus, it is practical to calculate pole positions in order to compare results from various sites or to perform plate tectonic reconstructions.

Ideally, as a time average, a palaeomagnetic pole (calculated from the declination, inclination, and the geographical site location) for a newly formed rock will correspond with the geographical north or south pole. If a continent moves later, the palaeomagnetic pole must move with the continent. To perform a reconstruction with palaeomagnetic poles, we therefore have to calculate the rotation (Euler) pole and angle which will bring the palaeomagnetic pole back to the geographical north or south pole, and then rotate the continent by the same amount (Figure 7A). In our example, a palaeomagnetic pole (latitude, 49.3° N; longitude, 152.3° E), calculated from the situation depicted in Figure 5C, will position the Baltica continent (most of northern Europe eastward to the Urals) at latitudes between 15 and 50° N, causing the city of Oslo to have been located

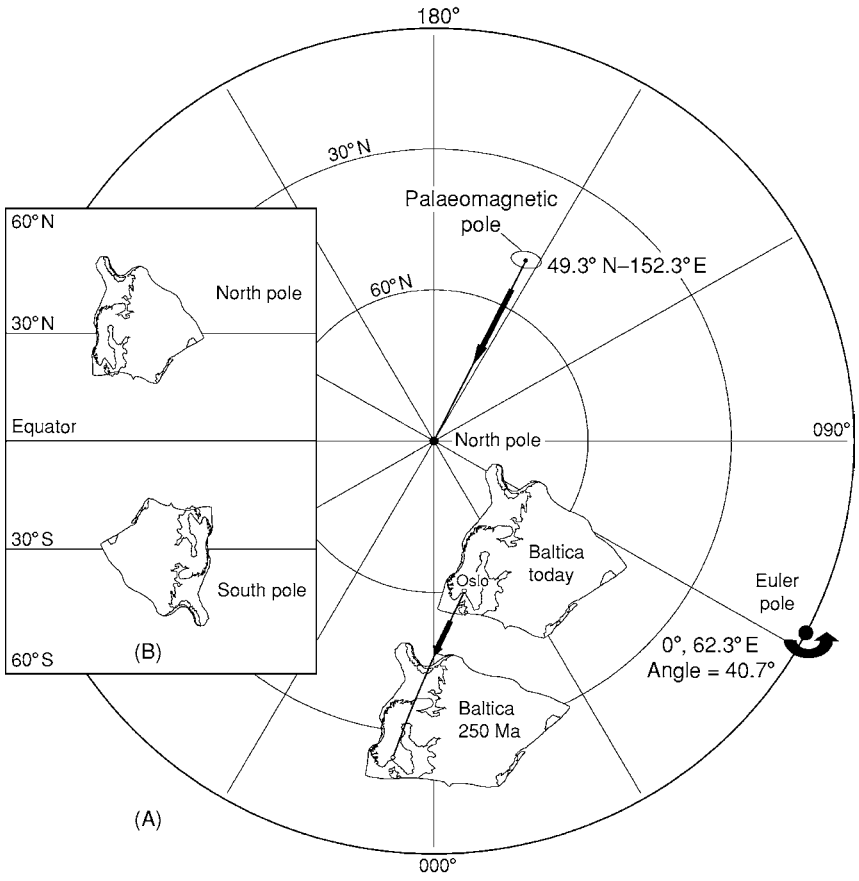

Figure 7 (A) The reconstruction of a continent, for example Baltica, is performed as follows. Determine the Euler pole needed to rotate a palaeomagnetic pole (in our case 49.3° N, 152.3° E) to the geographical north pole (we calculate 0°, 62.3° E and a rotation of 40.7°). This Euler pole is then used to rotate the continent by the same amount. Thus, Baltica today is rotated back about this pole to the position it occupied in Permian times. (B) In (A), we assumed that the palaeomagnetic pole was a north pole. If we assume a south pole, then the continent will be placed in the opposite hemisphere and geographically inverted.

at 24° N in the Late Permian (Figure 7A). Because the current latitude of Oslo is 60° N, Baltica must have drifted northwards since the Permian.

Palaeomagnetic data can only constrain latitude (based on inclination) and the amount of angular rotation (based on declination). Because the palaeolongitude is unknown, we can position Baltica at any longitude we wish, subject to other geological constraints. In addition to that uncertainty, we cannot tell in old rocks whether a palaeomagnetic pole is a south or north pole. In Figure 7A, we assumed that the pole was a north pole, but if we used a south pole, Baltica would plot in the southern hemisphere but in a geographically inverted orientation (Figure 7B). Hence, there is freedom to select north or south poles when producing reconstructions, placing the continent in an opposite hemisphere and rotated by 180°.

Apparent Polar Wander Paths

Apparent polar wander (APW) paths represent a convenient way of summarizing palaeomagnetic data for a continent or terrane, instead of producing palaeogeographical maps at each geological period. APW paths represent the apparent motion of the rotation axis relative to the continent, depending on whether one plots the movement of the north or south pole. APW paths can therefore be constructed as north or south paths. To construct an APW path, a set of palaeomagnetic poles of varying geological age

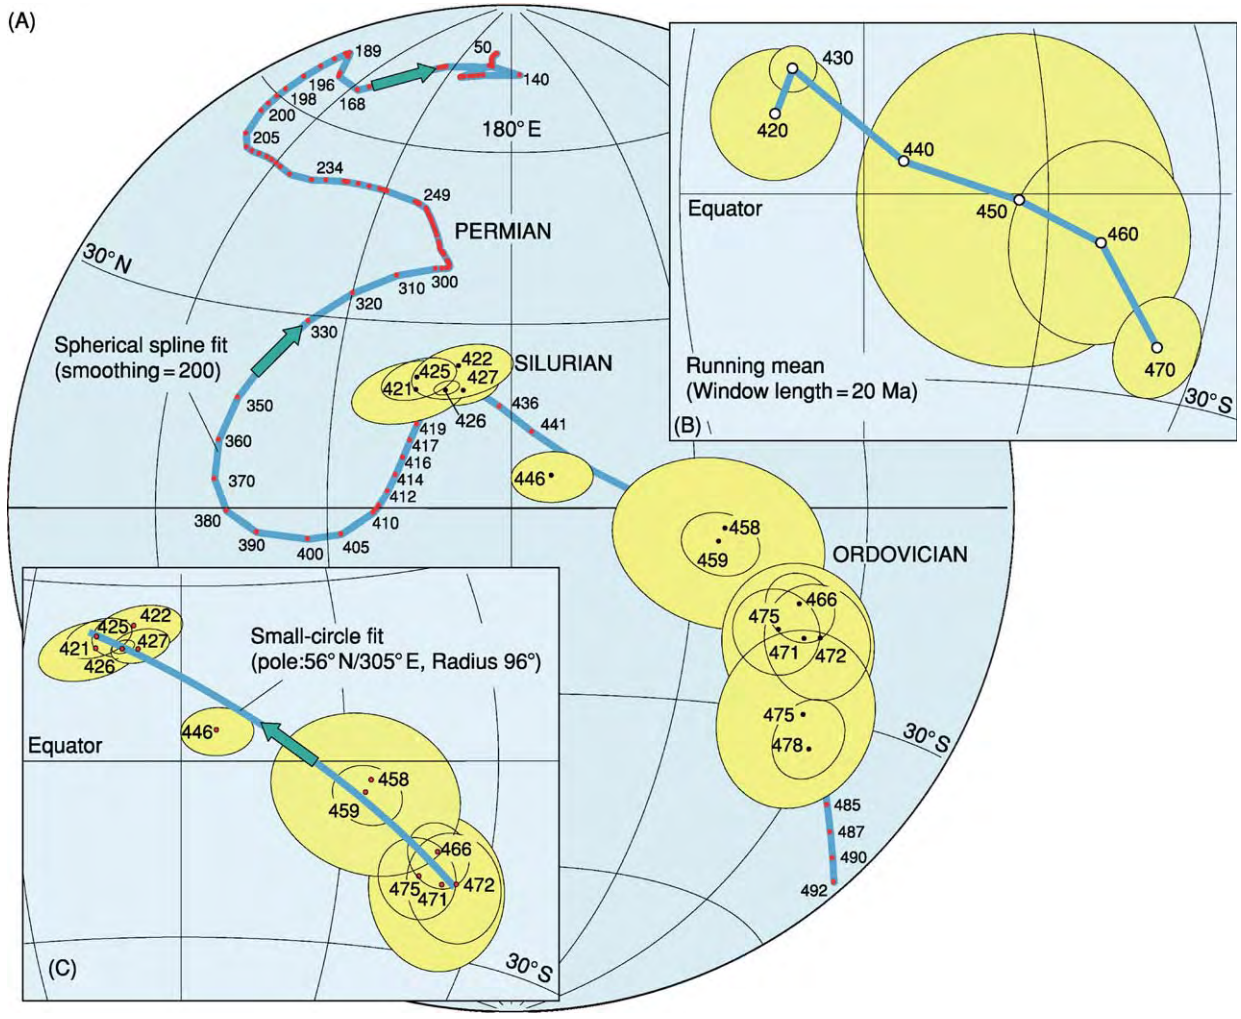

Figure 8 Examples of apparent polar wander (APW) paths for Baltica (include stable European data from Permo Carboniferous times). (A) Moderately smoothed spherical spline APW path from Early Ordovician to Early Tertiary times. Only Ordovician through Silurian input poles are shown. (B) Running mean path using the same input poles as in (A) and a 20 million year window. Mean poles are shown with 95% confidence ellipses (A95), except for the 440 Ma mean pole for which there was only one pole entry. The running mean path is only shown for the Ordovician Silurian section of the APW path. (C) Small circle path fitted to Ordovician Silurian poles as in (A). Input poles in (A) and (C) are shown with 95% confidence ovals (known as dp/dm).

are presented in a single diagram, and a synthetic path is fitted to the incrementing poles (Figure 8A). There are three common methods for generating APW paths: (1) spherical splines; (2) running mean (sliding time window); and (3) the small circle method.

The spherical spline method of modelling APW paths has been employed since the late 1980s. In brief, a spline constrained to lie on the surface of a sphere is fitted to the palaeomagnetic poles (Figure 8A), themselves weighted according to the precisions of the input palaeopoles. In the running mean method, palaeomagnetic poles from a continent are assigned absolute ages, a time window is selected (e.g., 20 million years), and all palaeomagnetic poles with ages falling within the time window are averaged. Using Fisher statistics, 95% confidence ellipses (known as A95 when averaging poles) can be calculated for each mean pole (Figure 8B). Both the spline method and the running mean technique are effective in averaging out random noise and allowing the basic pattern of APW paths to be determined.

The small circle method is based on the fact that movements of continents, APW paths, hotspot trails, ocean fracture zones, etc., must describe small circular paths if the Euler pole is kept constant. It is reasonable to assume that continents may drift around Euler poles that are kept constant for, say, some tens of millions of years. One can therefore fit APW segments along an APW path. This is demonstrated in Figure 8C where we can fit a small circle to Baltica poles from 475 to 421 Ma. However, after 421 Ma, the path changed direction markedly and this resulted from the collision of Baltica with Laurentia (North America, Greenland, and the British Isles north of the Iapetus Suture), which radically changed the plate tectonic boundary conditions and the APW path for Baltica.

Palaeolatitudes and Drift Rates – Links to Facies

Based on APW paths, we can calculate palaeolatitudes and plate velocities for a specific geographical location. Plate velocities are minimum velocities as the longitude is unconstrained; we only calculate latitudinal velocities. Figure 9 shows an example of such calculations based on the APW path in Figure 8A. In this diagram, we have also separated the northward and southward drift of Baltica. Drift velocities are typically below 8 cm per year, but peak velocities of around 14 cm per year are seen after collision of Baltica with Laurentia in Late Silurian–Early Devonian times.

The calculation of latitudinal velocities is important in order to check whether drift rates are

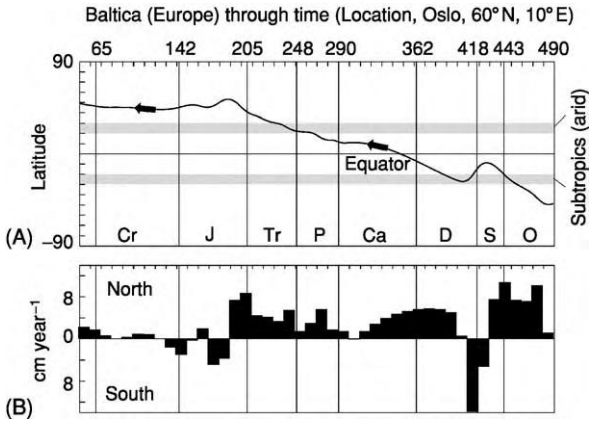

Figure 9 Latitude motion (A) and velocities (B) for Baltica (city of Oslo) from Ordovician to present times based on palaeomagnetic data (Figure 8A). Baltica was in the southern hemisphere during Ordovician through Devonian times, crossed into the northern hemisphere in the Early Carboniferous, and continued a general northward drift throughout the Mesozoic and Cenozoic. Northward and southward latitudinal translations throughout the Early Palaeozoic were accompanied by velocity peaks in the Early Silurian (northward) and the earliest Devonian (southward). Cr, Cretaceous; J, Jurassic; Tr, Triassic; P, Permian; Ca, Carboniferous; D, Devonian; S, Silurian; O, Ordovician.

compatible with 'modern' plate tectonic velocities. A rate of 18 cm per year (India) is the highest reliable value reported for the last 65 million years. When values appear unrealistically high (e.g., more than 20–30 cm per year), some authors have appealed to true polar wander (TPW) as a plausible explanation. TPW is a highly controversial subject that implies rapid tilting of the Earth's rotation axis, and is not generally accepted.

The distribution of climatically sensitive sediments, such as glacial deposits, coal, carbonates, and evaporites, is useful to check the palaeolatitudes derived from palaeomagnetic data. Glacial deposits are usually confined to polar latitudes and, except during the recent ice ages, there is no evidence for such deposits in Southern Baltica, as predicted by the palaeomagnetic data (maximum 60° S in the Early Ordovician). Carbonates, particularly in massive build-ups, such as reefs, are more common in lower latitudes. During Ordovician and Silurian times, Baltica drifted to subtropical and tropical latitudes, as witnessed by the presence of Bahamian-type reefs in Southern Baltica. Evaporites typically record dry climates within the subtropics (20–30°). During the Late Permian, Baltica was located at subtropical northerly latitudes, and the Late Permian coincides with large evaporite deposits in the North Sea area that subsequently became important in hydrocarbon trap development.

Palaeomagnetism and Palaeogeography: the Big Picture

Quantitative reconstructions are most commonly derived from hotspot traces (Cretaceous–Tertiary times) and ocean-floor magnetic anomalies, but prior to the earliest *in situ* ocean floor preserved today (approximately 175 Ma), the positioning of continents can only be quantitatively recognized by palaeomagnetism. As longitude is unknown from palaeomagnetic data, the identification and discrimination of faunas and floras can indicate that continents with similar faunas were in proximity to one another; conversely, different faunas of the same age can indicate the separation of the continents.

In order to construct a global palaeogeographical map, palaeomagnetic data from individual continents or terranes must be compiled and evaluated in terms of reliability. At any given time, palaeomagnetic data may not exist for all continents and additional criteria, such as fauna, flora, facies, and tectonic and

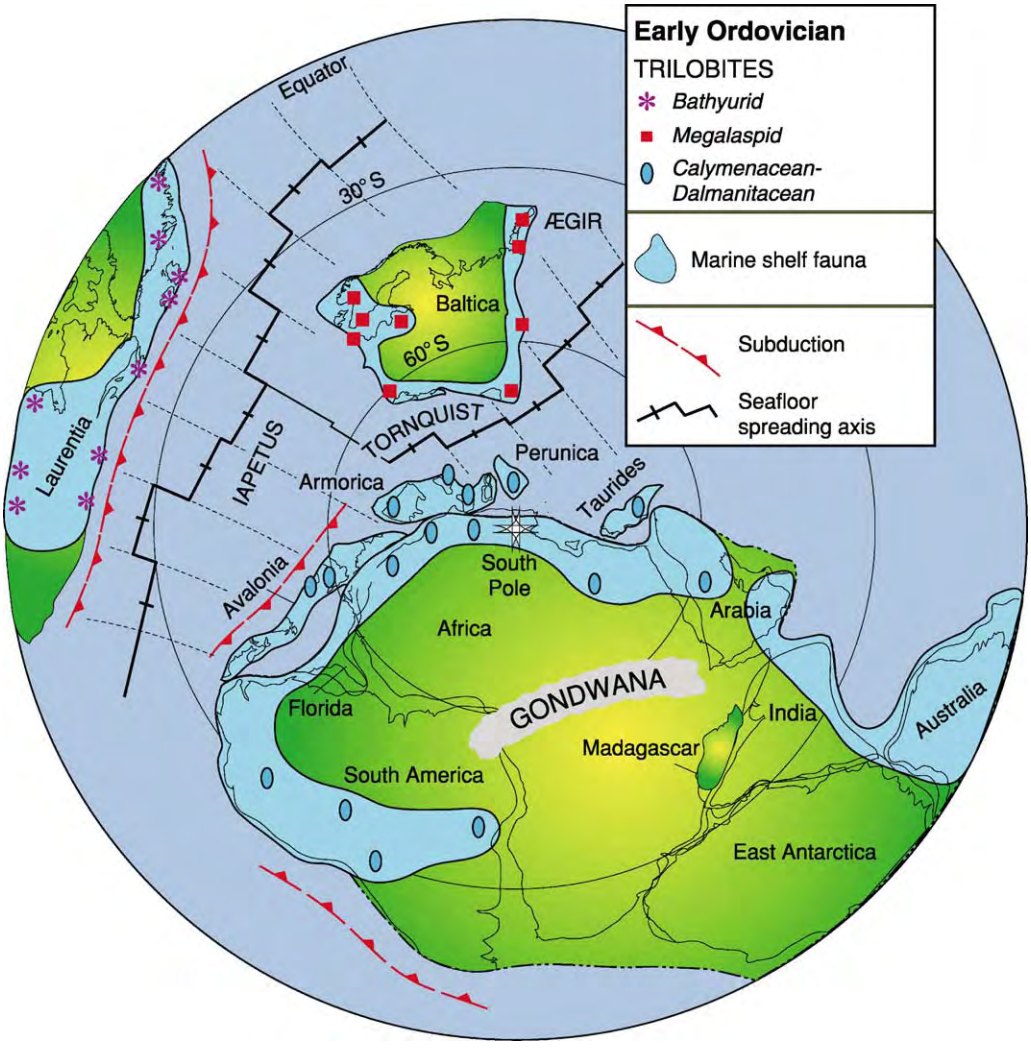

Figure 10 Reconstruction for Early Ordovician times (490 470 Ma) with the major terranes and some key Arenig Llanvirn trilobite faunas. Laurentia (located at the equator) includes North America, Greenland, and the British Isles north of the Iapetus Suture. Baltica (intermediate southerly latitudes) includes most of Scandinavia and Russia eastwards to the Urals. The core of Gondwana consists of Africa, Arabia, Madagascar, Greater India, most of Antarctica, most of Australia, Florida, and most of South America. Gondwana formed at around 550 Ma and covered more than 90° of latitude in the Early Ordovician. Gondwanan dispersal history commenced with the rifting off of Avalonia at *ca.* 465 Ma. Avalonia includes the British Isles and north west Europe south of the Iapetus Suture, eastern Newfoundland, most of the Maritime Provinces of Canada, and parts of the eastern USA. Armorica includes the Armorican Massif of Normandy and Brittany, the Massif Central, and the Montagne Noire areas of France, together with parts of the Iberian Peninsula. Perunica comprises the area north of the Barrandian basin of Bohemia. The Taurides comprises most of central and southern Turkey.

magmatic history, must be incorporated in order to construct rational maps. **Figure 10** illustrates an Early Ordovician (490–470 Ma) reconstruction; it does not show all the continents or terranes that existed at this time, but some major players, such as Gondwana, Baltica, Laurentia, and some selected peri-Gondwanan terranes with palaeomagnetic and/or faunal data (Avalonia, Armorica, Perunica, and Taurides). Not all the Gondwanan continents have reliable palaeomagnetic data for this time. However, Gondwana was amalgamated at around 550 Ma and continental elements, such as South America and India (no palaeomagnetic data), remained attached to Africa until the breakup of the Pangea supercontinent during the Mesozoic.

An integrated approach of palaeomagnetic and faunal analysis is applicable for the entire Phanerozoic, but works best for the Early Palaeozoic and, notably, the Early Ordovician (**Figure 10**). At this time, Gondwana stretched from the south pole (Africa) to the equator (Australia and East Antarctica), Baltica occupied intermediate southerly latitudes, separated by the Tornquist Sea, whereas Laurentia straddled the equator. Laurentia was separated from both Baltica and Gondwana by the Iapetus Ocean that had opened in the Late Precambrian. The Iapetus Ocean (approximately 5000 km across the British sector) and the Tornquist Sea (approximately 1100 km between southern Baltica and Armorica–Perunica) were at their widest. This is probably why benthic trilobites from Laurentia (bathyurid) and north-west Gondwana (calymenacean–dalmanitacean) are so markedly different from those of Baltica (megalaspid).

In summary, palaeomagnetism can be seen to be the best and only quantitative method to establish the positions of old terranes and continents as they drifted across the globe over geological time.

PALAEONTOLOGY

L R M Cocks, The Natural History Museum, London, UK

Introduction

The word 'fossil' has no exact definition, but it is loosely taken to mean any organism whose remains or traces of remains are preserved in some kind of sediment. The term is derived from the Latin *fossare*, meaning 'to dig'. The definition implies nothing about age: fossils range from those that are about three billion years old to those that are preserved in lime-saturated water deposited only a few days or even hours ago. The study of fossils is termed palaeontology, which is a word derived from Greek that literally means 'knowledge of ancient things'; however, for more than two centuries the word 'palaeontology' has been restricted to the study of formerly living (organic) not inorganic remains or traces. The word palaeobiology is sometimes used as an alternative. In this encyclopaedia there follow numerous

articles on the various groups of fossils, and this article is designed simply so that the enquiring reader may find his or her own way through the ensuing contributions.

The Preservation and Condition of Fossils

Very few fossils are found that show no changes from the original organism. There is a very approximate correlation in many cases between the age of the fossil and the degree of change, but age is in itself no guide. For example, a fossil may be distorted by tectonic activity within a few hundred thousand years of its deposition, whilst other rocks and their contained fossils undergo little tectonic change over long periods. For example, the Lower Cambrian shale in the St Petersburg area of Russia, which is some 430 Ma old, is so soft that it can be dug with a spade, and the marine shells preserved within it can be washed out and look not dissimilar in preservation from those found on a beach today. The term diagenesis (*see* **Diagenesis, Overview**) describes the changes within both rocks and fossils as the sediments become dewatered and chemical transformations occur. Voids, from microscopic size upwards, present both in the original organism and in the surrounding sediment, are usually filled during diagenesis as a result of mineral-charged fluids circulating through the rock. This may occur at any time from soon after the fossil was deposited to many millions of years later, when the entombing rock is subjected to sedimentary pressure or tectonic events. Replacement of the chemicals in the fossils themselves is widespread; for example, the calcium carbonate ($CaCO_3$) of a brachiopod shell is often replaced by silica (SiO_2) during diagenesis.

Fossils may also be hugely distorted from the original shape of the organisms by tectonic processes. In addition the fossils may dissolve, and their chemical contents may form other substances; for example all 'fossil fuels', such as crude oil (*see* **Petroleum Geology:** The Petroleum System) and natural gas, are made up of the concentrated remains of fossil plankton, and coal is formed from the now usually unrecognizable remains of fossil plants.

Another process is termed disarticulation. Obviously, if an animal or plant has only a single hard part, such as the shell of a snail, then that may become weathered or broken, but there is still only the one shell. However, if an organism has more than one hard part (ranging from the two shells of a bivalved mollusc or brachiopod to the several hundred bones found in a mammal skeleton), then the process of transport from its place of death to its final burial place, where it will eventually form a fossil, will often cause the organism to break up or disarticulate. The degree of disarticulation often depends on how strong or weak the original articulation was; for example, some brachiopods have weak hinge structures, and others, such as the common Silurian genus *Atrypa*, have complex interlocking mechanisms between the two valves and are thus very commonly found fossilized with their two valves still closed together.

Classification of Organisms

Fossils and organisms living today are all included within the same system of classification: whether an organism is living or dead, or the species extinct, is not relevant to its position in the classification. Of course, all the various systems of classification, whilst attempting to reflect truly natural relationships and groupings, are actually man made and in the last analysis subjective, although objective measurements and methods of analysis have in many cases assisted the systematists in their analyses and helped them to reach their taxonomic conclusions. The term 'systematics' is used in a specialized sense by biologists and palaeontologists to describe the study and arrangement of organisms into classifications and hierarchies.

All organisms are classified within the binomial method; in other words, each organism or taxon is defined as a species within a genus. The binomial system was invented by the eighteenth-century Swedish naturalist Carl Linnaeus (or Linné). Linnaeus published many classificatory books and papers, and subsequent systematists have agreed that the 12th edition of his book *Systema Naturae*, published in 1758, should be the technical starting date for animal classification; however, there are several different starting dates for plant names. All generic names start with capital letters, and all species names are written in lower case: for example, our own genus is named *Homo* and our species name is *sapiens*. Although the generic and specific names are the formal minimum for all distinctively named organisms, some genera are divided into subgenera (which are therefore above the species level), and some species are divided into subspecies. For example, the English song thrush is the species *Turdus philomelos*, and those birds in my garden in London are the main subspecies *Turdus philomelos philomelos*, whilst the subspecies occurring only in northwest Scotland is *Turdus philomelos hebridensis*. Generic, subgeneric, specific, and subspecific names are normally printed in italic. Above the genus level, organisms are grouped within families, which may again be divided into subfamilies or grouped together as superfamilies. Above the family are the order, the class, the

phylum, and the kingdom. Plants are one kingdom, animals are another. Within the animal kingdom, the phylum Mollusca (*see* **Fossil Invertebrates:** Molluscs Overview), for example, is divided into the class Bivalvia (*see* **Fossil Invertebrates:** Bivalves) (including oysters), the class Cephalopoda (*see* **Fossil Invertebrates:** Ammonites; Cephalopods (Other Than Ammonites)) (which includes ammonites, nautiloids, and squids), the class Gastropoda (*see* **Fossil Invertebrates:** Gastropods) (snails), and various smaller classes with few included orders and families. Family names and above are not normally italicized in print. Families, genera, and species are subject to the Law of Priority, but orders and the higher taxa are not. This means that if a genus is named but is subsequently recognized as being within the same generic concept as another genus named earlier (but after 1758), then the later-named genus is placed within the synonymy of the earlier-named one.

Organisms are also classified, but less formally, according to their mode of life. They are obviously divided into marine (living in the sea), freshwater, and non-marine. Those that drift in the water without substantial self-propulsion are termed plankton, those that swim are termed nekton, and those that are restricted to the ocean floor are termed benthos. Benthic animals may be anchored to the seafloor (like most corals), move around on it (like most gastropods and trilobites), or burrow within the sediment (like most bivalves).

Trace Fossils

As stated in the introduction, the term 'fossil' includes not only the remains of an organism but also its traces preserved in the rock. These traces fall into two main groups. The first is when, for example, the shell of a bivalve is preserved in a sediment that is subsequently changed through diagenesis into a lithified rock, after which the shell vanishes, usually through the action of circulating fluids, leaving only the mould of the original creature's hard parts (in that case the shell) in the rock. That mould will, in favourable circumstances, faithfully reproduce the image of the shell (Figure 1). The second group of trace fossils are the burrows, tracks, feeding scrapes, and other biological traces preserved in soft sediment that has eventually hardened into rock. These are often found even though all the remains of the organism that caused the traces have entirely disappeared.

Human Understanding of Fossils

Fossils have been noticed by humans from time immemorial. Their use as grave goods dates back at least to the Neolithic, and superstitions abounded; for example, the incurved fossils of the bivalve *Gryphaea* were identified as toenails of the Devil, and the Chinese thought that dinosaur bones were the remains of dragons. The naturalist Gilbert White described the ammonites from the Cretaceous chalk of Selbourne in

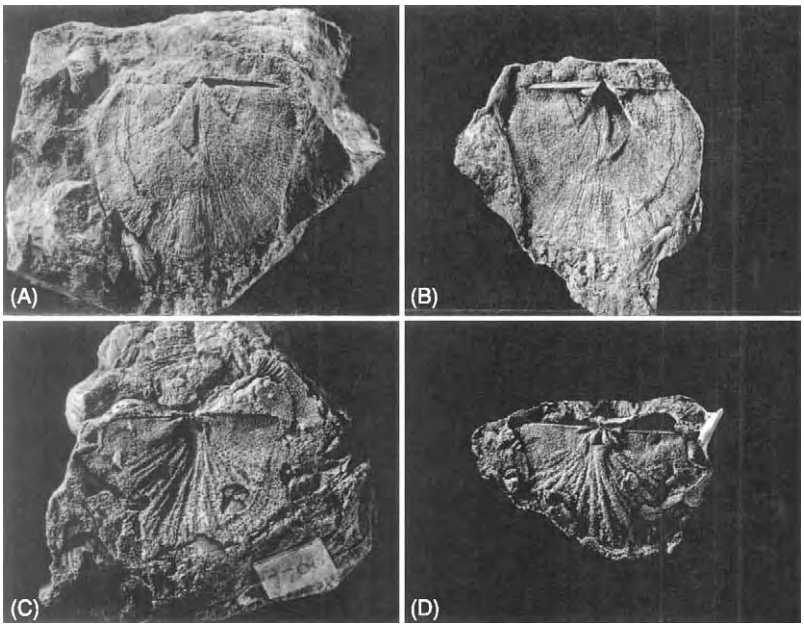

Figure 1 The (A,B) ventral (×1.5) and (C,D) dorsal (×2.0) valves of the Late Silurian brachiopod *Castelloarina fascifer* from Argentina. The views in (A) and (C) are natural internal moulds, as found in the geological outcrop, with the original carbonate shell entirely dissolved by the action of circulating groundwater. The views in (B) and (D) are artificial latex casts of the moulds, faithfully reproducing the topology of the original shell.

Hampshire, England, and retold the legend of St Keyna, of Keynsham near Bristol, who lived alone in a wood full of snakes, which she turned into stone (ammonites) by the power of prayer. It was usually thought that fossils represented dead specimens of living species of animals and plants, but it was not until the eighteenth century that it was realized that in many cases those animals and plants were now extinct. It was William Smith (*see* **Famous Geologists:** Smith) who realized that rocks could be dated in a relative way because different suites of fossils were found in rocks of successive ages. In the past 200 years all Phanerozoic (Cambrian to Holocene) rocks have been dated using fossils, and it is only since about 1960 that relatively reliable radioisotopic ages have been assigned to those zones. Even today, isotopic dates are not precise to within a million or so years over most of the Phanerozoic, whilst by interpolation many fossil zones are understood to have lasted for as little as 100 000 years. Thus, fossils have been extensively used to correlate rocks over considerable distances, and this knowledge has been of vast economic benefit in the exploration and discovery of coal and hydrocarbons, as well as being used to understand past Earth geographies.

Fossils in this Encyclopaedia

Animals are divided into those without backbones (invertebrates) and those with backbones (vertebrates). The chief Encyclopedia entries on fossils are arranged under the major headings of "Fossil Invertebrates", "Fossil Vertebrates", "Fossil Plants" and "Microfossils". Invertebrates are the most varied and commonest fossils. They are arranged here in order of increasing biological complexity. For about 50 years, each genus of fossil invertebrate has been illustrated and described in the 40 or so volumes of *The Treatise on Invertebrate Paleontology* (published jointly by the Geological Society of America and Kansas University Press between 1953 and 2004, and which is continuing), which is to be found in most geological libraries and in which much more detail on each group may be found; however, publication intervals between successive editions of the various parts of the *Treatise* are usually substantial. Despite the fact that fossils with original hard parts only occur in Cambrian and later rocks, a very substantial amount is now known about Precambrian fossils. In this Encyclopedia those are treated under **Origin of Life, Biosediments and Biofilms**, and also in the four articles within the Precambrian section, namely **Precambrian:** Eukaryote Fossils; Prokaryote Fossils; Vendian and Ediacaran.

There are also, at appropriate and separate places, articles on more general palaeontological and biological topics, namely **Biodiversity, Biological Radiations and Speciation, Creationism, Evolution, Fake Fossils, Lagerstätten, Palaeoecology, Palaeopathology, Pseudofossils** and **Trace Fossils**. In addition, the treatment of fossil specimens is considered in **Conservation of Geological Specimens** and **Micropalaeontological Techniques**. Of course the names of many fossil biozones are given in every one of the main stratigraphical articles on systems, which are grouped into Palaeozoic, Mesozoic, and Tertiary to Present, and also in other articles, particularly those on regional geology.

PALAEOPATHOLOGY

S G Lucas, New Mexico Museum of Natural History, Albuquerque, NM, USA

Introduction

In 1913, the British scientist, Sir Armand Ruffer, originally defined palaeopathology as "the science of diseases which can be demonstrated in human and animal remains of ancient times". Palaeopathology thus encompasses two distinct areas, one palaeoanthropological, in which ancient human remains are examined, and the other more strictly palaeontological, in which non-human animal fossils are examined. Furthermore, not only disease, but also evidence of injuries, is normally studied by palaeopathologists. Moreover, pathological conditions are not only known in fossil animal remains, but have also been reported in fossil plants. Here, discussion focuses on the strictly palaeontological aspects of palaeopathology. Palaeopathology is also used here as a noun to refer to any evidence of disease or injury in a fossil.

Assumptions and Methods

Palaeopathology relies on a straightforward uniformitarian assumption, namely that the manifestations of diseases have been relatively stable through time. Thus, for example, a disease that produces a particular skeletal abnormality at present would have done just the same millions of years ago. If this is the case, then it will be possible to diagnose medically (determine the underlying cause of) a palaeopathology.

Also critical to palaeopathology is the need to distinguish an abnormal structure in a fossil, caused by disease or injury, from the effects of post-mortem damage, the processes of rock formation and fossilization, and of erosion and weathering. Abnormal structures in fossils are sometimes caused by these effects, and have been mistakenly identified as manifestations of pathology.

Once a pathological condition is identified in a fossil, diagnosis is strictly by analogy. The palaeopathology is compared with similar pathologies in extant plants and animals, and a match in pathologies suggests identical underlying causes in the living organism (for which we know the cause) and the fossil (for which we infer the cause). Bacteria and viruses that cause disease are almost never preserved in fossils, and so the 'diagnosis by analogy' method is the principal way to determine the underlying causes of palaeopathologies.

Palaeopathologies in Fossil Plants

Pathologies caused by diseases have been identified in fossil leaves and wood. These include evidence of bacterial and fungal infections of ancient plants (*see* **Fossil Plants:** Fungi and Lichens). Most important, however, in the study of fossil plant pathologies is the fossil record of predation and infestation of plants by insects.

This record of predation and infestation is seen in damage of the fossil plant, and specific types of damage include:

- leaf mining – the extraction of living leaf tissue by larvae or mites;
- galling – when an insect or mite inserts an egg into or burrows into plant tissue, so that an abnormal, three-dimensional expansion of the plant tissue (a gall) is formed;
- wood boring – when insects burrow into wood;
- piercing and sucking – when insects penetrate plant tissue to remove fluid;
- sporivory, pollinivory, and nectarivory – consumption by insects of spores, pollen, and nectar, respectively.

The most significant aspect of these palaeopathologies is that they provide direct evidence of plant–insect interaction in the fossil record. This enables palaeontologists to determine the history and intensity of insect herbivory in the fossil record, and allows inferences to be made about the evolution of plant defences against such herbivory.

Palaeopathologies in Fossil Invertebrates

Evidence of deformities and other abnormalities in fossil shells is attributed to disease or genetic defects. Evidence of parasitism on the shells of stationary Palaeozoic animals, such as crinoids (sea lilies), is also well documented. Amongst the fossil invertebrates, there has been extensive study of healed injuries due to predation, especially in fossil clams (bivalves) and snails (gastropods). This evidence of predation (Figure 1) is particularly significant as it allows palaeontologists to understand the history and evolution of attack and defence behaviours in fossil invertebrates.

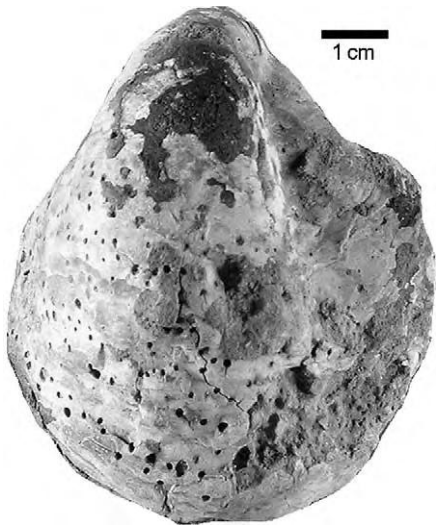

Figure 1 Shell of a 100 million year old clam (*Texigryphaea*) from eastern New Mexico covered with tiny holes, which are the drill marks left by snails (gastropods) that attempted to prey on the clam.

Palaeopathologies in Fossil Vertebrates

The majority of palaeopathologies (and the vast majority of the literature on them) are found in the teeth and bones of extinct vertebrates, especially reptiles and mammals. The most commonly identified palaeopathologies are: (1) so-called arthritic conditions, although many are not demonstrably arthritis; (2) mechanical injuries (Figure 2) and related infections, and the healing of these injuries if the animal survived them; (3) wounds due to predation or combat between animals; (4) dental anomalies, including caries (tooth decay); and (5) bone lesions caused by infections and/or parasites.

A list of the most common skeletal pathologies of fossil vertebrates includes:

- arthritis – joint diseases that can be caused by infections or mechanical injuries;
- dental anomalies – rotated, misplaced, malformed, or extra teeth (Figure 3);
- dental caries – cavities (decay) in the teeth;
- exostosis – swellings on bone surfaces;
- fracture – broken bones which, when naturally healed, leave a bone callus (a patch of healed bone) (Figure 2);
- hypertrophy – increase in size of the bone or portions of the bone;
- necrosis – pitting and disintegration of dead bone;
- osteomyelitis – bone infections;
- osteoma – bone tumours;
- osteoporosis – loss of bone density;

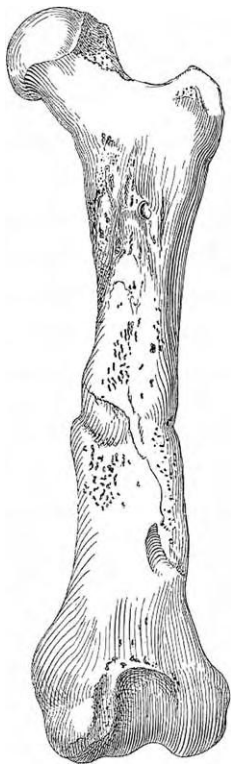

Figure 2 Anterior view of the left femur (thigh bone) of a Pleistocene cave bear from Europe, showing a healed fracture of the bone shaft. The pits above and below the fracture may also indicate necrosis. From Moodie RL (1930), Fig. 5.

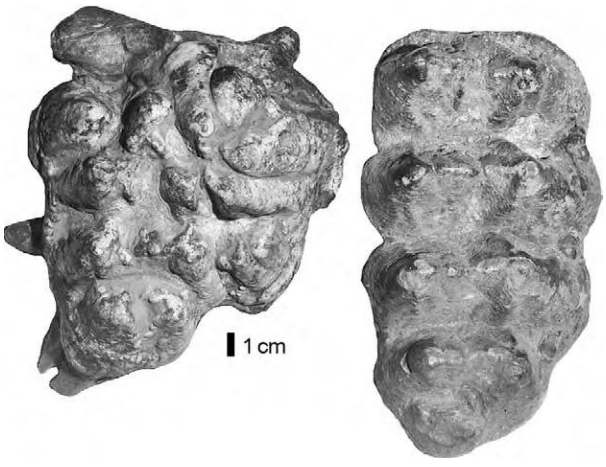

Figure 3 Left: crown view of a pathological molar of an American mastodon (*Mammut americanum*) from the Pleistocene of Oklahoma. Right: normal mastodon molar for comparison. On the pathological molar, there is a normal shaped molar (left side) covered by a second (right side), highly deformed molar. This secondary (or supernumerary) tooth probably resulted from the fusion of two tooth buds where, normally, only one tooth bud would have been present.

- synostosis – co-ossification (fusion) of normally separate bones.

Dinosaur Palaeopathology

The study of palaeopathology in fossil vertebrates is very active, with many new cases documented in the technical literature each year. This is especially true of dinosaur palaeopathology, which, during the last two decades, has become the largest field of palaeopathological research on non-human fossils. Prior to this interest, reports of palaeopathologies in dinosaurs go back to the 1800s, but they were mostly of isolated curiosities that often led to unfounded speculation. A good example of this is the unsupported suggestion that the frills (head shields) of horned dinosaurs (ceratopsians) grew so large because the dinosaur had too much growth hormone.

More recent studies of dinosaur palaeopathology have examined large samples (populations) using stringent standards for disease recognition. They have been accompanied by attempts to identify blood cells, DNA, and disease pathogens in dinosaur bone. These studies have identified a variety of common palaeopathologies in dinosaur skeletons. Most obvious are broken and healed bones (Figure 4), fused bones, and certain types of bone tumour. These palaeopathologies are well known in horned dinosaurs (ceratopsians), duck-billed dinosaurs (hadrosaurs), and tyrannosaurs. Indeed, the famous skeleton of *Tyrannosaurus rex* nicknamed 'Sue', has many healed injuries in its bones. The new studies of dinosaur palaeopathology demonstrate that dinosaur skeletons show much evidence of injury and trauma, but little evidence of disease.

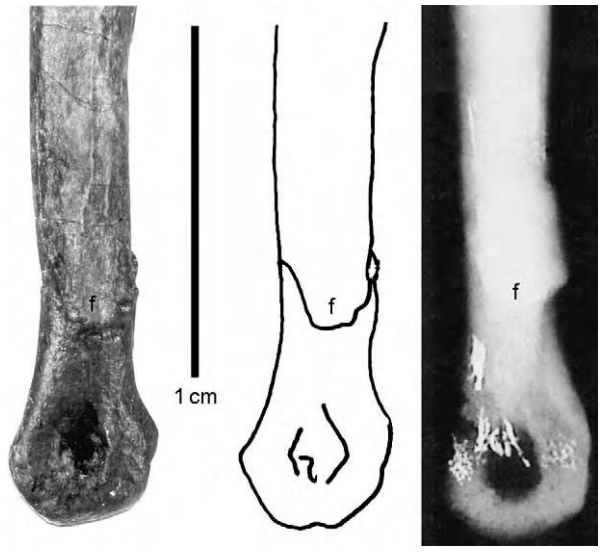

Figure 4 Toe bone (metatarsal) of a small, meat eating dinosaur from the Upper Cretaceous of New Mexico (about 73 million years old) with a healed fracture (f) visible in the photograph (left) and the X ray (right). Courtesy of R. M. Sullivan.

Application of Palaeopathology

As the above paragraphs make clear, the study of palaeopathology provides important information about more than just the history of disease. It also provides direct evidence of interaction between plants and animals, and between animals, mostly between predators and prey. It is thus important to the understanding of the evolution of behaviour. Palaeopathology can also contribute to an understanding of palaeoecology. For example, leaf mining by insects is extremely intense in today's tropics, and the intensity of fossil leaf mining has been used to infer the presence of ancient tropical conditions. Palaeopathology is thus an important subject in its own right, and a valuable tool for inferring ancient behaviour and ecology from the fossil record.

Although observations of palaeopathologies have been made for nearly two centuries, it is fair to say that the study of palaeopathology remains a relatively understudied field. Disease-causing agents generally do not fossilize, and so their history, which would be gleaned directly from the fossils of bacteria and viruses, is still very poorly understood. New technologies promise the ability, at least in some cases, to identify fossil bacteria and viruses associated with palaeopathologies.

Most diseases do not affect the fossilizable parts of an animal (its skeleton), and so much about ancient disease may never be extracted from the fossil record. Most published records of palaeopathologies are of isolated occurrences, often questionably diagnosed. Surveys that provide an idea of the frequency of palaeopathologies are almost unknown. Moreover, sweeping claims about the role of disease in the past – such as the idea that disease caused dinosaur extinction – lack supporting evidence. What is needed, and what is being pursued today, are more extensive efforts to identify palaeopathologies in all kinds of fossils, coupled with more rigorous attempts at diagnosis.

Cambrian

N C Hughes, University of California, Riverside, CA, USA
N A Heim, University of Georgia, Athens, GA, USA

Introduction

The Cambrian period, the oldest division of the Phanerozoic time-scale, encompasses several important global-scale environmental and evolutionary transitions. Recent advances in the understanding of Cambrian environments, faunas, and chronostratigraphy have all provided an enriched view of this critical interval in the history of the Earth – the time during which life's direct impact upon the rock record first became explicit. The term 'Cambrian' was first applied by Sedgwick (*see* **Famous Geologists:** Sedgwick) in 1835 to a series of sedimentary rocks well exposed in north Wales. The Cambrian system, as defined today, equates to only a portion of what Sedgwick originally considered to be 'Lower Cambrian'. Cambrian deposits are distributed widely, and a basic stratigraphical and palaeogeographical framework has been established for almost all regions. Nevertheless, a great deal of additional research will be necessary to secure our understanding of the geological framework in which the events of the Cambrian were structured. This article presents an overview of the defining temporal, geographical, and environmental attributes of the Cambrian, and then considers these in relation to the most striking aspect of the Cambrian system – the diversification of abundant metazoan life.

Chronostratigraphical Framework

The ratification of formal boundaries for the Cambrian system and improvements in the precision of isotope geochronology have recently resulted in substantial adjustments to views concerning the absolute age and duration of the Cambrian period. These results have fundamentally changed perspectives on the historical events encompassed within the Cambrian.

The Bounds of the Cambrian System

Formal definitions for both the base and the top of the Cambrian system have been ratified within Global Standard Stratotype Sections and Points (GSSPs) in recent years, both with type sections in Newfoundland, Canada. The base of the Cambrian system is currently placed at the occurrence of the trace fossil, *Treptichnus pedum*, 2.4 m above the base of Member 2 of the Chapel Island Formation at Fortune Head, Newfoundland. The base of the subsequent geological system, the Ordovician system, is placed at the first occurrence of the conodont, *Iapetognathus fluctivagus*, at a level of 101.8 m, within Bed 23, in the measured section of the Lower Broom Point Member, Green Point Formation at Green Point, western Newfoundland.

Stratotype points are located at the occurrence of diagnostic markers within particular stratotype sections, and both the top and the base of the Cambrian system rely on the occurrence of fossils. Such boundaries commonly relate to the stratigraphically lowest occurrence of the diagnostic marker fossil in the stratotype section. In the case of the base of the Cambrian, this is not so, because unequivocal specimens of *Treptichnus pedum* have recently been described some 4 m below the GSSP at the stratotype section. The occurrence of other *Treptichnus* specimens still lower in this faulted section could compromise the utility of this section as a stratotype. Nevertheless, the diversification of trace fossils during the Precambrian–Cambrian boundary interval was a significant evolutionary event, and offers the possibility of global correlations based on the impressions of homologous morphological characteristics.

The absolute ages of both the base and the top of the Cambrian system rely on recent U–Pb zircon dating of volcanic deposits intercalated within sedimentary successions. Suitable volcanic deposits are not known from the critical intervals of either of the stratotype sections. Hence, all absolute age estimates of the boundaries of the Cambrian rely on radioisotopic dates obtained from other sections that have been correlated with the stratotypes using alternative criteria, such as fossils or geochemical signatures. The base of the Cambrian system is commonly considered to be at about 542 Ma. This view is based on a minimum date for the first appearance of *Treptichnus pedum* of 539.4 ± 1.0 Ma in the Swartkloofberg section of Namibia, and a maximum age of 543.3 ± 1.0 Ma based on the occurrence of an assemblage of Ediacaran fossils in the same section. An age of 542 Ma also corresponds with a sharp negative excursion in carbon isotope ratios found in several parts of the world. Nevertheless, Ediacaran fossils have recently been recovered from rocks bearing *Treptichnus pedum* in South Australia, and the exact correlation of the Namibia section with the Newfoundland stratotype awaits resolution. The maximum age of the Cambrian–Ordovician boundary has recently been estimated from latest Cambrian volcaniclastic sandstone beds in north Wales to be 489 ± 0.6 Ma. The minimum age is 483 ± 1.0 Ma based on a Tremadocian ash from Nova Scotia.

Stratigraphical Subdivision of the Cambrian System

Formal stratigraphical stages have been established for Cambrian sequences around much of the globe. These sequences are correlated using cosmopolitan fossils, isotopic signatures, and correlative stratigraphical surfaces. Certain key horizons, characterized by distinctive and widespread markers, can be correlated with some accuracy around the globe. Other portions of the Cambrian are less securely correlated due to such factors as faunal endemism (partly real, partly the result of provincial biases in taxonomic descriptions) or questionable alignments of isotopic profiles. All global correlation schemes for Cambrian stratigraphical sequences (e.g., **Figures 1** and **2**) should be viewed as provisional.

The Cambrian period is commonly divided into three portions (**Figure 3**), although the global utility and bounds of these divisions have yet to be formalized. The perception of the nature of the Cambrian period has changed dramatically recently. The decision to place the base of the system near the first occurrence of *Treptichnus pedum* has meant that the first appearance of trilobites (and some other skeletonized macrofossils) occurs after about one-third of Cambrian time had passed. Furthermore, the discovery that the oldest trilobites date from around 520 Ma has dramatically reduced the apparent duration of the trilobite-bearing Cambrian to an interval of approximately 35 million years in duration. This suggests that the biostratigraphical zones of trilobite-bearing portions of the Cambrian are of a time resolution comparable to those of Mesozoic ammonites, on average as short as 1 million years.

Cambrian Palaeogeography

Palaeogeographical reconstructions for the Cambrian, constructed by different earth scientists, generally agree in terms of the overall distribution of the major landmasses, although doubts are commonly expressed about the quality of the palaeomagnetic database used to underpin such reconstructions. The assembly of the core Gondwana components is

generally considered to have been completed prior to the onset of the Cambrian. The positions and movements of many of the 'outboard' terranes that jostled about the margins of Gondwana, however, remain poorly constrained. This is particularly true of the equatorial sector of Gondwana, where faunal provinciality – commonly useful for regional demarcation – was low. Overall, Cambrian palaeogeography was characterized by open water in the northern polar region, and dominated by the major landmass, Gondwana, that stretched from the lowest latitudes in the south, across the equator, and well into the northern hemisphere. Other major landmasses, such as Laurentia, Siberia, and Baltica, were equatorial or lay within the southern hemisphere (Figure 4).

With the exception of the movements of minor terranes, global palaeogeography remained broadly consistent throughout the Cambrian period, with most of the changes apparently related to the rotation and dispersion of Laurentia, Siberia, and perhaps Baltica relative to a stable Gondwana. These movements, coupled with the patterns of sedimentation, are consistent with the breakup of a late Precambrian supercontinent that has been named Pannotia. Details of late Neoproterozoic palaeogeography remain hotly debated and these debates have important implications for interpreting secular changes during Cambrian time.

Cambrian Environments and Climates

The deposits of most major palaeocontinents record a substantial transgression during much of the Cambrian. Such a pattern is clearly displayed in Laurentia, where deposits encroached progressively further into the interior of the continent. Cambrian sedimentation patterns are consistent with relatively high rates of thermal subsidence, perhaps related to the fragmentation of Pannotia. In equatorial settings, particularly within Gondwana, latest Neoproterozoic carbonate platforms were drowned by relatively rapid flooding events that were followed by the deposition of phosphorites and black shales. The shoreward spread of oxygen-depleted and nutrient-enriched waters onto the shelf was associated with the replacement of fossils by secondary phosphates and within cherts. Substantial evaporite deposits developed within interior basins. In the absence of evidence of persistent glaciation, the Cambrian transgression is inferred to have been related to high rates of seafloor spreading.

The analysis of secular changes in the stable isotopes of strontium and carbon provides supplementary tools for correlation amongst sections, together with insights into the evolution of Cambrian environmental conditions (Figure 5). The striking rise in Cambrian stable isotopic ratios is thought to reflect enriched ^{87}Sr values due to the uplift and erosion of cratonic material. This rise in $^{87}Sr/^{86}Sr$ ratios is comparable with that seen in the Neogene, associated with the uplift of the Himalaya. Events associated with the latest stages of the prolonged 'Pan-African' orogeny (*see* **Africa:** Pan-African Orogeny) and the final consolidation of Gondwana may have been responsible, but the sequence and timing of these events remain incompletely resolved.

Investigations of Cambrian seawater chemistry, both directly from fluid inclusions and indirectly from inorganic and organic precipitates, suggest that Cambrian seawaters were generally characterized by relatively low Mg/Ca ratios. This is consistent with the deposition of calcitic, as opposed to aragonitic, biomineralized metazoan skeletons. The late Proterozoic to Cambrian interval witnessed the transition from an 'aragonite sea' to a 'calcite sea', corresponding to a transition from 'icehouse' to 'greenhouse' climatic conditions, and a change from $MgSO_4$ to KCl late-stage salts in evaporites. When viewed in the context of trends seen throughout the Phanerozoic, such transitions correspond with long-term changes in plate tectonic regime. The rapid seafloor spreading associated with the breakup of Pannotia probably drove changes in mid-ocean ridge brine fluxes, caused a global sea-level rise, and increased global volcanism.

Marked fluctuations in Cambrian carbon isotopic ratios over short time-scales have been noted in association with the base of the Cambrian and the Early–Middle Cambrian boundary. In these cases, the excursions were towards lighter carbon isotopes. A more prolonged, positive excursion towards the heavier isotope, ^{13}C, has been defined within the Late Cambrian Steptoean stage within Laurentia, Kazakhstan, and portions of core and outboard Gondwana. The determinants of such fluctuations are complex because carbon isotopic ratios are influenced by multiple factors. Explanations commonly invoked include alternations between periods of well-oxygenated, warmer waters on continental shelves and periods in which the shelves were flooded by cooler, oxygen-poor waters. These explanations receive additional support from marked periodic fluctuations in macrofaunal diversity that roughly parallel the excursions, at least in some cases. Cambrian oceans were similar to oceans throughout the Phanerozoic in that oxygen penetrated the sediment–water interface even within deep ocean basins. Recent models of atmospheric oxygen levels throughout the Phanerozoic suggest that O_2 constituted between 10% and 20% of the composition of the atmosphere. Although these estimates are subject to considerable uncertainty, they suggest that Cambrian

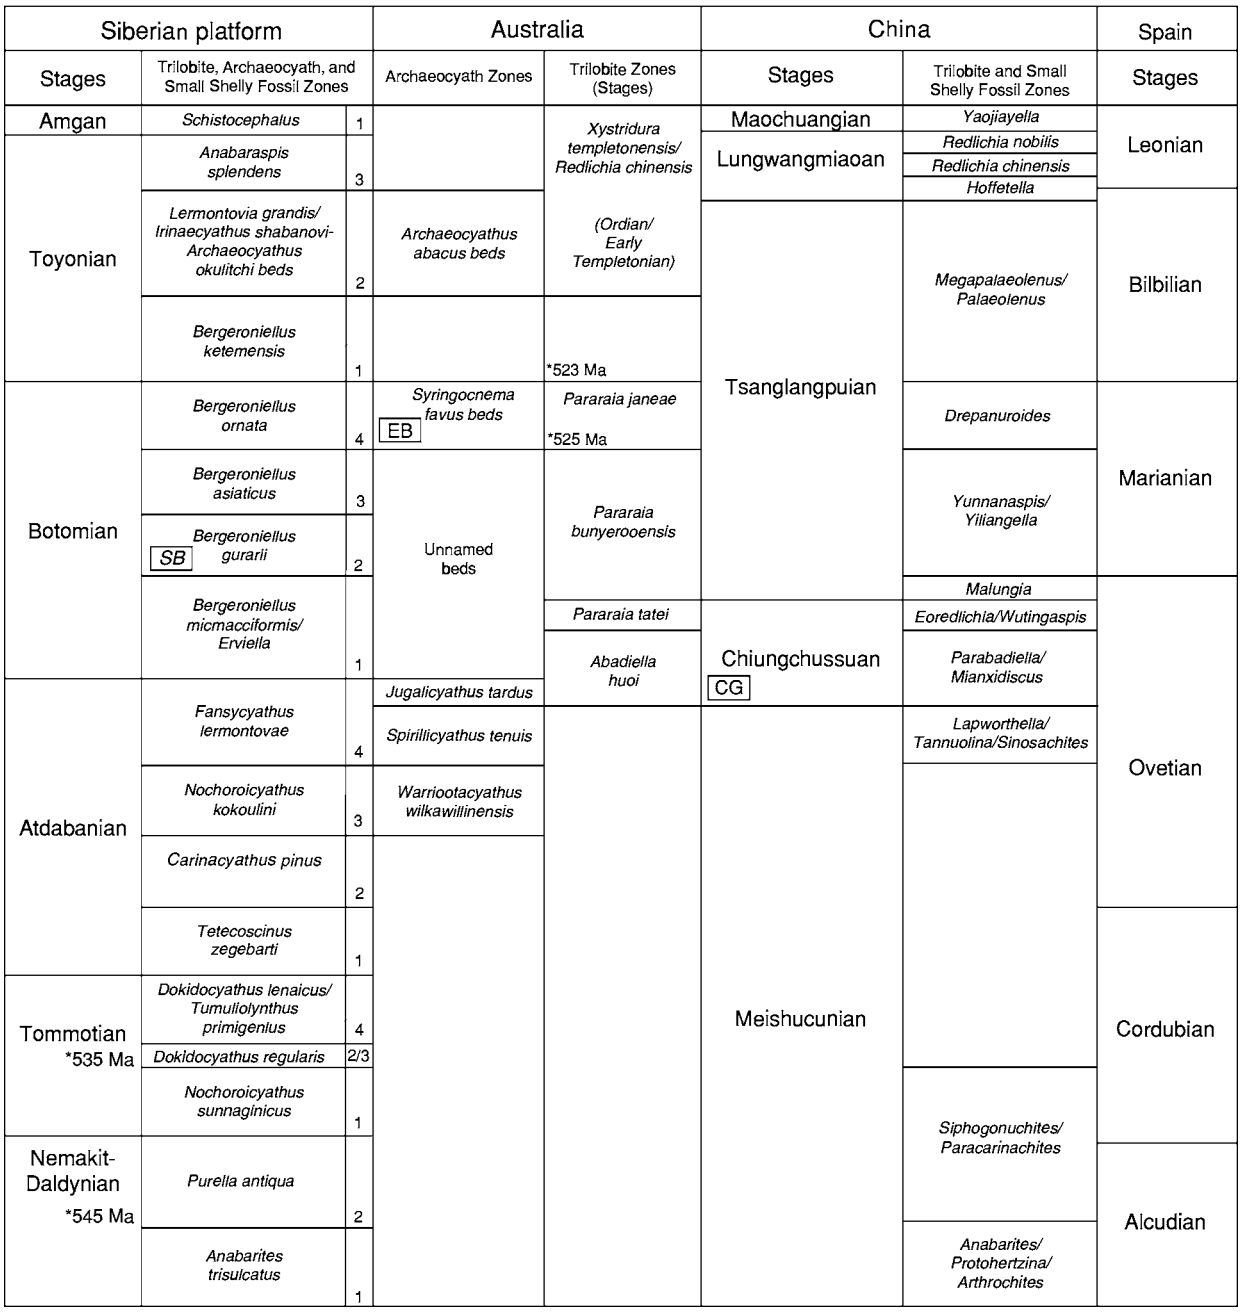

Figure 1 Correlation chart for the major regions of Lower Cambrian rocks. oxygen profiles and levels in both ocean and atmosphere were essentially modern in aspect.

As noted above, the Cambrian marked a transition interval between 'icehouse' and 'greenhouse' climatic conditions. The details of this transition are poorly resolved, however. Direct evidence of warm conditions in the later Cambrian, derived from oxygen stable isotope ratios, is questioned by some authorities. Yet, the presence of widespread evaporites suggests warm conditions, at least in the equatorial Gondwana region. Broad, but indirect, climatic indicators, such as the distributions of evaporites, ironstones, and carbonates, are consistent with climatic gradients similar to those that characterized much of the Palaeozoic. Recent suggestions of Early Cambrian glacial deposits in West Africa are yet to be accepted generally, but it is likely that the overall climatic conditions warmed through the Cambrian.

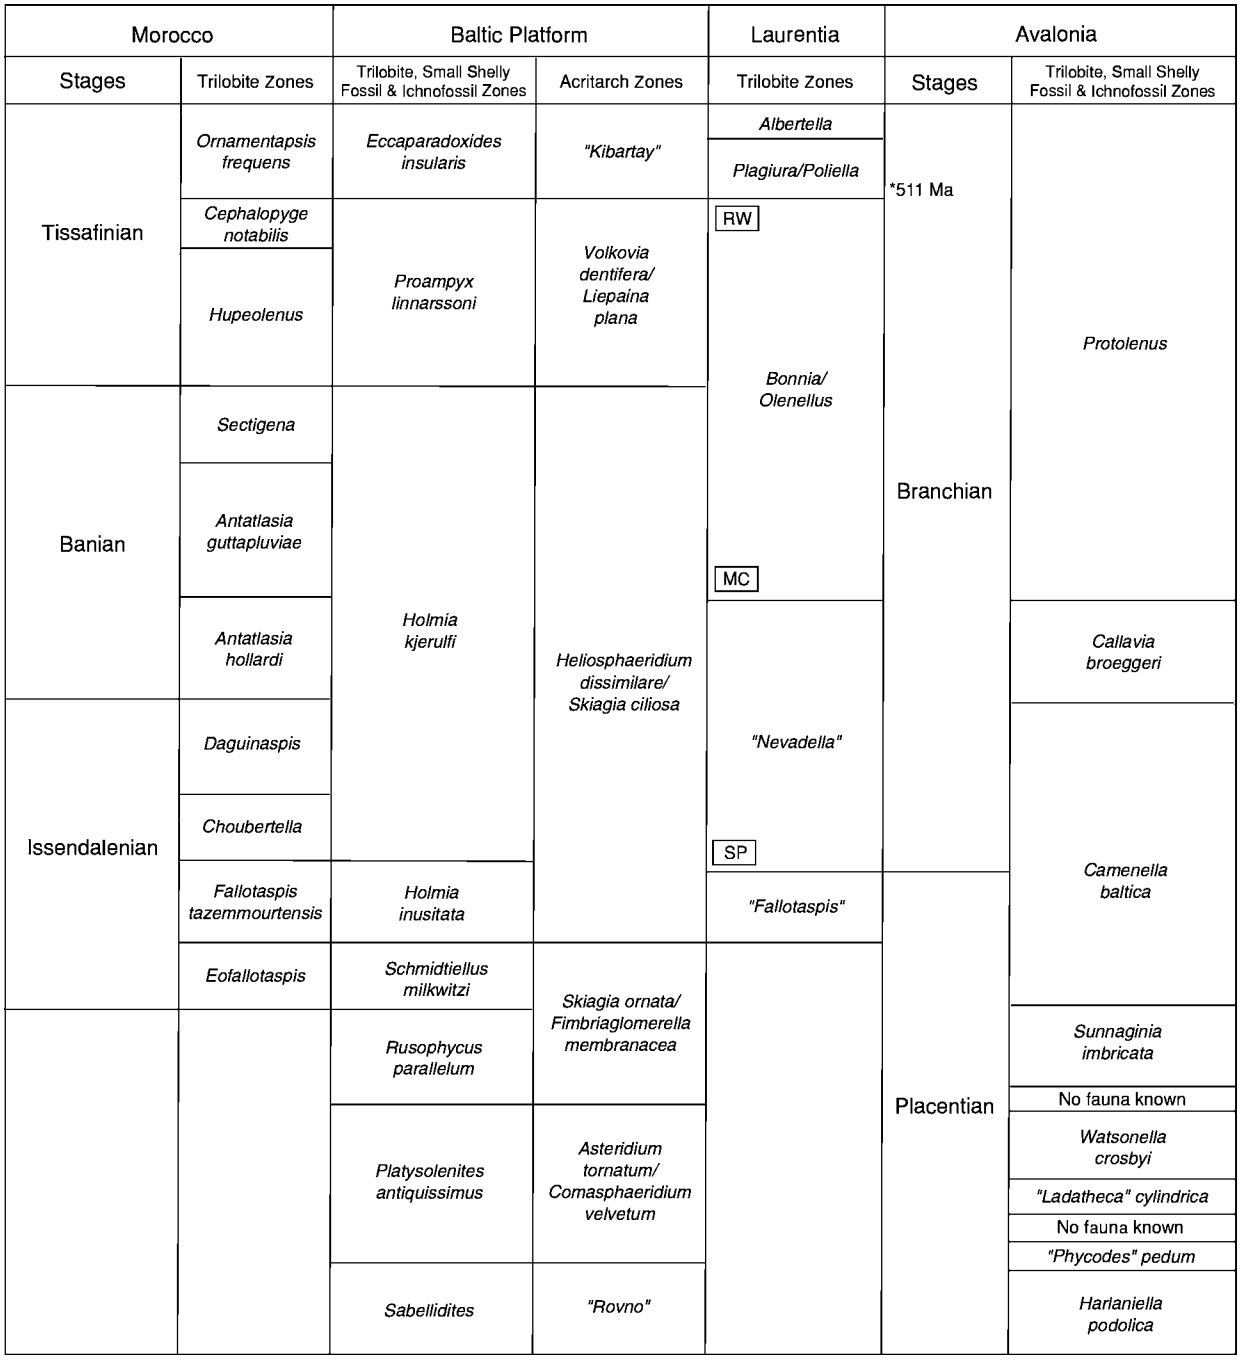

Figure 1 Continued

Information on Cambrian terrestrial conditions is sparse, and the transition between marine and terrestrial sedimentary rocks is difficult to determine in many Cambrian sequences, partly because fine-grained sedimentary particles were easily winnowed in the absence of binding by macroflora. Definitive non-marine sedimentary structures are relatively rare within Cambrian sandstones. Nevertheless, the common tacit assumption of an abiotic terrestrial realm during the Cambrian is probably unrealistic. A diverse microbiota may have existed in some settings. Furthermore, there is abundant trace fossil and sparse body fossil evidence of both diploblastic and triploblastic metazoans active in marginal marine environments, together with spores that are apparently non-marine in origin.

Due to the decreasing rotation speed of the Earth, the Cambrian year would have contained more days

than at present, and each day would have been shorter than 24 h. The Cambrian year was likely to have been about 420 days long. If the shorter distance between the Earth and its moon resulted in a stronger tidal action during the Cambrian, as might also be expected, Cambrian epeiric seas may have been dominated by tides. However, there is no observational support for increased tidal dominance in the Cambrian relative to comparable recent settings. Overall, Cambrian environmental conditions were apparently primarily controlled by the global tectonic setting. The dispersion of the continents, rates of thermal subsidence, and seafloor spreading strongly influenced both the accumulation of sedimentary rocks and their preservation potential. Cambrian environmental conditions were similar to those seen at other parts of the Phanerozoic and essentially modern in aspect. In marked contrast, several aspects of ocean chemistry and stratification during the Neoproterozoic apparently differed significantly from the Phanerozoic conditions. Hence, the Neoproterozoic–Cambrian interval remains a fascinating and important time of environmental transition, in addition to encompassing critical biotic transitions.

The Neoproterozoic–Cambrian Evolutionary Radiation

Cambrian Life

The morphological and taxic diversity of trace fossils expanded markedly in association with the basal Cambrian boundary. Surficial trails of simple morphology present in Late Neoproterozoic Ediacaran assemblages were joined by varied morphologies, suggesting motile, triploblastic organisms that mined the sediment infaunally and possessed complex anterior–posterior body patterning. The first traces that can be attributed to the scleritized appendages of arthropods also occurred at about 530 Ma, significantly before the appearance of arthropod body fossils, but after the base of the Cambrian system.

Biomineralized skeletons were present in the latest Neoproterozoic, but were uncommon there relative to their abundance in the Early Cambrian. The pre-trilobitic Cambrian contains a myriad of relatively small biomineralized fossils, collectively known as 'small shelly fossils'. These were commonly composed of calcium carbonate or calcium phosphate and displayed shapes that ranged from simple conical tubes to highly sculptured plates. The diversity of these forms increased through the lowermost Cambrian. Although the phylogenetic relationships of many small shelly fossils remain obscure, in some instances considerable progress has been made in assessing their affinities. Whilst some small shelly fossils represented protective skeletons surrounding the bodies of a variety of diploblastic organisms, others are known to be components of a sclerite meshwork containing hundreds or thousands of separate units that covered portions of the external surface of triploblastic organisms (Figure 6). The synchronous biomineralization of numerous separate metazoan and protist lineages, together with the appearance of Foraminifera that agglutinated inorganic minerals to their external surfaces, suggests that the possession of a reinforced external surface conferred a selective advantage in the Early Cambrian. This pattern, together with evidence from body fossil size and mouthpart anatomy of some Early Cambrian arthropods, suggests that Cambrian marine ecologies were structured with significant feedback between higher and lower food chain levels.

The appearance of trilobites marked the start of the traditional Cambrian fauna, as it has come to be known following Jack Sepkoski's static modelling of Phanerozoic marine diversity. This assemblage of fossils, based on the record of biomineralized fauna, was dominated by certain basal trilobite, linguliform brachiopod, echinoderm, and poriferan clades, and persisted into the lower Ordovician. Although the designations 'Cambrian fauna' and 'Palaeozoic fauna' aptly describe the marked contrast in the composition of biomineralized faunas, dynamic modelling of diversity does not suggest that these two faunas behaved as distinct ecological entities. Moreover, it is clear that basal representatives of many of the clades that rose to dominance in the Ordovician were also present in the Cambrian.

Cambrian benthic macrofossils were also characterized by a periodic series of major evolutionary radiations and extinctions. Several of these extinctions (e.g., those associated with the Early to Middle Cambrian transition) had a cosmopolitan effect,

Figure 6 The Early Cambrian triploblastic metazoan *Halkieria evangelista*. Note the external surface consisting of multiple skel etal elements. Each element individually constitutes a 'small shelly fossil', many of which were combined on a single individ ual. Photograph: John S. Peel.

during which important groups, such as the archaeocyathid sponges and olenelloid trilobites, were exterminated. Marked episodes of diversity expansion were typically followed by stratigraphically sharp extinctions. These striking cycles of diversity fluctuation occurred repeatedly during the Cambrian, and have been documented most clearly in the Late Cambrian 'biomeres' of Laurentia. Although the mechanisms responsible for the biomere pattern are still debated, it appears that large-scale eustatic changes of sea-level, probably coupled with fluctuations in seawater temperature and oxygen levels, were driving factors.

Cambrian Faunal Provinces

The distributions of Cambrian taxa can be used as tools for both biostratigraphical correlation and palaeogeographical reconstruction. Geologically short-lived, abundant, and cosmopolitan species (e.g., agnostoid trilobites) have great utility for global correlations. Other forms had more restricted distributions, with their geographical ranges limited by barriers (e.g., temperature tolerances, the inability to cross deep ocean basins; Figure 7). Distributions of fossils can be used as independent criteria to constrain palaeogeographical reconstructions based on other data. Laurentian shelf faunas were apparently the most distinctive, which is consistent with the notion that Laurentia was geographically isolated during Cambrian times. A wide-ranging shelf fauna also occurred about the peri-Gondwanan margin, although restriction of some elements to specific regions suggests some palaeolatitudinal limits on faunal distribution. In general, species adapted to cooler waters had more widespread occurrences than those restricted to equatorial shelf environments. Additionally, the occurrence of Cambrian faunas diagnostic of one province surrounded by rocks of another province has proved key to the recognition of Cambrian microcontinents.

The Neoproterozoic–Cambrian Biotic Transition

The traditional criterion for recognizing the base of the Cambrian is the first appearance of macrofossils in the stratigraphical record – the change from 'hidden' to 'obvious' life. Although it is certain that Cambrian global tectonics favoured the accumulation and preservation of fossils, and may even have fuelled evolutionary radiation, the extent to which Cambrian tectonic settings triggered the metazoan radiation is less clear. Clarification of this depends on a knowledge of the nature of biotic diversity and structure prior to the base of the Cambrian. If the clades that first appeared in the Cambrian had phylogenetic origins significantly prior to the base of the Cambrian and had also assumed their 'modern' ecological roles within Neoproterozoic ecosystems, the appearance of abundant fossils in the Cambrian may be related to conditions that favoured both biomineralization and the preservation of shelfal sediments. Alternatively, the Cambrian might chronicle the fundamental steps in metazoan phylogenetic and ecological diversification, in which case clues for the trigger might be sought within Cambrian deposits.

It is now apparent that the base of the Cambrian did not coincide with the phylogenetic appearance of most of the clades, both metazoan and protist, that became common in Cambrian rocks. Although metazoan divergence patterns and times based on molecular data are fuzzy, they are consistent in several major aspects, placing the origins of diploblastic organisms before the triploblasts at least tens of millions of years before the base of the Cambrian. Furthermore,

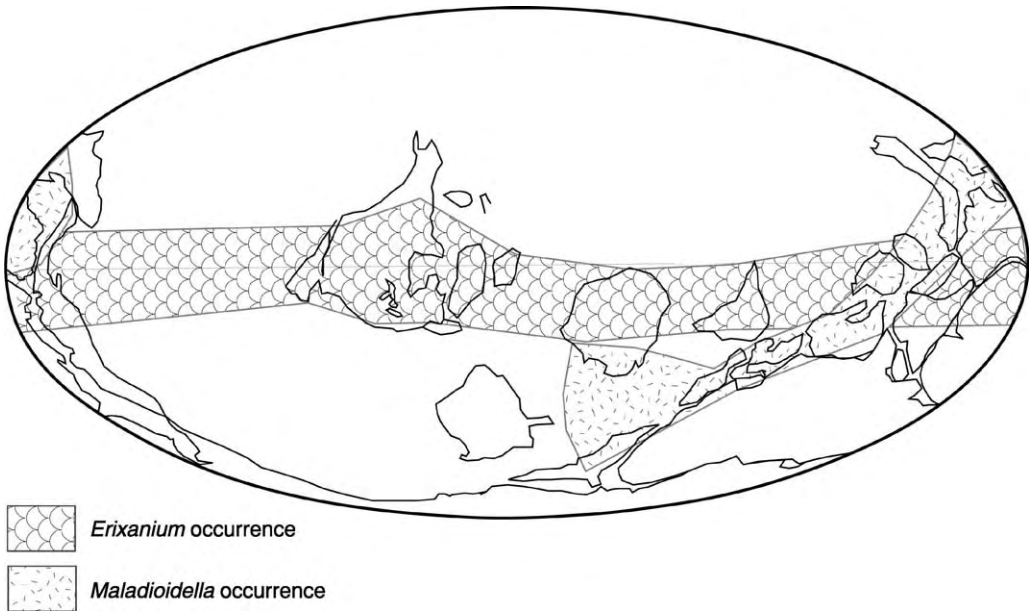

Figure 7 Contrasting biogeographical distributions of two widespread Late Cambrian trilobite genera. The *Erixanium* distribution was apparently constrained by factors related to latitude. In contrast, the *Maladioidella* distribution was apparently limited by open ocean basins. Modified with permission from Zhuravlev AY and Riding R (2000) *The Ecology of the Cambrian Radiation*. New York: Columbia University Press. © Columbia University Press, 2000.

direct fossil evidence of Neoproterozoic metazoans is provided by phosphatized embryos aged about 575 Ma from southern China, in addition to other various late Neoproterozoic fossils such as definitive sponges and possible cnidarians. Evidence for Neoproterozoic triploblasts is still being debated. The phylogenetic affinities of the famous Ediacaran fossil assemblages (*see* **Precambrian:** Vendian and Ediacaran), consisting of large bodies commonly constructed metamerically, also remain hotly contested. Even for some of the best known forms, such as *Dickinsonia*, recent interpretations range from it being a member of an extinct kingdom, a multicellular prokaryote, a lichen, a cnidarian, and a basal triploblastic metazoan capable of movement. Unequivocal Precambrian triploblasts pursuing ecologies closely comparable to their roles in the Phanerozoic have yet to be described, although the Ediacaran *Kimberella* – which may be a mollusc with an associated grazing trail – provides the most plausible candidate.

The presence of likely Late Precambrian metazoans that differed in gross morphology and ecology from their Cambrian counterparts suggests that the transition into 'obvious life' was not merely an artefact related to the advent of biomineralized skeletons with high preservation potential (although biomineralization clearly did appear synchronously and independently during Early Cambrian time in various metazoan and protist clades). Such a suspicion is confirmed by two other data sets that are arguably free of strong preservational biases across the Neoproterozoic–Cambrian boundary. The first of these is the record of trace fossils. Ediacaran fossils are commonly found preserved in sandstones with evidence of mat-like bedding surfaces bound by algae. Finer grained substrates, such as mudstones, were apparently quite firm throughout the Neoproterozoic to Cambrian transition interval. Such substrates would have provided a suitable medium for the preservation of surficial movement traces and shallow, infaunal burrowing. Examination of the trace fossil record shows that the diversity, complexity, depth, and extent of bioturbation increased progressively across the Neoproterozoic–Cambrian boundary, with trends begun in the Neoproterozoic continued into the Early Cambrian. These observations suggest that this interval witnessed important evolutionary innovations in metazoan size, morphology, and behaviour coincident with the establishment of benthic ecologies of essentially modern aspect. The second critical data set is the burst in morphological diversity of pelagic microflora at the onset of the Cambrian following marked conservatism during the late Neoproterozoic. New morphologies found in the Cambrian are consistent with the presence of active pelagic herbivores (mesozooplankton) of which there is direct evidence from Lower

Cambrian rocks. If mesozooplankton were essential to the establishment and maintenance of the Cambrian benthic communities, as they are in modern marine communities, it could be that innovations in the zooplankton drove diversification of the Cambrian macrobenthos.

It seems that the phylogenetic origins of the clades that first appeared in the Cambrian probably predated the base of the Cambrian by at least 50 Ma (and possibly far longer), as did most of the genetic regulatory architecture required to organize large, complex, body plans. This is indicated by the remarkable extent to which body patterning mechanisms are shared amongst disparate metazoan groups. For this reason, it seems unlikely that the Cambrian radiation was directly coupled to basic biological innovations that made metazoan diversity mechanistically possible. Nonetheless, the Cambrian radiation was more than a simple expansion of biotic diversity and ecological structure present in the terminal Neoproterozoic triggered by favourable tectonics. Cambrian ecologies, both pelagic and benthic, were different from those of the Neoproterozoic in ways that suggest enhanced trophic interactions and ecospace utilization. Biotic innovations coincident with the Neoproterozoic–Cambrian transition, both morphological and ecological, appear to have been critical to the adaptive radiation that clearly took place during Cambrian time.

Although there were marked differences between late Neoproterozoic and Cambrian biotas, this does not imply that the transition between the two was sharp, even on a geological time-scale. Both the sequence and apparent spacing of events are consistent with evolutionary processes and mechanisms operative today, although the rates of anatomical and behavioural innovations may have been elevated in some lineages relative to later times. This pattern, and the persistent compatibility of new data with the expectations of the evolutionary model, belies any basis for the idea that the Cambrian radiation requires alternative, non-evolutionary explanations. Furthermore, it can be argued that the types of evolutionary transformation that took place during the Precambrian–Cambrian boundary interval persisted into the Cambrian.

Many Early Cambrian body fossils arguably belong to stem group lineages of clades whose derived crown group representatives only appeared later in the Cambrian or thereafter. According to this view, many varieties of early arthropods present in Cambrian Lagerstätten (*see* **Lagerstätten**) (e.g., Chengjiang in Yunnan, China; the Burgess Shale in British Columbia, Canada) represent steps *en route* to derived euarthropods, and scenarios for the evolution of basic features of arthropod morphology, such as rigid, metameric sclerites, can be postulated on the basis of character state transformations seen amongst Cambrian fossils. Although the specifics of such scenarios are subject to debate, the fact that they can be reasonably postulated affirms that major aspects of arthropod evolution were probably accomplished subsequent to the appearance of the earliest arthropod body fossils. Furthermore, the opportunity to explore the connection between the ontogenetic and phylogenetic development of body patterning in early Palaeozoic arthropods (e.g., Figure 8) suggests that aspects of the basic control of body plan (e.g., the numbers and varieties of segments) evolved during the Early Palaeozoic. Although such opportunities may offer a fascinating glimpse of the evolution of developmental processes, they apparently concern relatively minor adjustment of developmental systems established prior to the base of the Cambrian.

Ordovician

R A Fortey, The Natural History Museum, London, UK

Introduction

The Ordovician System, which is radioisotopically dated to have lasted from 495 Ma to 443 Ma, follows the Cambrian in the geological time-scale and is overlain by the Silurian. The Ordovician comprises the middle part of the Lower Palaeozoic, and has been traditionally divided into six series, of which two (Llanvirn and Llandeilo) have been combined to give a five-fold subdivision. These series are currently in the process of revision, largely to bring them into line with the threefold division (Lower, Middle, and Upper) used in other geological systems. It is still, however, convenient to describe Ordovician rocks in terms of five classical subdivisions, which are in ascending order: Tremadocian (489–483 Ma), Arenigian (483–463 Ma), Llanvirnian (463–*ca*. 455 Ma), Caradocian (*ca*. 455–*ca*. 448 Ma), and Ashgillian (*ca*. 448–443 Ma). Of these, the Tremadocian was previously included in the topmost part of the Cambrian by some authorities, but has now been assigned to the Ordovician by international agreement. The top of the Ordovician is marked by a major ice age and an important mass extinction of marine organisms, which forms a natural boundary with the base of the Silurian. Ordovician rocks are found on every continent except the Indian Peninsula. During the Ordovician the continental masses were widely dispersed, other than the Gondwana supercontinent. Ordovician geology, therefore, varies richly from one area to another. The Ordovician saw the inception of several marine ecosystems that are still with us today.

Several important animal groups (e.g. corals and nautiloid cephalopods) also underwent evolutionary radiations during the Ordovician.

History

The Ordovician System was a comparative latecomer to the geological column. It was born out of a historical compromise between competing claims of what strata should be included in the underlying Cambrian and overlying Silurian systems. The seminal studies of this part of the stratigraphical succession were carried out in the British Isles. Cambrian rocks had been studied in Wales by the Woodwardian Professor at the University of Cambridge, the Reverend Adam Sedgwick (*see* **Famous Geologists:** Sedgwick) – a pioneering field geologist whose classes had been attended by the young Charles Darwin. Rocks comprising the Silurian System were described in considerable detail by Sir Roderick Murchison (*see* **Famous Geologists:** Murchison) in one of the classics of geology, *The Silurian System* (first published in 1839). Murchison was a gentleman of private means and a dominant personality, who had studied rock successions in Shropshire and across southern Wales, where inevitably he overlapped stratigraphically with Sedgwick's ground. Murchison's attempts to 'appropriate' some of Sedgwick's Cambrian rocks into the Silurian met with stern opposition from the Cambridge cleric, and a vigorous controversy ensued, which was still not resolved on the death of both protagonists. A compromise solution to the problem was devised by Charles Lapworth, a Professor in the Department of Geology at the new University of Birmingham. This compromise involved hiving off the disputed middle ground into a separate System, the Ordovician. The name was derived – like that of the Silurian – from the name of an ancient British tribe. Although Lapworth's proposal was made in 1879, it was a long time before it was universally accepted. Indeed, one can find Murchison's 'Silurian' still in use in Russia more than 50 years later. However, as with many of Lapworth's innovations, it came to be seen as a wise solution, and the Ordovician has since been accepted as one of the more natural divisions of geological time.

An outstanding confusion remained, however, about whether to include the rocks around the north Welsh town of Tremadoc in the Cambrian or in the Ordovician. Lapworth had originally stated that the base of the Ordovician should be drawn at the base of the Arenigian rocks, thereby assigning the underlying Tremadocian rocks to the Cambrian. To many observers at the close of the nineteenth century, the Tremadocian seemed to show 'intermediate' features between the two stratigraphical contenders. In Scandinavia, the Tremadocian was incorporated in the Ordovician. The situation was further complicated because in much of North America – where fossil faunas are very different from those in Europe – Tremadocian rocks were not recognized as such, and a different set of names (e.g. 'Ozarkian' and 'Canadian') were applied to rocks of Late Cambrian and Early Ordovician age. Only when correlation between these separate continents improved did it become practicable to apply a standard series of names to the subdivisions of Ordovician time. As late as 1972, the Tremadoc 'series' continued to be allocated to the Cambrian by British scientists, although by then a majority of other nations had settled on a horizon for the base of the Ordovician that approximated the base of the Tremadocian. Such problems lend themselves to arbitration by the International Union of Geological Sciences, and the Tremadocian was eventually deemed to be the basal Ordovician subdivision, by general consensus, in 1988. The horizon chosen to mark the base of the Ordovician also marks the appearance of planktonic graptolites of *Rhabdinopora* (formerly *Dictyonema*) *flabelliformis* type, and thus respects the spirit of Lapworth, who recognized the stratigraphical utility of these ubiquitous fossils well over a century earlier.

Type Areas and Sections

Since Ordovician rocks are so varied, it has not proved possible to define a single 'type area' for subdivision of the System, although the Anglo-Welsh area remains historically important. The base of the Ordovician System has recently been defined by international agreement within the Cow Head Group at Green Point, on the western coast of Newfoundland, Canada. Here, graptolite and conodont fossils occur together in a series of limestones and shales, permitting ready international correlation. In some areas (e.g. the western USA) conodonts are found in the absence of graptolites, whereas the situation is reversed in Spain and northern Africa. The index fossil is the first appearance of the conodont *Iapetognathus fluctivagus*. The base of the Silurian is, by definition, the top of the Ordovician System and has been similarly defined by international agreement in one of Lapworth's classical sections at Dob's Linn, near Moffat, in Scotland. This horizon lies at the base of the *Akidograptus acuminatus* biozone, which is characterized by the eponymous graptolite.

Attempts to define Lower, Middle, and Upper Ordovician Series are in progress. The base of the Middle Ordovician has been mooted, on the basis of conodonts, to lie at a horizon within the Arenig 'Series' of traditional usage. Correlation remains a problem,

however, and to date a type section has yet to be chosen. A standard time division close to the Middle Ordovician, the Darriwilian, has been recognized on the basis of graptolites. The base of the Upper Ordovician has been agreed to be the base of the widespread *Nemagraptus gracilis* biozone. This horizon coincides with the base of the Caradoc 'Series' as now defined. A type section in the Fågelsang section, Sweden, has been selected for its definition. Because this threefold series subdivision has not yet achieved wide currency, it is expedient to continue to use the fivefold subdivision in this chapter. Strictly speaking, these should no longer be referred to formally as 'Series', as they are effectively regional stages. The suffix '-ian' is therefore employed below. Because of the high degree of regional differences in Ordovician strata, several widely separated areas have become important in defining Ordovician temporal subdivisions on a regional to global scale. Biozonal standards have been based on graptolites, conodonts, and trilobites, but these are found together in only a minority of rock sections and they, too, show provinciality. Much effort has accordingly been expended in tying together graptolitic and conodont-based zonal schemes.

Tremadocian

The small town of Tremadoc lies in North Wales at the northern end of Cardigan Bay. A series of dark shales and mudstones of the Dol cyn Afon Formation – often cleaved and weakly metamorphosed – overlie rocks of the Upper Cambrian. There is often a stratigraphical break between the two, but in at least one section a complete and conformable transition between the two systems has been demonstrated. The Tremadocian is recognized by the incoming of net-like rhabdosomes of the widespread graptolite *Rhabdinopora flabelliformis* subspecies, the oldest planktonic graptoloid species. These rocks were deposited in comparatively open shelf environmental conditions, and the graptolites are accompanied by a variety of trilobites, of which members of the Family Olenidae are a prominent component, some species of which are also very widespread. The genus *Jujuyaspis*, for example, is known from North and South America, Scandinavia, and China in earliest Ordovician strata. In North America, the stage name Ibexian (approximately the same as 'Canadian' used by earlier authors) is employed for Early Ordovician strata, based on well-exposed sections in Utah in the Great Basin. The Ibexian embraces all of the Tremadocian and part of the Arenigian. Both the Tremadocian and Ibexian have been further subdivided into chronostratigraphical subdivisions of regional application. The graptolite and conodont succession is particularly well-known in the Baltoscandian area and indicates the presence there of an upper part of the Tremadocian (Hunnebergian) that is not well-developed in Britain.

Arenigian

Arenigian rocks overlie the Tremadocian rocks in North Wales, and were named after a mountain, Arennig Fawr, where they are well exposed. However, in North Wales there is an unconformity at the base of the Arenigian, which is marked by a transgressive sandstone, and so it is inadequate as a type area (Figure 1). The Arenigian succession is better developed in South Wales and Shropshire, where thick sequences of mudstones, shales, sandstones, and turbidites have yielded diverse trilobite faunas of shallow-to-deep shelf aspect with, more locally, graptolites and brachiopods. Because of the disparate biogeography of the Early Ordovician, most of the species are of relatively local occurrence, and correlation of these strata internationally can be difficult. For some years a *de facto* base of the Arenigian has been recognized at the base of the widespread graptolite *Tetragraptus* (*Etagraptus*) *approximatus* biozone, which can be identified in North and South America,

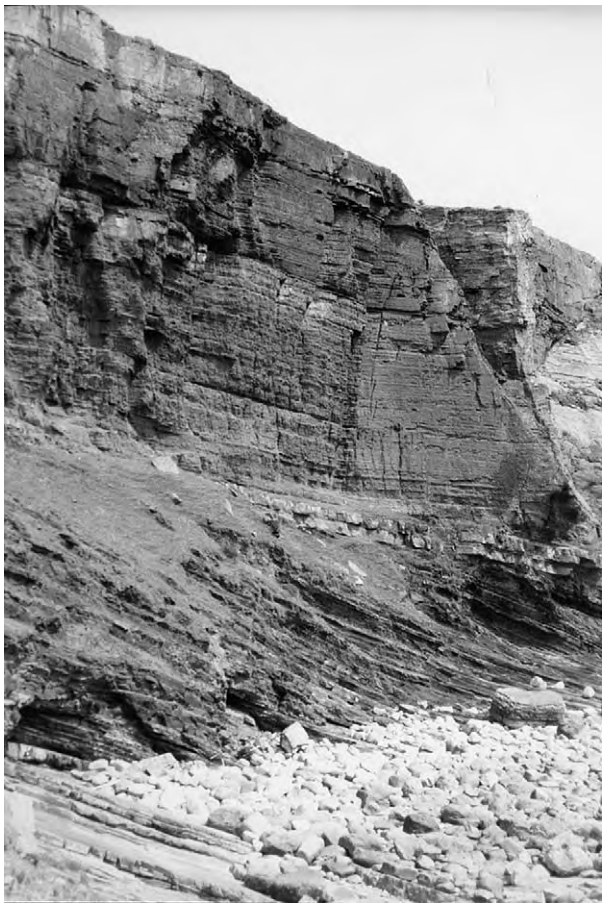

Figure 1 Ordovician (Arenigian) strata lying unconformably over Cambrian rocks on the Llyn Peninsula, North Wales.

Scandinavia, Australia, and New Zealand. The most varied succession of graptolite faunas is found in the shales of the region of Bendigo, Victoria, Australia; this has achieved the status of a global standard, and a fine-scale division into biozones (and stages) has been established, which has been widely applied elsewhere. In south-western China sequences span facies from inshore to deep-water, as do sequences in Scandinavia and the Russian Platform. In North America, strata equivalent to the Arenigian embrace the upper part of the Ibexian and the lower part of the Whiterockian, and have been documented in largely calcareous successions in the Great Basin. In many limestone sequences, conodonts have become the biostratigraphical standard. This disparity of stratigraphical criteria together with regional differences have meant that a plethora of stratigraphical subdivisions of Arenigian strata has grown up over the years, and different regional names are used in, among others, China, Scandinavia, Britain, Australia/New Zealand, and North America. Correlation between these schemes is difficult. However, certain horizons have proved to have international utility. Near the top of the Arenigian, for example, the appearance of biserial graptolites marking the *austrodentatus* biozone has been recognized on most palaeocontinents, and this will form one basis of future standardization.

Llanvirnian

The Llanvirn 'Series' was recognized in the nineteenth century in black slates exposed on the coast in south-western Wales, where it takes its name from an insignificant farmhouse. It is typified by a multitude of 'tuning fork' graptolites (e.g. *Didymograptus artus*, *D. murchisoni*, and related forms), appearing in the Aber Mawr Formation, which have been recognized widely in continental Europe and Scandinavia. The type area is complicated by volcanics and difficult structure, as is the area around Fishguard, and the succession of strata in Britain is better inspected in Shropshire and central South Wales. In Scandinavia, the Upper *Didymograptus* Shales and their equivalents in limestone strata have enabled comparisons to be made with a rich conodont fauna, which provides an international basis for correlation. The Llandeilan (the lower part of the original Llandeilo 'Series') has recently been incorporated into the upper part of the Llanvirnian. The flaggy limestones around the town of Llandilo in central South Wales were already well known by Murchison's time and are among the most fossiliferous rocks of the British Ordovician. Similar problems to those of the Arenigian apply to the international correlation of subdivisions of the Llanvirnian. The Whiterockian of the North American standard includes the Llanvirnian but extends downwards into the Arenigian. Across Europe and Asia the base of the Llanvirnian is marked by a transgressive event, indicated by a deepening in the biofacies and the appearance of graptolites.

Caradocian

The type area of the Caradocian is in Shropshire, England, and it takes its name from a prominent hill, Caer Caradoc, in the vicinity of Church Stretton. In that area the Caradoc is transgressive and its base is defined by an unconformity at the base of the Hoar Edge Grit. As the sequence deepens upwards into a varied succession of mudstones, sandstones, and siltstones (from which several formations are mapped), a great variety of trilobites and brachiopods appear, which were originally studied in detail by B. B. Bancroft. He divided the Caradocian into fine subdivisions ('stages') based on faunal turnover, which, while useful at a local level, are of limited service internationally. In the Shelve Inlier, in South Wales, and near Builth the facies represent deeper water and the sections are without unconformities. However, the effect of the Caradocian transgression is to bring in many graptolite species of stratigraphical utility, including *Dicellograptus* and *Nemagraptus*, replacing the restricted fauna of the Llandeilan *teretiusculus* biozone beneath. This event is of worldwide significance, and the graptolite species concerned can be widely employed for correlation purposes.

The base of the Caradocian (and of the Upper Ordovician) is defined as the base of the *Nemagraptus gracilis* biozone, which can be traced into many areas including the Laurentian platform edge, Bohemia, continental Europe, and the standard graptolitic sequences of Australia and New Zealand. *Nemagraptus gracilis* itself is probably associated with relatively 'oceanic' conditions, and its appearance in basinal successions is probably not entirely synchronous, but the co-occurrence of some of its attendant species of *Dicellograptus* usually places correlation on a sound footing. This, together with the beginnings of a breakdown of the faunal provinciality typifying the earlier Ordovician, means that international correlation of Caradocian strata is less of a problem than is the case with Arenigian and Llanvirnian strata. Nonetheless, there are still distinctive fossil faunas and concomitant separate stratigraphical schemes in the platform limestone successions (Trentonian and Blackriverian) of North America and the Baltic areas. In China, a distinctive diachronous red often nautiloid-rich deep-water formation, the Pagoda Limestone, appears in the Caradocian and continues

into the Ashgillian. North African Gondwanan Caradocian successions include endemic genera adapted to cool-water conditions close to the pole. In deep-water sites, graptolitic successions are well-studied, particularly in the Glenkiln and Hartfell Shales of the Southern Uplands of Scotland, where Lapworth was a pioneer in establishing the succession of faunas. In Wales, the Caradocian was a time of intense volcanic activity in the area around Snowdon, with several kilometres of varied pyroclastic and eruptive rocks, which are classics in the study of 'fossil' volcanoes.

Ashgillian

The youngest, and shortest, subdivision of the Ordovician System (Figure 2) has a type section in the English Lake District, at Ash Gill. A correlative section at Foggy Gill shows continuous passage downwards into the Caradocian. The base of the Ashgillian at the base of the Pusgillian local 'stage' is recognized entirely on a shelly fauna of brachiopods and trilobites. Conodonts and, until recently, graptolites were unrecognized from this locality, and this has made it difficult to locate the base of the Ashgillian in the graptolitic (and conodont) schemes, although a horizon within the *Pleurograptus linearis* biozone has often been accepted. Fossil faunas are not strikingly different from those of the underlying beds and are diverse, but higher in the succession there is a decline in the Rawtheyan local 'stage', presaging a much more drastic reduction as the climate deteriorated at the end of the Ordovician. Shallow-water tropical strata in North America correlative with the Ashgillian, the Cincinnatian limestones, are prodigiously fossiliferous. The stratigraphy of Ashgillian strata in Bohemia, Scandinavia, and China is known in equal detail. There is, in general, a more cosmopolitan fauna in this part of the Ordovician, but cool-water high-latitude faunas still endured close to the pole in northern Africa at the core of the Gondwana supercontinent. Graptolitic deposition continued in deep-water sites distant from continental influences, as in southern Scotland and Taimyr. The youngest subdivision of the Ashgillian, the Hirnantian, marked the onset of the Ordovician glaciation, which is accompanied by drastic lithological and faunal changes in most stratigraphical sections caused by a worldwide regression. In many places there is an unconformity at this horizon, while in all sections spanning the interval there is a reduction in faunal diversity, often accompanied by shallow-water clastic sedimentation.

Figure 2 Late Ordovician (Ashgillian) strata underlying Conway Castle, North Wales.

Life in the Ordovician

The Ordovician is arguably the period of greatest marine diversification in the fossil record. Groups of animals that appeared in the Cambrian (e.g. bivalved molluscs and gastropods) became much more diverse and widespread. Other groups appeared and diversified for the first time. These included corals and bryozoans, which, after a rare occurrence in the Tremadocian, formed diverse bioherms and even reefs before the Caradocian. Cephalopod molluscs – the nautiloids – achieved great size and variety of form, and presumably were among the most effective predators that served to structure the ecosystem. The free-floating graptolites (*see* **Fossil Invertebrates:** Graptolites) became widespread in the world's oceans and are often abundant macrofossils in off-shelf sites where few Cambrian animals can be found. Trilobites (*see* **Fossil Invertebrates:** Trilobites) continued to diversify from the Cambrian and included free-swimming as well as benthic forms, which did not survive into the Silurian. Filter-feeding trilobites were highly characteristic of soft substrates; for example, trinucleid trilobites are abundant in, and confined to, Ordovician strata. Among predatory trilobites, the largest example known from the whole group (*Isotelus*) was discovered in Ordovician strata in Canada.

Articulated brachiopods became numerous enough to form shell beds and evolved into the orders that would dominate the Palaeozoic shallower seas. Echinoderms saw radiations in the starfish, sea lilies, and the earliest sea urchins. By the mid-Ordovician vertebrates with phosphatic external skeletons had become quite varied. Conodonts (now considered to be related to vertebrates) (*see* **Microfossils:** Conodonts) became abundant, and showed a variety of feeding apparatuses. It is likely that the first land plants, allied to liverworts, had appeared by Llanvirnian times, although their fossil record is dominated by spores alone. Moreover, because of the diverse palaeogeography of the time, various groups of animals evolved differently on different palaeocontinents, adding to the total biodiversity. Climatic zonation aided this differentiation. If there was a watershed between Cambrian-style faunas and those characterizing later strata, it occurred at the base of the Whiterockian, when taxa typical of younger strata increased at the expense of those with an archaic history extending back into the Cambrian. It has also been shown that there was an increase in the complexity of trace fossils and bioturbation through the period, with younger Ordovician animals burrowing deeper in the sediment and making 'galleries'. The kind of tiering characteristic of later infaunal assemblages had its origins in the Ordovician. It is possible that increased predation drove these innovations forwards. Allowing for fluctuations in the fossil record, there was an increase in global biodiversity through the Ordovician until the Caradocian (**Figure 3**). The enrichment process was interrupted by the extinction event at the end of the Ordovician, but communities were able to re-establish comparable complexity in the Silurian.

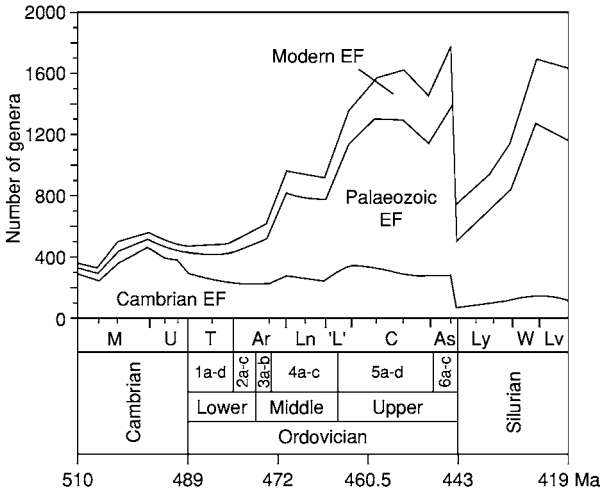

Figure 3 Changes in biodiversity through the Ordovician, showing changes in the diversity of taxa belonging to the different 'evolutionary faunas' (EF) identified by JJ Sepkoski. Maximum diversity is reached late in the Ordovician. The numbers 1a d, 2a c etc., refer to finer scale temporal subdivisions used in cali brating this diagram. Reproduced from Webby BDE, Paris F, Droser ML, and Percival IG (eds.) (2004) *The Great Ordovician Biodiversification Event*. New York: Columbia University Press.

The End-Ordovician Extinction and Glaciation

The mass extinction at the end of the Ordovician is one of the major events in the fossil record, being exceeded only by those at the end of the Palaeozoic and at the Cretaceous–Tertiary boundary. While the ultimate controls on the latter events are still a subject of dispute, the end-Ordovician extinction coincided closely with a short-lived but very extensive glaciation, and it is natural to link the biological event with the physical event. Exactly how the secondary effects associated with the glaciation caused the extinction is still the subject of research.

The ice age climaxed in the final subdivision of the Ordovician, the Hirnantian 'stage'. It was evidently short-lived, and current evidence indicates that the Hirnantian may have been as brief as 0.5 Ma. There is good reason to suppose that the climate was deteriorating before the glacial climax. Evidence for glacial deposits is widespread near the Ordovician south pole in North Africa, and they have also been discovered in South America and the Arabian Peninsula. All these areas were part of the Gondwanan continent in the Ordovician, and the scenario of an extensive ice-sheet expanding outwards from a Gondwanan core is supported by evidence on the ground. In Morocco, there are spectacular glacial pavements, which are associated with tillites and finer-grained diamictites. Evidence of ice movement away from the polar centre has been obtained from striae, roches moutonées, and the fining directions of glacial deposits (*see* **Sedimentary Processes:** Glaciers). The glacial event does not seem to have involved multiple advances and retreats, as in the Pleistocene, although a double ice-advance pulse has been claimed. Correlation within non-marine sediments is difficult at this early time, however.

The effects of the glaciation extended well beyond Gondwana. Oceanic water became tied up in the ice-sheet, resulting in a general marine regression. This event was accompanied by climatic cooling, such that the tropical carbonate belt became extremely restricted. This obviously affected the many organisms adapted to warm carbonate environments, which either died out or were pushed into small refugia. Clastic deposits are typical of the Hirnantian, but in many localities the interval was one of general scouring and erosion. A striking faunal change occurs

in the same interval. A low-diversity set of fossil genera known as the *Hirnantia* Fauna is found almost ubiquitously in strata deposited during the regression. *Hirnantia* itself is a brachiopod, and brachiopods are probably most characteristic, but a dalmanitoid trilobite, *Mucronaspis*, is almost invariably found alongside the other shelly fossils. Nearer the palaeoequator a somewhat more diverse fossil fauna can be collected, but there is little sign of the extraordinarily diverse life of the Early Ashgillian. The fact that most members of the *Hirnantia* fauna had a previous Gondwanan pedigree supports the idea that it represents an invasion of cool-water taxa into lower latitudes – a 'crisis' fauna. It even appears in the midst of graptolitic sequences in China, where the sea-level must have dropped sufficiently to allow the colonization of the seafloor by benthos.

This extinction event was much more profound than one just affecting the shelf benthos. The diversity of those animals inhabiting the open ocean was severely reduced. The fossil record is probably better for the planktonic graptolites than for anything else, and they were extinguished to the extent that only two or three species survived through the crisis. These are thought to have given rise to all the Silurian faunas. Oceanic trilobites such as agnostids and olenids, which had endured for tens of millions of years, disappeared completely, along with many of the typical Ordovician families of shelf trilobites (asaphids and trinucleids among them). It has been suggested that these trilobites had planktonic larvae, in which case an oceanic event affecting graptolites and larvae alike is implied. Such an event could have been extensive anoxia. Some, at least, of the shelf faunas were able to lurk in refugia through the crisis, and in some cases they reappeared as Lazarus taxa as late as the Wenlock (Silurian).

Ordovician Geography and Tectonics

The Ordovician was a period when major continents were separated by wide oceans. At the edges of these continents, microcontinents and islands arcs – many of which were subsequently accreted to one continent or another – produced a complex local geography, which was an additional factor in the rich biotic composition of the Ordovician.

The largest continent was Gondwana, which comprised Africa and the southern part of Europe, South America, the Indian and Arabian Peninsulas, Antarctica, and Australia (Figure 4). It extended from the south pole in Africa to north of the palaeoequator in Australia. Much of it, especially central Africa and India, was land throughout the period and largely lacks Ordovician strata. But shallow seas immersed northern Africa, Arabia, and large parts of Australia, and these areas preserve strata rich in fossils. South China was close, if not actually attached, to Gondwana through much of the Ordovician. The kinds of rocks that accumulated reflect the Ordovician palaeolatitudes: mostly clastic rocks near the pole, and predominantly carbonate rocks as the palaeoequator is approached. Spanning the palaeoequator, but well removed from Gondwana, the Laurentian palaeocontinent included what is now North America and Greenland, plus some fragments that lie today on the opposite side of the Atlantic Ocean. Throughout most of the Ordovician, thick deposits of limestones accumulated over platform Laurentia (Figure 5). The Laurentian continent appears to have been stable in

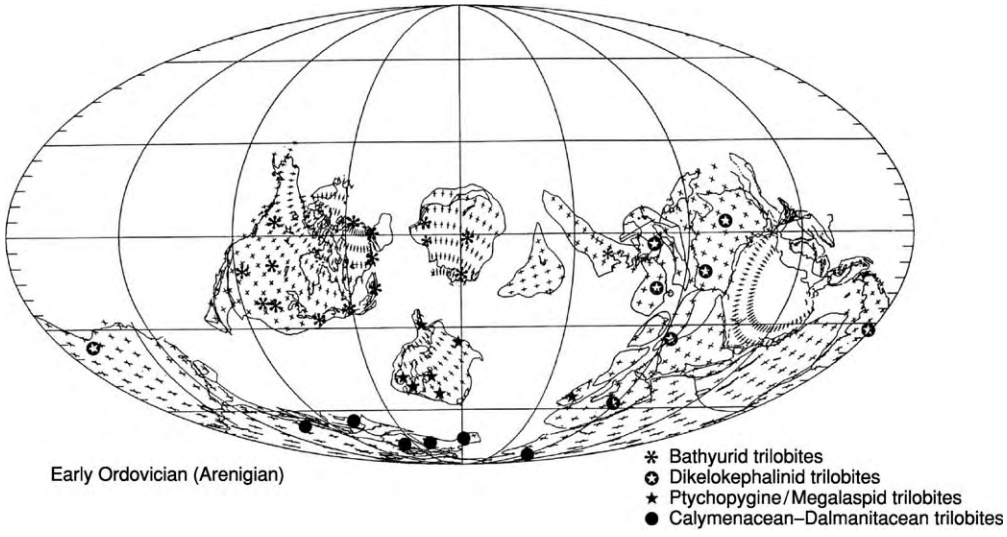

Figure 4 World geography in the Early Ordovician. The distributions of some of the characteristic trilobites are shown.

Figure 5 Limestone strata typical of Ordovician tropical palaeolatitudes: the white limestones of the Meiklejohn Bioherm (Middle Ordovician) near Beatty, Nevada, USA.

Figure 6 A Caradocian world reconstruction showing the migration of the Avalonian Terrane across Iapetus in the middle of the map.

its palaeoequatorial position throughout the Ordovician. The Siberian continent lay between Laurentia and Gondwana. Lying at an intermediate latitude through much of the Ordovician, the continent of Baltica comprised most of present-day Scandinavia and the Russian platform as far east as the Urals. Palaeomagnetic evidence suggests that it rotated between the Middle Cambrian and the Middle Ordovician to attain its current orientation. The palaeocontinents were surrounded by continental shelf and slope deposits or marginal basins related to offshore island arcs. In these, graptolite-bearing shales and mudstones accumulated, and benthic animals different from those inhabiting the shallow shelves were able to prosper. Further seawards again there were oceans, direct evidence for which is provided by obducted ophiolites preserved in mountain belts. These vanished oceans have been given several names: Iapetus separated Laurentia from Baltica and Gondwana; the Tornquist Sea separated Baltica from Gondwana. The oceans separated the major continents sufficiently for each to evolve its own endemic faunas in the earlier Ordovician.

Geography changed continually during the Ordovician, as oceans waned. For example, the Tornquist Sea closed, and Iapetus became much narrower. As this happened, former ocean islands became added to the edges of active continental margins along the subduction zones. The changing geography also facilitated the migration of faunas from one continent to another. Microcontinents migrated across the oceans: Avalonia – comprising the Anglo-Welsh area plus part of what is now eastern North America – moved from Gondwana towards Laurentia, and a new ocean (the Rheic Ocean) opened up behind it (Figure 6). Simultaneously, part of Laurentia drifted away to become accreted to what is now South America before the end of the period. This crustal mobility makes the Ordovician one of the more difficult geological periods for which to reconstruct the geography in detail.

Mountain belts grew along the lines of the subduction zones. The Ordovician saw the early phases of the growth of the Appalachian–Caledonian chain along the western margin of Iapetus. Another mountain belt (now partly buried beneath younger strata) marks the suture between Baltica and continental Europe. Another belt runs along eastern Australia. Volcanic activity along island arcs and in connection with subduction produced varied local rock sequences in different marginal terrains, in which volcanogenic and sedimentary rocks are interbedded. Palaeogeographical (latitudinal) coordinates for these contentious fragments can be determined from palaeomagnetic data, which, combined with evidence from lithology and faunas, contribute to a kinematic description of the shifting palaeogeography. Some mineralization of economic significance is associated with the Ordovician mountain belts. Extensive lead and silver deposits were mined in Wales and elsewhere along the Caledonian chain. Gold is known from many sites close to the main Iapetus oceanic suture in, for example, Ireland and Newfoundland.

Vulcanicity and Geochronology

The high level of tectonic activity during Ordovician times means that there is much evidence of explosive volcanic eruptions that spread ash deposits widely over the seafloor. These are recognized today as bentonites, which usually appear as very soft pale clay beds contrasting with the stratified deposits with which they are associated. In some successions, such as that of the eastern USA, bentonites occur more or

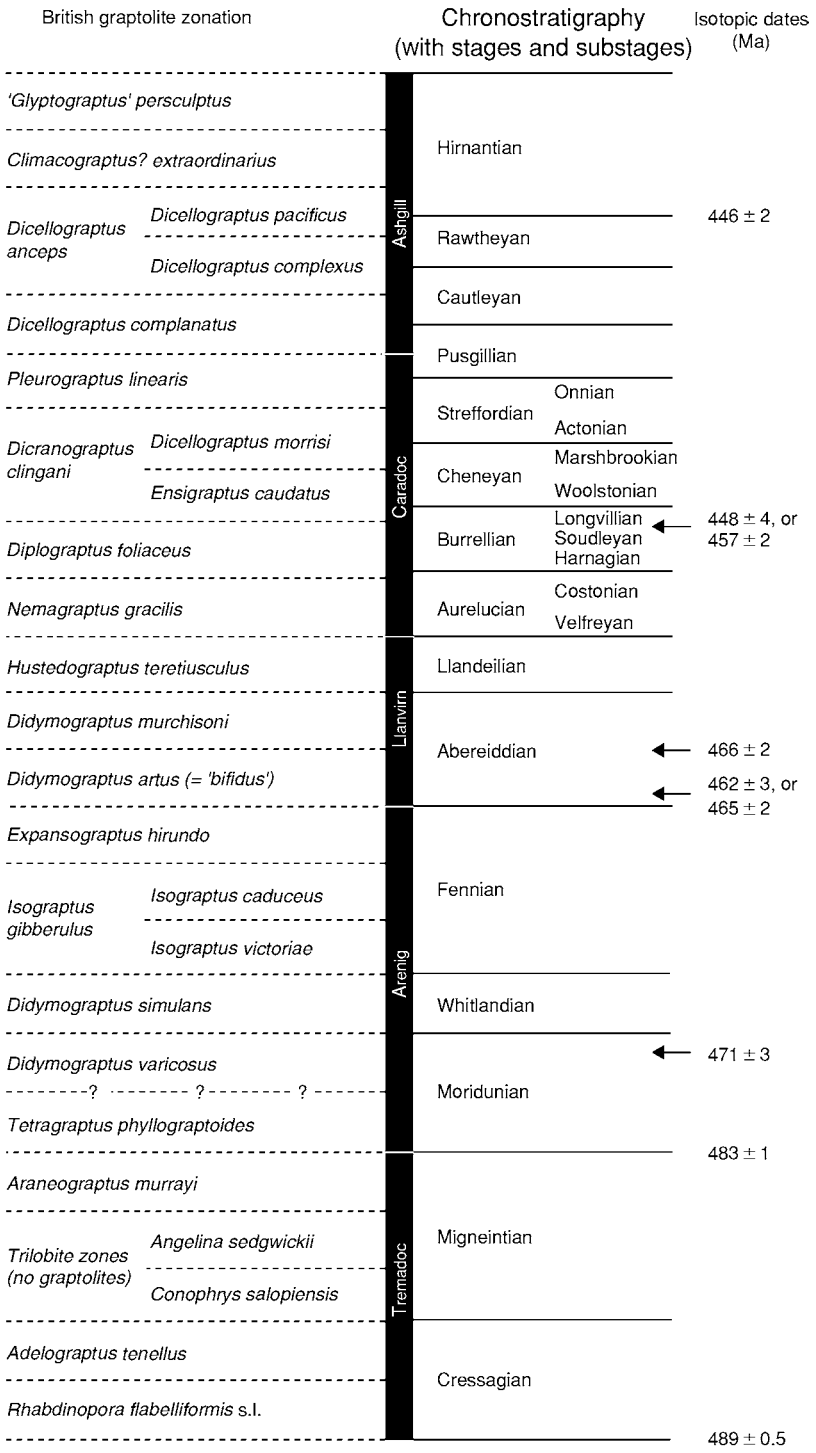

Figure 7 Chronostratigraphy of the Ordovician, showing some of the radioisotopic dates on the right. The traditional series names are employed without the ' ian' suffix in this diagram. Taken from Fortey RA, Harper PAT, Ingham JK, Owen AW, Parks MA, Rushton AWA and Woodcock NH (2000). A revised correlation of Ordovician Rocks in the British Isles. Geological Society. Special Report No. 24, pp. 38.

less regularly through hundreds of metres of strata. The Caradocian 'Big Bentonite' has been claimed to be the product of the explosion of an enormous 'super-volcano', an eruption greater than any that has been recorded in historical times. Bentonites useful in geochronology because they yield datable zircons and are often interbedded with graptolitic deposits, enabling a precise biostratigraphical tie-in (Figure 7). Other

sources of zircons include ash beds and tuffs. Subdivisions within the Ordovician are well-dated with zircon ages, often to an accuracy of ±1.0 Ma.

Biostratigraphy

Historically, biostratigraphical zonation using graptolites was the first scheme to be applied to Ordovician rocks for the purposes of international correlation of strata. Graptolites underwent a successive series of easily recognizable evolutionary changes through the Ordovician, which, even today, give a rapid method of estimating geological age. The 'stipe reduction series' – in which the graptolite fauna as a whole changes from species with many (eight or more) stipes to species with just two – still affords a 'ready reckoner' to distinguish Tremadocian to Llanvirnian strata in the field. Caradocian strata often include numerous Y-shaped colonies of *Dicranograptus*. However, finer zonal subdivision requires the accurate determination of species. Currently, about 25 biozones have been recognized. The solution of limestones to yield conodont fossils provided an additional and refined biostratigraphical system. This was especially useful because it could be applied to the bulk sampling of otherwise unpromising carbonate rocks. Since the 1950s conodont stratigraphy has complemented the graptolite-based schemes, with only slightly lesser refinement. However, such work requires dedicated laboratories. Recently, the stratigraphic utility of organic-walled microfossils – acritarchs and chitinozoa – has been appreciated, especially for dating clastic rocks from which conodonts are difficult to extract. Laboratory facilities capable of handling hydrofluoric acid are essential for this kind of work. These microfossils have proved exceptionally useful in dating rocks from high palaeolatitudes in the Ordovician. Trilobites and brachiopods have been used in local stratigraphy, but individual species are not usually of wide intercontinental geographical distribution, the notable exception being the *Hirnantia* Fauna. For international correlation, sections that include more than one index group are considered ideal: a combination of graptolites and conodonts is especially useful.

Silurian

L R M Cocks, The Natural History Museum, London, UK

Introduction

The Silurian System, which is radioisotopically dated to have extended from 443 Ma to 418 Ma (*see* **Time Scale**), follows the Ordovician (*see* **Palaeozoic:** Ordovician) in the geological time-scale and is immediately overlain by the Devonian (*see* **Palaeozoic:** Devonian). The Silurian forms the latest part of the Lower Palaeozoic and is divided into four standard series: the Llandovery (from 443 Ma to 429 Ma), the Wenlock (from 429 Ma to 424 Ma), the Ludlow (from 424 Ma to 420 Ma), and the Pridoli (from 420 Ma to 418 Ma). The type sections for the first three are in Great Britain and the last in the Czech Republic. The base of the Silurian is marked by an unconformity in many parts of the world, since the glaciation that occurred near

the Ordovician–Silurian boundary was responsible for a global lowering of sea-level. The system is well represented in most regions today, apart from Antarctica and peninsular India, which both formed interior parts of the immense supercontinent of Gondwana.

This article describes the history, type areas, other key areas, palaeontology, tectonic activity, climate, and palaeogeography of the Silurian.

History

The Silures were an ancient British tribe who occupied southern Wales before the Roman occupation in the first century AD. The name 'Silurian' was coined by Roderick Impey Murchison (1792–1871) (*see* **Famous Geologists:** Murchison) to denote a geological system in a short paper in 1835. That paper was followed in 1839 by *The Silurian System*, a substantial book that not only described the geology of the Silurian, particularly of Wales and the Welsh Borderland of England, but also contained many illustrations and descriptions of characteristic Silurian strata and fossils. Successive editions, with the shortened title *Siluria*, followed until just after Murchison's death in 1872, by which time the scope of both the book and the system had been extended to cover the whole world (Figures 1 and 2).

The Silurian System was originally envisaged as encompassing the rocks between the Cambrian below and the Devonian above. However, it became increasingly clear that the 'Lower Silurian' of Murchison included the same rocks and geological time as the upper part of Adam Sedgwick's underlying Cambrian System. Sedgwick (*see* **Famous Geologists:** Sedgwick) was originally a friend of Murchison's (they named the Devonian together), but as time progressed fierce arguments broke out between the two men over the scope and definition of both the Cambrian and the Silurian. The matter was not resolved until after both Sedgwick and Murchison had died, when, in 1879, Charles Lapworth erected the Ordovician System to encompass both the upper part of Sedgwick's Cambrian and the lower part of Murchison's Silurian, which had at its base the Llandeilo Flags.

For many years the restricted Silurian was divided into three parts: the lowest was termed the Llandovery (or sometimes the Valentian from the graptolite-dominated faunas in the southern Uplands of Scotland), and this was followed by the Wenlock and the Ludlow. At the type area in the Ludlow area of Shropshire, marine Silurian rocks are conformably overlain by the Old Red Sandstone. At the boundary between the Ludlow and the non-marine Old Red Sandstone is a remanié deposit rich in disarticulated fish remains, known as the Ludlow Bone Bed. This thin bed was, for many years, regarded by British geologists as defining the top of the Silurian. However, in continental Europe, beds stratigraphically higher than the Ludlow Bone Bed equivalent were regarded as Silurian in age, largely because they contained graptolites. It was not until the 1960s that the views of British and continental geologists were reconciled by erecting the Pridoli Series (type area in the Bohemian part of the Czech Republic), which is now internationally accepted as a separate series within the Silurian, above the Ludlow Series and below the Devonian System.

Type Areas and Sections

The base of the Silurian System, which is also the top of the Ordovician System, the base of the Llandovery Series, and the base of the Rhuddanian Stage, has been set by international agreement within the mudstones of the Birkhill Shale Formation at the base of the *Parakidograptus acuminatus* graptolite Biozone (*sensu lato*) at Dob's Linn, near Moffat, Scotland. Some biostratigraphers, however, now divide that zone into a lower *P. ascensus* Biozone and an upper *P. acuminatus* Biozone (*sensu stricto*). The Birkhill Shales, and most of the southern Scottish Uplands in which they occur, were deposited as deep-water ocean-floor deposits and thus represent fairly continuous deposition of sediments, and faunas occurred without substantial break over the Ordovician–Silurian boundary time interval. At Dob's Linn, the underlying latest Ordovician *complexus, extraordinarius*, and *persculptus* graptolite biozones are all represented by diagnostic graptolite faunas, as are the Early Llandovery *atavus, acinaces*, and *cyphus* graptolite biozones above the *acuminatus* Biozone. Fossils other than the abundant graptolites are less common in the Dob's Linn section, but include some inarticulated brachiopods, the blind dalmanitid trilobite *Songxites*, and conodont, acritarch, and chitinozoan microfossils, the last of which are helpful in international correlation.

The Llandovery Series

Llandovery is a town standing on late Ordovician rocks in the Twyi Valley, central Wales, but the low hills to the east of the town are formed from rocks of Early Silurian age. These form the type area of the Llandovery Series (Figure 3). This series is formally divided into three stages, which are, in ascending order, the Rhuddanian, Aeronian, and Telychian. The base of the Rhuddanian, which is synonymous with the base of the Silurian, is formally defined at Dob's Linn, Scotland, some 300 km from Llandovery. Nevertheless, Rhuddanian rocks are well exposed in the type Llandovery area, consisting of up to 250 m of

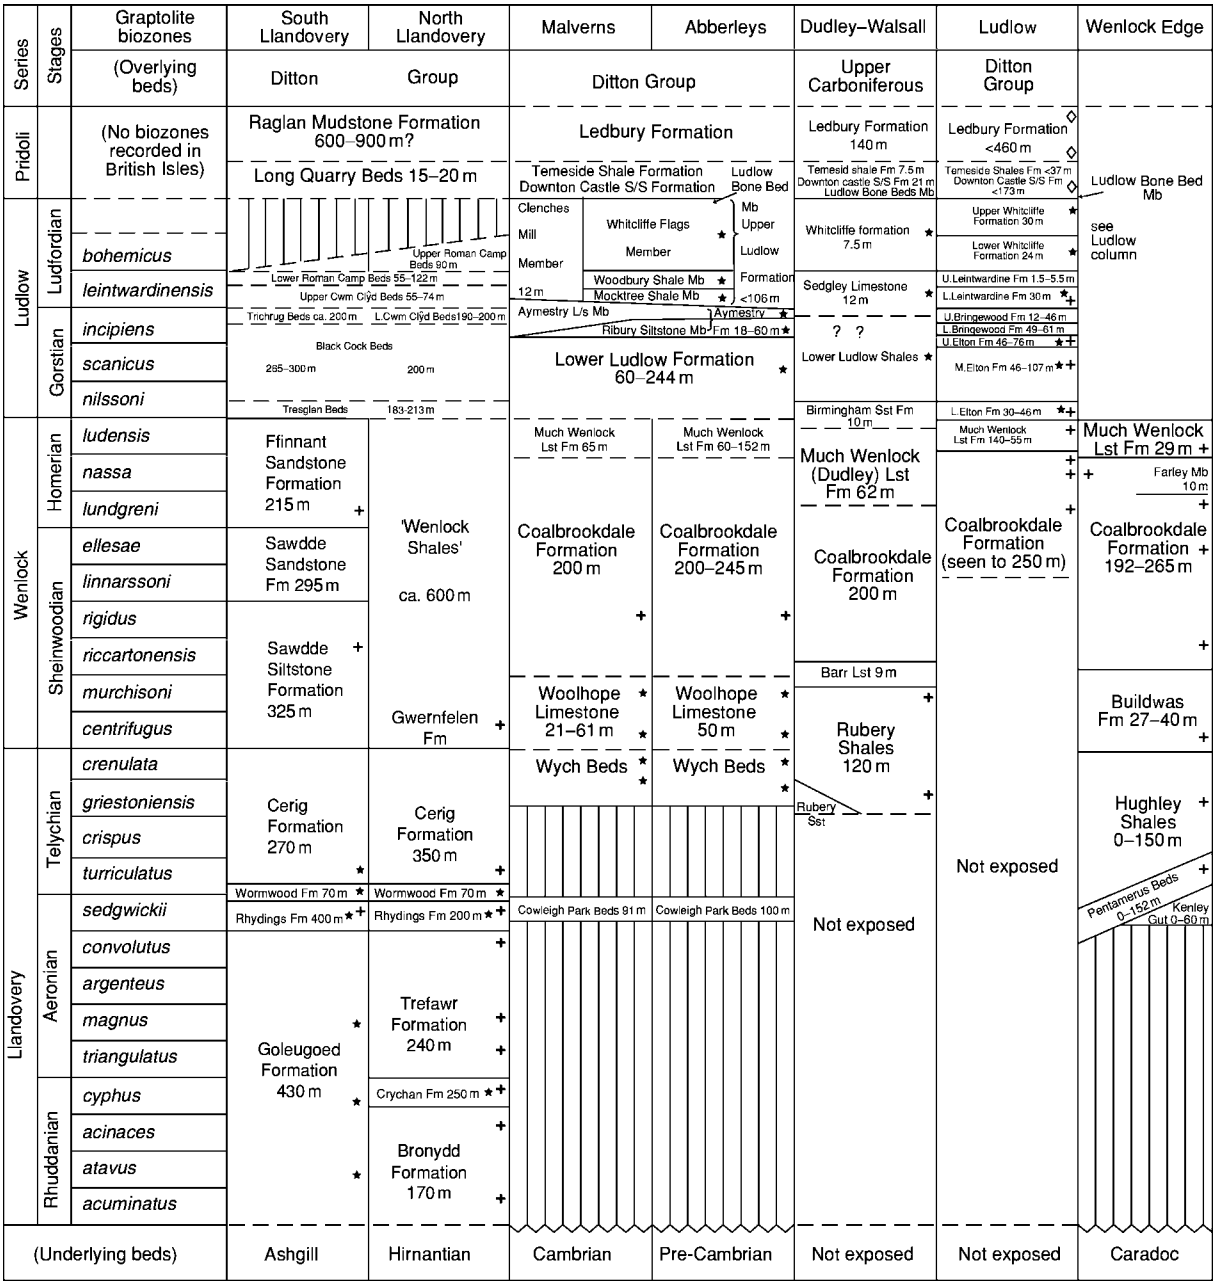

Figure 1 Correlation of key Silurian sections in the British Isles. (Reproduced from Cocks LRM, Holland CH, and Rickards RB (1992) *A Revised Correlation of Silurian Rocks in the British Isles*. Special Report 21. London: Geological Society.)

clastic rocks varying from sandstone through siltstone to shale. These sediments contain a wide variety of fossils. Macrofossils are dominated by brachiopods, including the early members of the *Stricklandia* lineage, whose species are so important for correlating Llandovery and Early Wenlock rocks internationally. Over 35 brachiopod genera are recorded from the Rhuddanian Bronydd, Crychan, and Lower Trefawr formations and their lateral equivalents at Llandovery, together with numerous trilobites, molluscs, and echinoderms and rare corals, bryozoans, and dasyclad algae. Microfossils are represented by conodonts of the *Icriodella discreta–I. deflecta* Assemblage Biozone, as well as by various acritarchs, chitinozoa, and scolecodonts.

The Aeronian Stage has its 'golden spike' base in the Forestry Commission Trefawr track near Cwm Coed Aeron Farm, Llandovery, and its base lies within the blocky mudstones of the Trefawr Formation at a horizon corresponding to the base of the *triangulatus*

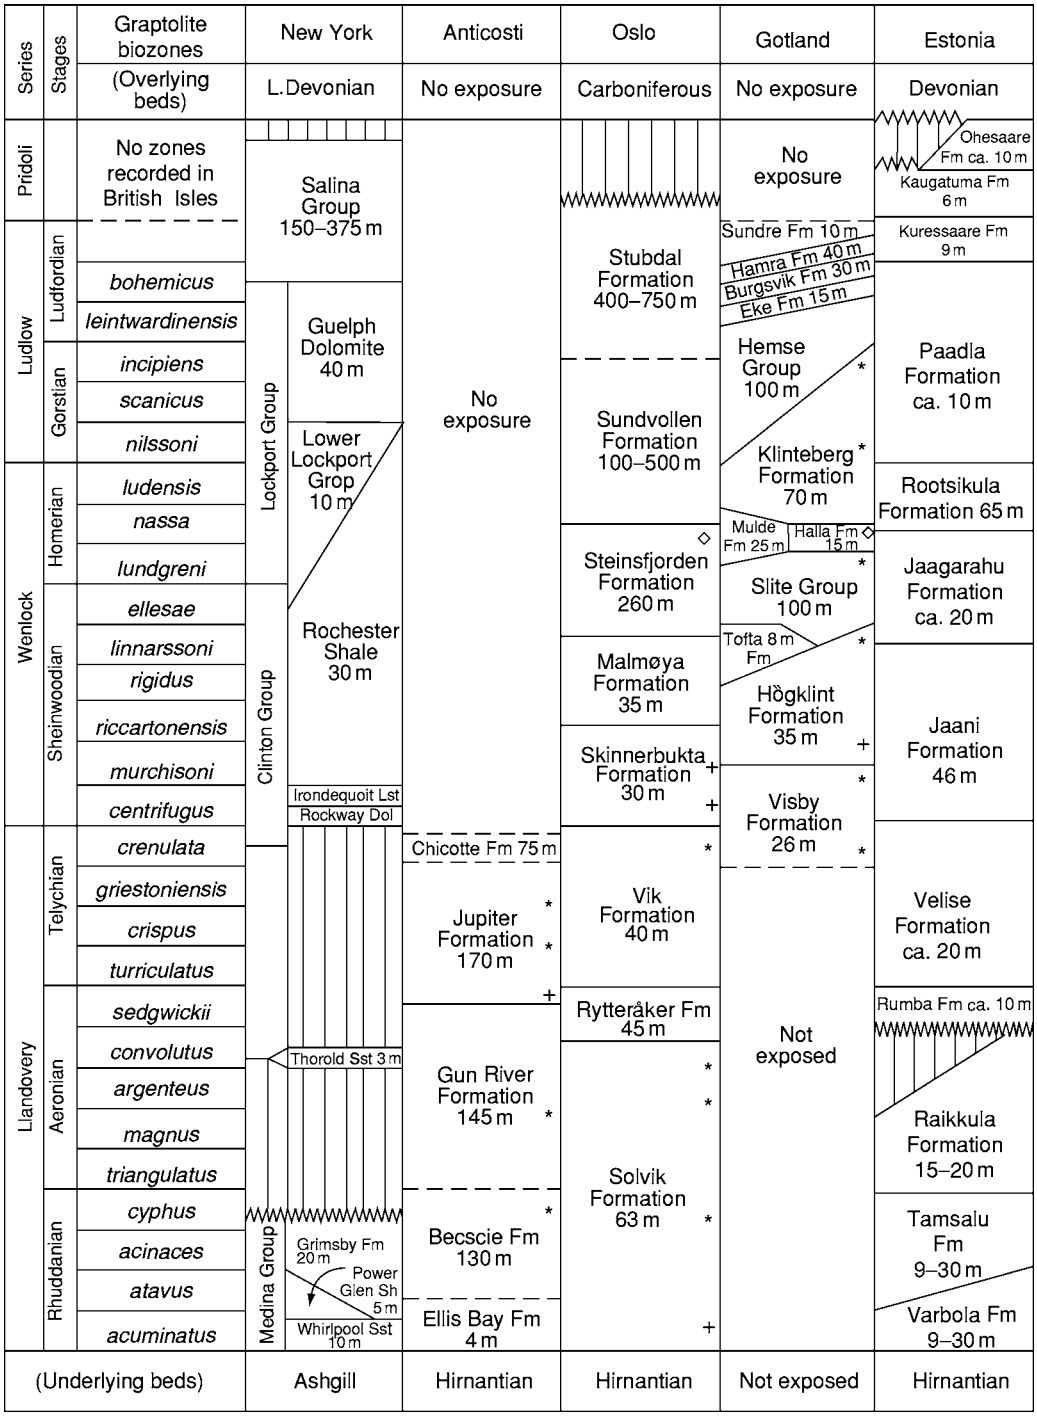

Figure 2 Correlation of key Silurian sections in New York State, Anticosti Island (Canada), the Oslo Region of Norway, the island of Gotland (Sweden), and the northern area of Estonia. (Reproduced from Cocks LRM, Holland CH, and Rickards RB (1992) *A Revised Correlation of Silurian Rocks in the British Isles*. Special Report 21. London: Geological Society.)

graptolite Biozone. The Aeronian is represented at Llandovery by over 450 m of rocks carrying, once again, an abundant macrofauna, microfauna, and microflora, including two more *Stricklandia* brachiopod species. Also present for the first time are two species of the rhynchonellide *Eocoelia*, a brachiopod genus that, in the upper half of the Llandovery, evolved even more quickly than *Stricklandi* and whose species are therefore invaluable for detailed correlation. The Aeronian formations at

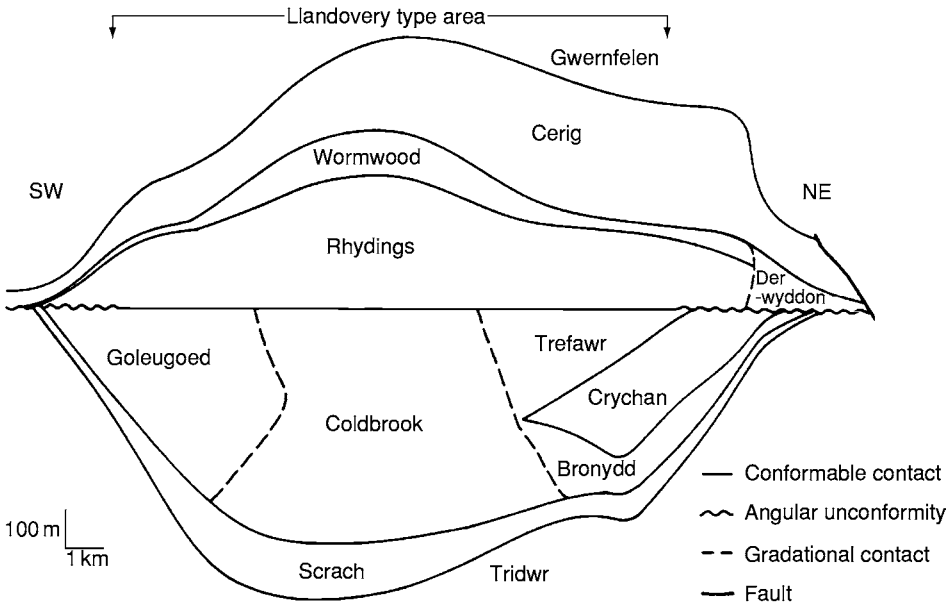

Figure 3 Schematic cross section of the formations and their thicknesses in the type Llandovery area, Wales. (Reproduced from Cocks LRM, Woodcock NH, Rickards RB, Temple JT, and Lane PD (1984) The Llandovery series of the type area. *Bulletin of the British Museum* (*Natural History*) *Geology* 38: 131 182.)

Llandovery are the Upper Trefawr, Rhydings, and Lower Wormwood Formations and their lateral equivalents.

The Telychian Stage has its formal base within a 30 cm sandstone in a small quarry near Pen-lan-Telych Farm, east of Llandovery. This sandstone occurs just below the top of the Wormwood Formation at a horizon that correlates with the base of the *turriculatus* graptolite Biozone. It is also just above the last occurrence of the brachiopod *Eocoelia intermedia* and just below the earliest record of *Eocoelia curtisi*. The higher levels of the Telychian in the type Llandovery area, the Cerig Formation, consist of over 350 m of monotonous and rather poorly fossiliferous purple mudstones. The thickness of this sequence, along with the fact that the overlying Gwernfelen Formation carries the basal Wenlock *centrifugus* Biozone graptolites, suggests that the great majority of Llandovery time is represented by rocks in the type Llandovery area.

The Wenlock Series

The Wenlock has its type area near the town of Much Wenlock in Shropshire, England, after which the series is named. The Wenlock is divided into two stages, a lower Sheinwoodian Stage and an upper Homerian Stage. The base of the Wenlock Series and the Sheinwoodian Stage is defined in Hughley Brook, Shropshire, where the Llandovery Purple (or Hughley) Shale Formation grades upwards into the overlying Buildwas Formation. This horizon, which is in an area of apparently continuous sedimentation, correlates with the base of the *centrifugus* graptolite Biozone and is accompanied by abundant and superbly preserved microfossils as well as many macrofossils, chiefly brachiopods and molluscs. The Buildwas Formation, which contains sporadic large calcareous nodules, was deposited fairly deep on the Silurian continental shelf and is about 35 m thick. This is followed conformably by the 192–265 m thick Coalbrookdale Mudstone Formation. The base of the type Homerian Stage lies within the Coalbrookdale Formation in a stream section at Whitwell Coppice, Shropshire, at a horizon corresponding to the base of the *lundgreni* graptolite Biozone. The Coalbrookdale Formation becomes more limey near its top, formally termed the Farley Member, and is overlain by the famous Much Wenlock Limestone Formation, which caps the escarpment of Wenlock Edge for more than 30 km. The Wenlock Limestone (as it is more commonly called) is only 29 m thick, but contains massive bioherms exposed in the many quarries along Wenlock Edge. The Wenlock Limestone is very extensive laterally both to the south and east of Shropshire and crops out substantially near Birmingham, where it is known locally as the Dudley Limestone, in particular at a locality named Wren's Nest. The Coalbrookdale Formation carries an abundant macrofauna, especially cephalopods and brachiopods, and varied microfossils, but the Wenlock Limestone fossils are even more varied and are exquisitely

preserved: the trilobites and corals are the best known. The bioherms consist mostly of stromatoporoids and calcareous algae, with subsidiary tabulate corals. Above the Wenlock Limestone on Wenlock Edge the strata pass up without substantial break into the overlying Elton Formation, which is of Ludlow age and extends laterally into the type Ludlow area, some 25 km away.

The Ludlow Series

The mediaeval town of Ludlow lies south-west of Much Wenlock in Shropshire, England, and the low cliffs to the south and west of the town form a shallowly plunging anticline, which includes the type rocks of the Ludlow Series and its two stages, the lower Gorstian and the upper Ludfordian. The formal base of the Ludlow Series and Gorstian Stage is located in Pitch Coppice quarry, 4.5 km south-west of Ludlow, where the Much Wenlock Limestone Formation is succeeded conformably by the Elton Formation. This boundary correlates with the base of the *Neodiversograptus nilssoni* graptolite Biozone. The 110–225 m thick Elton Formation consists largely of blocky fine siltstones, which were deposited in the middle and deeper parts of the shelf and contain many macrofossils, particularly brachiopods, trilobites, and cephalopods, and a large variety of microfossils, particularly conodonts, acritarchs, chitinozoa, and ostracods. Above the Elton Formation is the 62–105 m thick Bringewood Formation, which includes the Aymestrey Limestone of Murchison, famous for its banks of the large pentameride brachiopod *Kirkidium knightii*. The formal base of the Ludfordian Stage is at Sunnyhill Quarry, 2.5 km south-west of Ludlow, where the Bringewood Formation is overlain by the Leintwardine Formation. The base of this unit is defined in beds correlating with the base of the *Saetograptus leintwardinensis* graptolite Biozone. The 35 m thick Leintwardine Formation and the overlying 55 m thick Whitcliffe Formation both consist of siltstones and mudstones with, again, common brachiopods and cephalopods and rich microfaunas and microfloras. At the top of the Whitcliffe Formation is the Ludlow Bone Bed (see above), which is overlain by the Downton Castle Sandstone. The latter can be correlated indirectly with beds of the Pridoli Series in its type section in the Czech Republic.

The Pridoli Series

The Pridoli (technically spelt Přídolí, but the Czech accents are often omitted) Series was of much shorter duration than the other three series of the Silurian and as a result is not subdivided into stages. Its type section is in the disused Požáry Quarry at Řeporyje, in the western suburbs of Prague, Czech Republic. There the Požáry Formation is a uniform facies of dark platy limestones with intercalations of calcareous shale. Brachiopods occur commonly throughout, with abundant cephalopods at certain horizons and rich microfossil floras and faunas. The base of the Pridoli Series is defined at the first appearance of the graptolite *Monograptus parultimus*, a key constituent of the *Monograptus ultimus* graptolite Biozone. This horizon is close to the gradational boundary between the underlying Kopanina Formation and the overlying Požáry Formation. The Pridoli Series lies entirely within one conodont biozone, that of *Ozarkodina eosteinhornensis*, whose first and last appearances fall below and above the Pridoli rocks. The upper limit of the series is about 8 m above the base of the Lochkov Formation, which overlies the Požáry Formation. The top of the Pridoli Series is defined by the internationally agreed base of the Devonian System and its basal Lochkovian Stage, which is taken at the base of the *Monograptus uniformis* graptolite Biozone, whose 'golden spike' is at Klonk, also in the Czech Republic and about 23 km south-west of Požáry.

Other Key Silurian Areas

New York

Niagara Falls, in New York State, USA, and bordering Ontario, Canada, runs over a Silurian escarpment of relatively flat-lying rocks. There the Medina Group, consisting of the Whirlpool Sandstone, the Power Glen Shale, the Grimsby Formation, and the Thorold Sandstone, is of Llandovery age and is overlain paraconformably by the Clinton Group, which is of Wenlock age. The latter unit includes the very fossiliferous Rochester Shale, famous for its trilobites and other invertebrate fossils, and other formations (Figure 4). Above this lie the Lockport Group, of late Wenlock and Ludlow age, and the Salina Group, which includes many anhydrites of latest Ludlow and Pridoli age. Much of the sequence is relatively unfossiliferous, since the limestones have been largely replaced by dolomites.

Norway and Sweden

The graben running north–south through the Oslo region of Norway includes a rich succession of Silurian rocks. The Solvik, Rytteråker, and Vik formations form a Llandovery sequence that conformably overlies the latest Ordovician rocks and underlies the Wenlock rocks. The latter include the Skinnerbukta, Malmøya, and Steinsfjorden formations. The Solvik

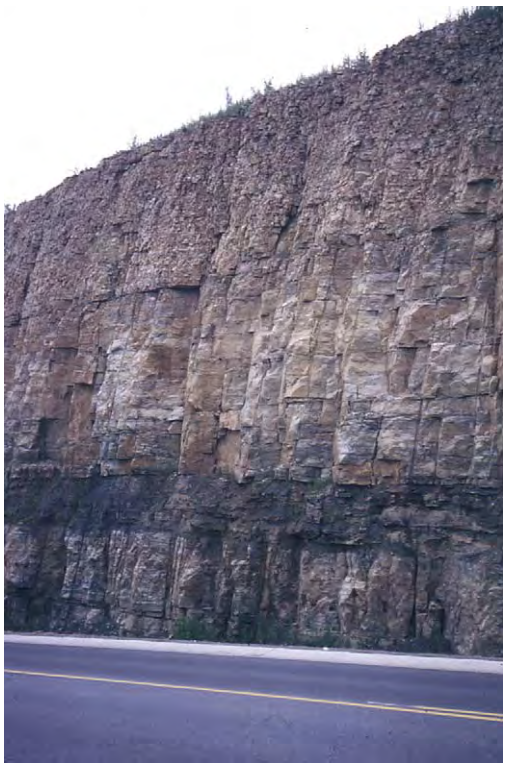

Figure 4 Section through most of the Silurian in southern Ontario, Canada, near Niagara Falls. The lower limestones are Late Llandovery and Early Wenlock; they are overlain by the Late Wenlock Rochester Shale Formation, which is in turn overlain by Ludlow, Pridoli and earliest Devonian limestones.

to the Steinsfjorden formations were all deposited in shallow-marine environments on the continental shelf and include abundant brachiopods and other macrofossils and microfossils. Above these, the Late Wenlock and Ludlow Sundvollen and Stubdal formations were deposited under freshwater or continental non-marine conditions. The Pridoli is not known in this region. On the Baltic island of Gotland, Sweden, there are flat-lying outcrops of Late Llandovery to Ludlow rocks, in many cases forming imposing sea cliffs and containing notable bioherms. The visible sequence starts with the Visby Marl, which spans the Llandovery–Wenlock boundary, and this is succeeded by the bioherms of the Högklint Formation. Ten further Wenlock and Ludlow formations follow, including the Klinteberg Formation, which spans the Wenlock–Ludlow boundary and is famous for its reefs of the pentameride brachiopod *Conchidium*, originally described by Linnaeus in the early eighteenth century.

Anticosti

Anticosti Island lies near the mouth of the St Lawrence River, Canada, and is nearly 100 km long, with a relatively flat-lying Late Ordovician and Early Silurian succession. The Silurian follows the latest Ordovician with only a minor break within the Ellis Bay Formation, which is followed by the Becscie, Gun River, Jupiter, and Chicotte formations, all of which are of Llandovery age. These rocks consist of alternating limestones and shales, all deposited on a shallow-marine continental shelf and yielding excellently preserved macrofossils (particularly brachiopods, corals, and bryozoans) and microfossils (particularly condonts, ostracods, acritarchs, and chitinozoans). Since graptolites are poorly represented, the principal correlations have been achieved by using conodont biozones.

Podolia

The area bordering the Dnestr River has been part of both Poland and the USSR in the past and is now in the west of Ukraine. A very thin band of Middle Llandovery rocks lies unconformably on Middle Ordovician rocks and is followed paraconformably by the Wenlock Kitaigorod Formation, the Bagovitsa Formation, which spans the Wenlock–Ludlow boundary, the Ludlow Malmovtsy Formation, and the Pridoli Rashkov and Dzwinogorod formations, which are themselves followed conformably by earliest Devonian strata. All are marine, with many limestones but much clastic fine-grained input, and have yielded very abundant macrofossils and microfossils. The latest Silurian rocks, locally termed the Skala Stage, were a strong candidate for the stratotype of the latest formal series of the Silurian, but the vote went to the Pridoli area of the Czech Republic.

Methods of Dating and Correlation

The system is well-constrained by radioisotopic ages down to the level of the series (see above for the dates in Ma), but within the series the dating and correlation are achieved by using quickly evolving fossils. The best of these are the graptolites, upon which more than 30 biozones have been based, covering the entire Silurian. Because of their planktonic mode of life, these quickly evolving lineages dispersed very rapidly, enabling correlation across all continents and terranes. However, graptolites are often uncommon or even absent in rocks deposited under very shallow-water conditions, and, in these rocks, microfossils, particularly conodonts, are used. However, there are often four or five successive graptolite biozones during the period of a single Silurian conodont biozone. Conodonts, acritarchs, chitinozoans, and spores can often be recovered from small samples, for example the rock chips produced through boring by

the hydrocarbon industry. In the Early Silurian (Llandovery and Early Wenlock), quickly evolving brachiopods, such as *Stricklandia* and *Eocoelia* (mentioned above), are also used for local and international correlation.

Life in the Silurian

Within the marine realm, invertebrates were abundant and diverse throughout the Silurian. The benthos was dominated by brachiopods, bivalves, gastropods, corals, stromatoporoids, bryozoans, various echinoderms (particularly crinoids), calcareous algae, and trilobites. The plankton included cephalopods (most of which swam), graptolites, and a variety of microplankton, particularly acritarchs, chitinozoans, and spores. Ostracods and conodonts were certainly mobile and in some cases dispersed quickly, but their detailed ecologies and modes of life are less certain. Fishes became progressively more abundant during the period. There is debate as to whether all Silurian fishes were marine or whether some were entirely freshwater: some fish fossils are to be found in apparently non-marine rocks. Fossils of land-living creatures are very rare, and the land was clearly not yet much colonized. Various groups of arthropods probably lived onshore at the time, as did some algae whose remains are equivocally preserved. Judging by the occurrence of fossil spores in marine rocks, some land plants probably lived as early as the Ordovician, but the oldest land plants yet represented by convincing body fossils are from rocks of Middle Silurian (Wenlock) age.

Tectonic Activity

The Silurian was considerably shorter than either the Ordovician or the Devonian, and thus there was a smaller variety of tectonic activity during the duration of the System. The docking between Avalonia and Baltica at the start of the period was relatively mild tectonically, since the collision was oblique and therefore relatively 'soft' in tectonic terms. Subsequently, during most if not all of Silurian time, there

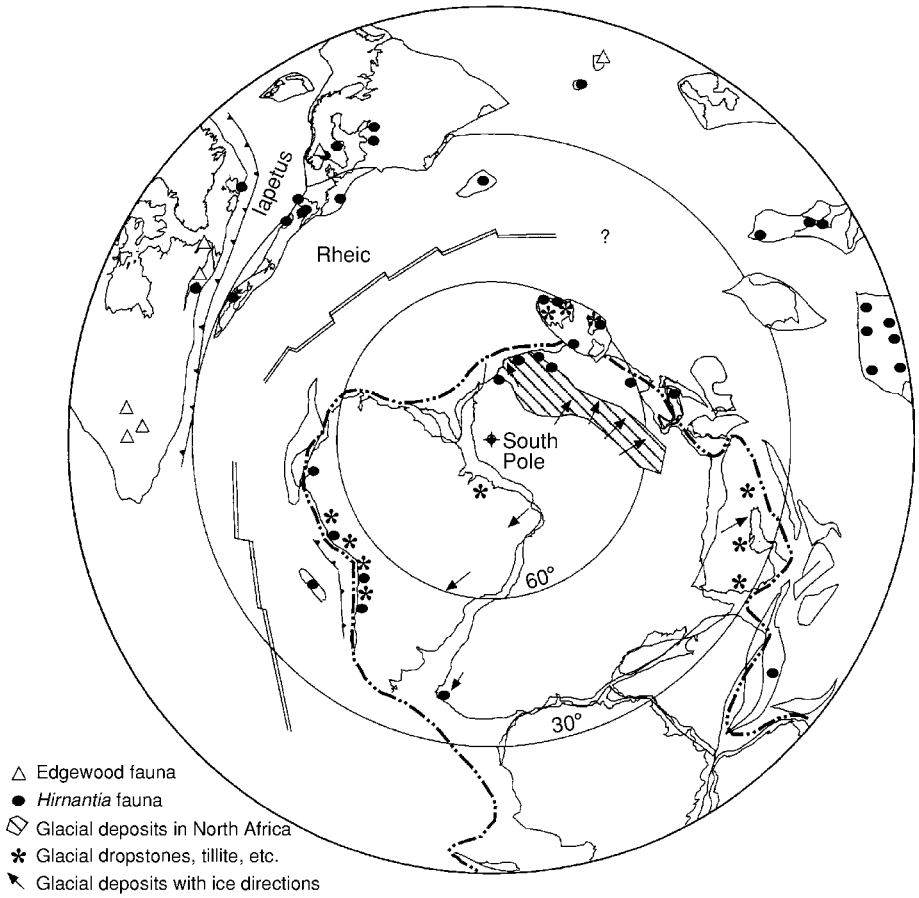

Figure 5 Palaeogeography at the Ordovician Silurian boundary (approximately 440 Ma), showing the distribution of the latest Ordovician glacial deposits and the *Hirnantia* brachiopod fauna. (Reproduced from Cocks LRM and Torsvik TH (2002) Earth geography from 500 to 400 million years ago: a faunal and palaeomagnetic review. *Journal of the Geological Society, London* 159: 631 644.)

was a major collision between Avalonia–Baltica and Laurentia, resulting in a major tectonic event termed the Caledonian Orogeny (*see* **Europe:** Caledonides of Britain and Ireland; Scandinavian Caledonides (with Greenland)), which led to mountain building and metamorphism along a belt that today embraces all of the North Atlantic rim from the eastern USA (Carolina) to Norway, including eastern North America, Ireland and Britain, and the Scandinavian Caledonides of Norway and Sweden. Away from this area, there appears to have been less tectonism, apart from in today's central Asia, where a number of small terranes and their marginal island arcs were breaking up and regrouping, particularly in Kazakhstan and adjacent countries. Around the vast Gondwanan margin there were also island arcs and tectonic activity in south-east Australia (Victoria and New South Wales) and New Zealand.

Palaeogeography and Climate

Silurian geography was dominated by the vast supercontinent of Gondwana (*see* **Gondwanaland and Gondwana**), which included today's South America, Africa, peninsular India, Antarctica, and Australasia, as well as adjacent terranes in southern Europe and the Middle and Far East, which may or may not have been physically attached to the supercontinent (Figure 5). Other substantial terranes were Laurentia (which included most of North America, Greenland, and the easternmost part of Siberia), Siberia (which was only part of today's political entity), and Baltica–Avalonia. Baltica, which today comprises most of northern Europe eastwards to the Ural Mountains, had been an independent terrane until about the Ordovician–Silurian boundary (443 Ma), when it collided with Avalonia, whose long narrow

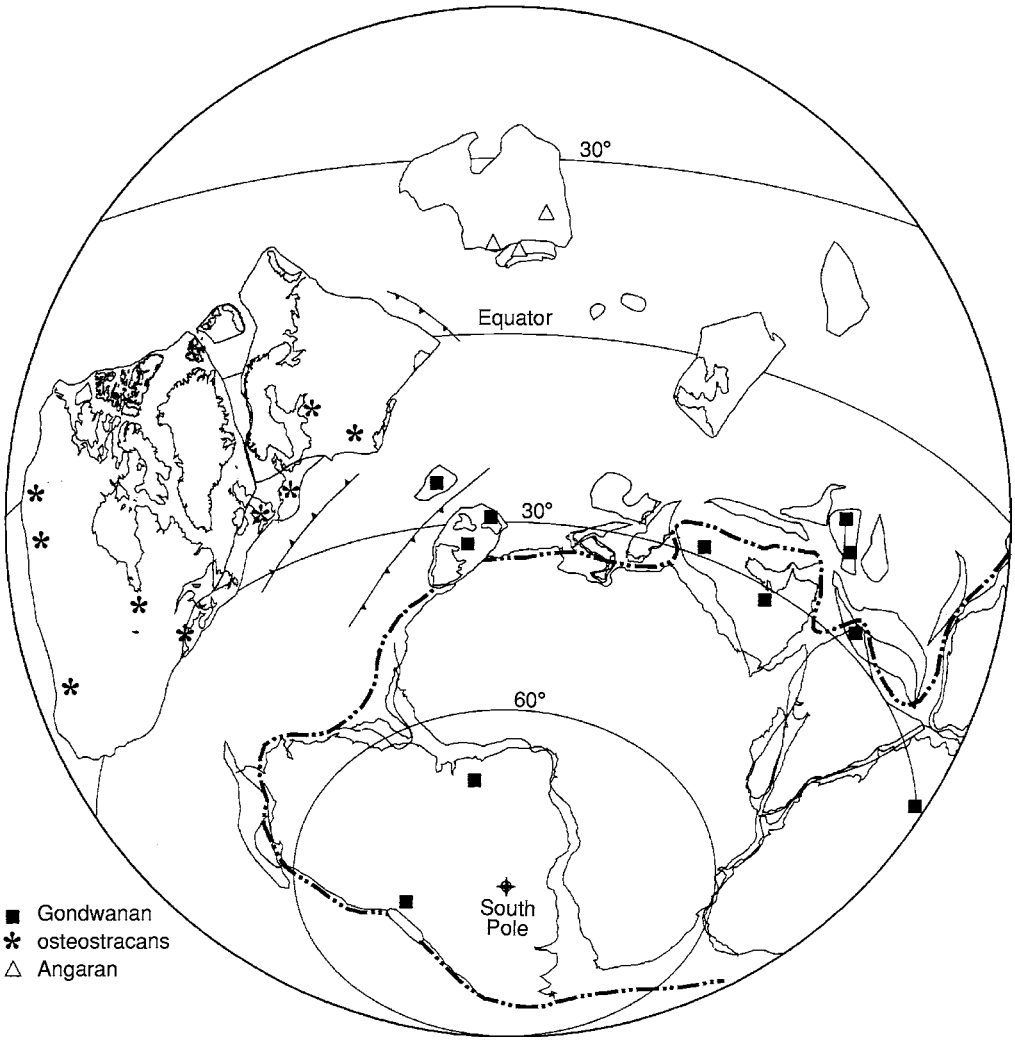

Figure 6 Palaeogeography at the Silurian Devonian boundary (approximately 420 Ma), showing the distribution of the earliest Devonian fishes. (Reproduced from Cocks LRM and Torsvik TH (2002) Earth geography from 500 to 400 million years ago: a faunal and palaeomagnetic review. *Journal of the Geological Society, London* 159: 631 644.)

area today includes the Maritime States of Canada and the USA as far south as Cape Cod, Massachusetts, eastern Newfoundland, southern Ireland, England, Wales, Belgium, Holland, and parts of northwestern Germany. North and South China were also independent terranes, as was Sibumasu, which stretched from Burma through Thailand and western Malaysia to Sumatra in Indonesia. There were also many smaller terranes, including Perunica (Bohemia, Czech Republic).

The oceans were dominated by the vast Panthalassic Ocean, which was comparable in size to today's Pacific. The Iapetus Ocean between Laurentia and Avalonia–Baltica, which had been very substantial in Cambrian and Ordovician times, was steadily closing. During the Late Ordovician some of the island arcs within Iapetus collided with and accreted to the eastern margin of Laurentia or the western margin of Avalonia–Baltica. The Silurian saw the major continent–continent collision between Laurentia and Avalonia–Baltica, which resulted in the closure of Iapetus and the Caledonian Orogeny (see above). This orogeny caused considerable uplift and formed the land supporting the Old Red Sandstone Continent in the Late Silurian and Devonian (**Figure 6**). The combined terrane that resulted from the Laurentia–Avalonia–Baltica collision is termed Laurussia. To the south of the Avalonian part of Laurussia the widening ocean between it and Gondwana is termed the Rheic Ocean.

Over a vast area of the continental shelf of Gondwana, today including France, Bohemia, the Iberian Peninsula, Italy, and much of northern Africa, anoxic conditions prevailed, precluding the colonization by benthos. The fossils preserved in the black shales deposited there consist largely of plankton, including graptolites and cephalopods. It was not until Late Silurian times in some of these areas, for example Bohemia, that the seafloor became oxygenated, enabling its colonization by brachiopods, crinoids, and other benthos.

The climate of the Silurian started cold. The latest Ordovician (Hirnantian) ice-cap was very widespread, but gradually receded in Llandovery times; the latest known Silurian glacial sediments are in the early Wenlock of Brazil, which was near the then south pole. It is not until the Late Llandovery (Telychian) that warmer-water carbonate deposits become common, but from then on into the Wenlock, Ludlow, and Pridoli the global temperature was obviously warm to hot. This can be deduced from the carbonate build-ups and bioherms present in the Wenlock type area of England and in Gotland and elsewhere and also from the Late Silurian evaporite deposits, which are widespread but best known from New York State, USA.

Devonian

G R McGhee, Rutgers University, New Brunswick, NJ, USA

Introduction

The Devonian Period of the Palaeozoic Era was only slightly shorter than the entire Cenozoic Era (63 million years as opposed to 65) and was a time of many 'firsts' in Earth history. The Devonian saw the explosive diversification of vertebrate life (e.g., new fish species that proliferated in both marine and freshwater environments) including the evolution of the first terrestrial vertebrates, the amphibians. In the oceans, the Devonian saw the evolution of the largest reef ecosystems in Earth history. Both plant and animal groups were rapidly evolving and invading the terrestrial realm, and in the Devonian the Earth's first forests evolved with trees that towered some 30 metres high. Yet it is also in the Devonian that the Earth suffered one of its greatest biodiversity crises, one of the 'Big Five' mass extinctions of life, and it is in the Devonian that the entire climate of the planet switched from a hot greenhouse state to a cold icehouse phase.

The Devonian System is named after fossiliferous marine strata exposed in Devonshire, southwest England. The English palaeontologists Adam Sedgwick (*see* **Famous Geologists:** Sedgwick) and Roderick Murchinson (*see* **Famous Geologists:** Murchison) first proposed that the fossils in Devon were younger than Silurian fossils, yet older than Carboniferous, in 1839. Subsequent stratigraphic work demonstrated that the Old Red Sandstone of Scotland and Wales, long thought to lie in the basal Carboniferous, was the non-marine facies equivalent of Devonian marine strata. The Devonian Period is divided into seven Ages, from oldest to youngest: the Lochkovian, Pragian, and Emsian (constituting the Early Devonian), the Eifelian and Givetian (Middle Devonian), and the Frasnian and Famennian (Late Devonian). Lochkovian and Pragian are in the Czech Republic, Emsian and Eifelian in Germany, and Givetian, Frasnian and Famennian in Belgium.

Life in the Sea

The Devonian was a time of major evolutionary innovation in the marine realm. The Devonian has been called the 'Age of Fishes', as it is in this period that the evolution of the major fish groups of today's oceans occurred (*see* **Fossil Vertebrates:** Fish). The explosive diversification of bony, ray-finned fishes (the Actinopterygii) took place in the Devonian, as did the origination of the first true sharks. Of particular note is the origination of the first lobe-finned fishes (the Sarcopterygii) as this group later gave rise to the amphibians, also in the Devonian. The ammonoids – externally shelled, swimming cephalopods distantly related to the modern-day chambered nautilus – first evolved in Devonian seas (*see* **Fossil Invertebrates:** Cephalopods (Other Than Ammonites)). These animals were active swimmers with widespread geographic ranges and possessed a characteristic high rate of speciation, two traits that made them valuable for biostratigraphic dating of sedimentary rocks for over 300 million years before their lineage perished in the Cretaceous–Tertiary mass extinction.

The largest development of reefal ecosystems in Earth history occurred in the Devonian. The great Devonian reefs are estimated to have covered over 5 000 000 square kilometres of seafloor at their maximum development, almost ten times the areal extent of reefal ecosystems seen in modern oceans. The Devonian was also the 'Golden Age of Biconvex Brachiopods' (*see* **Fossil Invertebrates:** Brachiopods), the period of maximum diversification of these 'shellfish of the Palaeozoic', an ecological role that is dominated by the bivalve molluscs today.

We are terrestrial animals, and we tend to think of life in terms of life on land, rather than in the seas. It was during the Devonian that life staged its dramatic invasion of the land, and that the origination of the first complex terrestrial ecosystems occurred.

The Invasion of the Land

The Plant Invasion

Life existed in the Earth's oceans for over three billion years before finally venturing out onto the harsh environments of dry land. The biological invasion of the land has deep roots, beginning with terrestrial autotrophic microbes in the Cambrian and progressing to simple mosses and liverworts in the Ordovician and Silurian. It was only in the Late Silurian to Early Devonian, however, that life's invasion of the land dramatically accelerated with the evolution of vascular land plants.

In the Lochkovian vascular land plants were confined mostly to lowland floodplains and stream margins. These plants were simple in structure, many with short vertical stems sometimes covered

with scale-like leaves (resembling asparagus spears), others with short vertical stems that branched into progressively smaller forks towards the top of the plant. The tallest of these plants was less than half a metre high, and they would remain the tallest terrestrial organisms on Earth for the first 17 million years of the Devonian (Figure 1).

By the time of the Emsian, competition for sunlight and space resulted in the development of woody tissues by several plant groups. Such support structures enabled plants that possessed them to grow taller than their neighbours. These included very primitive ferns and small tree-like lycopods (relatives of modern club mosses) that could reach two to three metres in height, and they were the tallest plants on Earth for the next 20 million years (Figure 1).

Vegetative height increased dramatically again in the Late Eifelian to Early Givetian with the evolution of arborescent plants that are characterized by secondary wood. The Earth's first forests evolved in the Givetian, and rapidly spread across the continents in the hot climates of the Frasnian, from tropical to almost subpolar regions. In the Early Frasnian the first true woody trees appeared, the progymnosperms of the genus *Archaeopteris* (ancient relatives of modern nonflowering evergreens). *Archaeopteris* trees towered from 10 to 30 metres high in Late Devonian forest landscapes (*see* **Fossil Plants:** Gymnosperms). These were accompanied by strange sphenopsid trees (which looked like gigantic reeds) and lycopsid trees 10 to 20 metres tall.

The last major Devonian advance in plant evolution was the evolution of seed plants in the Late Famennian. Reproduction by seeds (rather than spores) freed land plants from their confinement to moist lowland areas and allowed them to spread into much drier inland areas and into the harsher climates of highlands (Figure 1).

The evolution of increasing vertical height in land plants during the Devonian is mirrored in the evolution of deeper and deeper root penetration into the ground below, and the progressive formation and spread of new soil types. In the Late Pragian some of the herbaceous lycopods penetrated just a single centimetre into the ground. Root penetration increased to 20 centimetres with the evolution of arborescence in the Givetian, and in the Frasnian *Archaeopteris* trees had roots that penetrated to depths of over 100 centimetres. Both the evolution of land plants themselves, and their effects on soil formation (*see* **Soils:** Modern) and rock weathering on the land, were to have a profound impact on both the Earth's atmosphere (*see* **Atmosphere Evolution**) and hydrosphere, and precipitated the global climatic shift from the Early Devonian 'greenhouse' climate to the Late Devonian 'icehouse' climate.

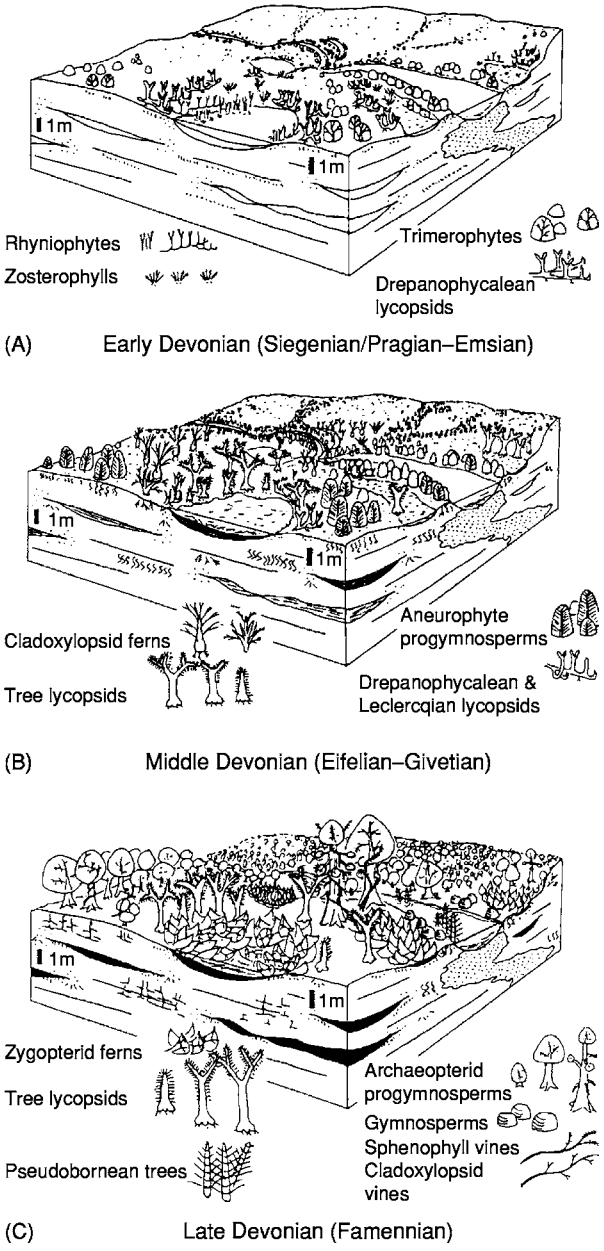

Figure 1 Palaeobotanical and palaeoecological reconstructions of Early Devonian (A), Middle Devonian (B), and Late Devonian (C) upland floodplains. (Adapted from Algeo, Scheckler and Maynard (2001), used with permission.)

The Animal Invasion

Plants are autotrophic organisms, producing their own food by photosynthesis. Plants are used as a food source by animals, and it is no coincidence that the evolution of land plants was quickly followed by the appearance of land animals.

Although millipedes may have made the transition to land as early as the Ordovician, it is in the Late

Silurian and Early Devonian that the animal invasion of the land began in earnest. Millipedes, centipedes, and extinct spider-like arachnids were present on land in the Late Silurian, and became much more numerous in the Early Devonian. Scorpions successfully invaded freshwater streams in the Late Silurian, and emerged onto dry land in the Early Devonian. The earliest known insect-like hexapods appeared in the Pragian, ancient ancestors of the insects that today comprise over 70% of all animal species.

Larger vertebrates were soon to follow, as many of these used the smaller arthropods (*see* **Fossil Invertebrates:** Arthropods) as a food source. The Devonian is justly called the 'Age of Fishes' due to the rapid diversification of numerous fish species that occurred during this period. Many of these species invaded freshwater habitats on land. The most important of these is *Eusthenopteron*, a lobe-finned fish that is anatomically very similar to – and has been cited as the direct ancestor of – the well-known Famennian amphibian *Ichthyostega*. Fossil trackways and fragmentary skeletal material suggests that the evolution of amphibians, the ancestors of all land dwelling vertebrates today, probably took place in the Frasnian.

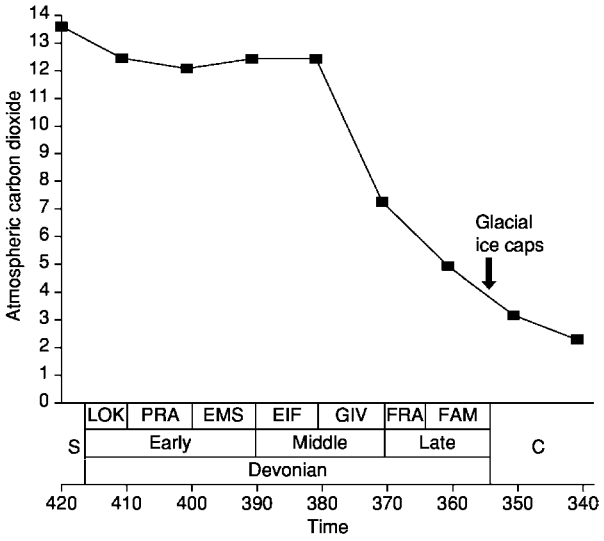

Figure 2 Atmospheric carbon dioxide concentrations during the Devonian, where the amount of carbon dioxide in the atmos phere is measured in factors of the carbon dioxide concentration in the atmosphere at the present (taken as the preindustrial level of 300 ppm). Timescale is in million of years before the present. Abbreviations: S Silurian, LOK Lochkovian, PRA Pragian, EMS Emsian, GIV Givetian, FRA Frasnian, FAM Famen nian. Data from Berner (2001), timescale after Gradstein and Ogg (1996).

The Devonian Global Climatic Shift

The Devonian is a critical period in the Earth's climate history. During this period the global climate switched from the hot greenhouse phase of the earlier Palaeozoic to the cold icehouse phase of the later Palaeozoic, a phase that would lead to continental glaciations in the succeeding Carboniferous and Permian.

The Devonian cooling trend was driven by a sharp decline in the partial pressure of carbon dioxide in the atmosphere from the Givetian to the Early Carboniferous (Figure 2), a decline driven by the establishment of extensive terrestrial land plant cover (discussed in the previous section) and associated soil weathering. Land plants themselves fixed atmospheric carbon in their tissues (*see* **Carbon Cycle**), and nutrient run-off produced by their activity on land triggered blooms of phytoplankton growth in the Devonian shallow seas. This, in turn, led to further atmospheric carbon fixing and organic carbon burial in extensive Middle and Late Devonian black-shale deposits. Chemical weathering of rocks by land plants also produced massive run-off of calcium and magnesium-rich minerals which precipitated as carbonates in the oceans, further drawing down the carbon dioxide partial pressure of the atmosphere.

From the Lochkovian through to the Eifelian the carbon dioxide concentration in the Earth's atmosphere was some 12 to 14 times greater than that of the modern atmosphere (Figure 2). By the end of the Givetian the carbon dioxide concentration had dropped to a little over seven times as great as the present, and in the Early Carboniferous the carbon dioxide content of the atmosphere was only about twice that of the modern atmosphere (Figure 2). Carbon dioxide is the most well-known of the greenhouse gasses, gasses that promote heat retention in the Earth's atmosphere. It is clear that the dramatic decline of carbon dioxide partial pressures in the atmosphere during the 40 million years from the Givetian to the Early Carboniferous must have made the atmosphere more transparent to heat loss, and it is no coincidence that glacial ice-caps formed and spread on the Earth's southern continent of Gondwana in the latest Devonian (Figure 2).

Late Devonian Biodiversity Crises

Life diversified and proliferated in the world's oceans during the first 30 million years or so of the Devonian (Figure 3). Then the trend reversed. Marine biodiversity began to decline in the Emsian and continued to decline, first slowly and then very abruptly, from the Eifelian through the Frasnian. Life rediversified briefly during the Famennian, but then marine biodiversity declined to a very substantial low at the close of the Devonian (Figure 3).

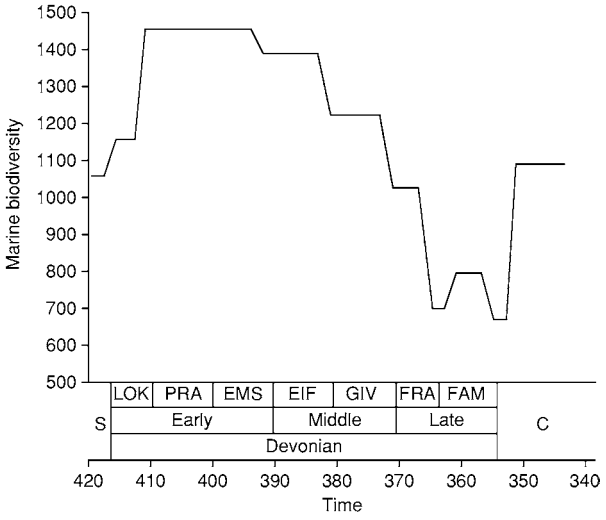

Figure 3 Marine biodiversity during the Devonian, where bio diversity is measured as the number of genera of marine organ isms that are well preserved in the fossil record. (Data from Sepkoski (1996).)

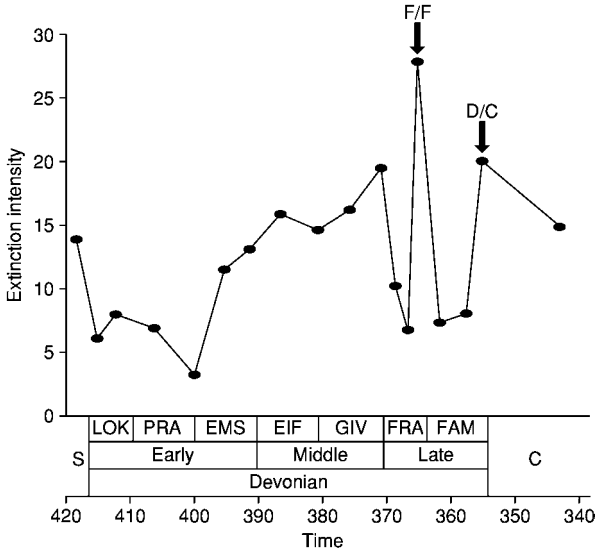

Figure 4 Extinction intensities during the Devonian, where intensity is measured as the percent of marine genera that go extinct per time interval. Positions of the Late Devonian (F/F) and end Devonian (D/C) extinction peaks are marked with arrows. (Data from Sepkoski (1996).)

The factors controlling the Devonian pattern of biodiversity gain and loss are complex, and not all factors are agreed upon to the present day. In general, the biodiversity gain seen in the Lochkovian was a recovery of biodiversity lost in extinctions that occurred in the Late Silurian. The Pragian saw the evolution of many new taxa, pushing Devonian marine biodiversity to levels higher than any that had existed previously in the Palaeozoic, but many of these new taxa were endemic, however, and having restricted geographic distributions and confined to local regions. Global sea-level began to rise in the Emsian and continued to rise through the Frasnian (perhaps due to the initiation of continental rifting in the Ukraine region of Europe), gradually breaking down barriers between marine regions and facilitating species migration. With the progress of rising sea-levels and increased species migration in the oceans, endemic local faunas successively became extinct and were replaced by more cosmopolitan migrants. By the Early Frasnian, biodiversity in the Devonian seas had dropped to levels comparable to those seen at the beginning of the Devonian (Figure 3), but these seas were now populated by cosmopolitan species with wide geographic distributions.

The gradual decline in marine biodiversity from the Emsian through to the Givetian was mirrored in the gradual increase in extinction intensity within marine faunas during this same interval (Figure 4). Extinction intensity reached a peak in the Late Givetian, with the elimination of most of the previously existing endemic faunas, and then fell to levels comparable with those seen in the Lochkovian and Pragian and within the cosmopolitan faunas of the Frasnian (Figure 4). Very abruptly, extinction intensity within these same cosmopolitan faunas jumped to a level seen only five times in Earth history, and precipitated an equally abrupt loss of marine biodiversity (Figure 3). This is the Late Devonian mass extinction, also termed the Frasnian/Famennian (F/F) mass extinction or the Kellwasser bioevent, and was the first of the Late Devonian biodiversity crises.

The second Late Devonian biodiversity crisis occurred at the very end of the Devonian, and is variously termed the end-Devonian extinction, the Devonian/Carboniferous (D/C) extinction, or the Hangenberg bioevent. The extinction intensity of the end-Devonian extinction was only slightly more severe than that seen in the Late Givetian (Figure 4), but was markedly different in that it was an abrupt jump in extinction, rather than the culmination of a long trend of increasing extinction magnitudes (Figure 4).

Causes of the Late Devonian Biodiversity Crises?

The End-Devonian Biodiversity Crisis

It is generally agreed that the end-Devonian biodiversity crisis, or Hangenberg bioevent, was triggered by global cooling and associated continental glaciation. In the very latest Famennian, just before the end of the Devonian, extensive glacial ice-caps formed in regions

of Gondwana (present day South America), ice-caps that extended to sea-level. Global sea level had begun to fall earlier in the Famennian, and continued to fall throughout the Famennian, indicating the probable formation of high-altitude mountain glaciers considerably before the end of the Famennian.

The end-Devonian extinctions began slightly earlier in the marine realm than the terrestrial, but the entire period of extinctions appears to have spanned only 100 000 years. Although the observed extinctions of marine animals were not as great as those in the Late Devonian mass extinction (Figure 4), the effect of the end-Devonian extinction on land plants and on phytoplankton in the sea was much more severe. In particular, the towering *Archaeopteris* trees that had been so widespread and characteristic of Late Devonian forests rapidly declined in abundance during the Late Famennian climatic cooling, barely surviving into the Early Carboniferous before dying out.

The end-Devonian ice caps were clearly the result of global cooling, which itself was most likely triggered by the dramatic decrease in atmospheric carbon dioxide throughout the latter half of the Devonian (Figure 2). By the end-Devonian, carbon dioxide concentrations in the atmosphere were only three to four times higher than those at present (Figure 2).

The Late Devonian Biodiversity Crisis

The principal cause of the Late Devonian extinction also appears to have been global cooling, but the pattern of cooling has a very different signature than that seen at the end of the Devonian, and the cause of the cooling remains controversial. Palaeobotanical evidence shows that the Frasnian world was quite warm, with extensive shallow seas covering much of the continental landmasses. In these warm seas the great Devonian reefs (*see* **Fossil Invertebrates:** Corals and Other Cnidaria), and other high-diversity marine ecosystems, proliferated. In contrast to Frasnian climates, the Early Famennian world appears to have been cold and arid. The great forests shrank in their areal extent, and were confined to low-latitude equatorial regions. The uplands and high-latitude regions of the Earth supported only very sparse vegetation in conditions that were not only very cold but were also very dry, without perennial snow. In the oceans, huge reef tracts died out all over the world during the latest Frasnian. The few reef organisms that managed to survive into the Famennian were confined to what few warm waters still existed on the Earth, in restricted regions along the equator.

It is still not clear what triggered the collapse of the Frasnian hot climates, and the rapid fall of global temperature into the cold Famennian world. The rapidity of the Late Frasnian cooling is particularly noteworthy, and quite different from the gradual pattern of cooling seen at the end of the Devonian that culminated in continental glaciation. Geochemical evidence indicates that tropical sea-surface temperatures fell by as much as 5° to 7°C in two abrupt pulses, separated by about 300 000 years, in the Late Frasnian to Early Famennian interval.

Three competing hypotheses are at present being debated concerning the ultimate cause of the Late Devonian biodiversity crisis. The 'Devonian plant hypothesis' proposes that both the Late Devonian and end-Devonian biodiversity crises were triggered by the evolution and spread of extensive land plant cover (Figure 1), and the effects of that new terrestrial plant biomass on the atmosphere (Figure 2) and on the oceans (particularly the massive increase in nutrient input to marine ecosystems). However, the Late Devonian biodiversity crisis occurred some 10 million years before the end of the Devonian (Figure 4). All attempts to find geologic evidence of glaciation in the Late Frasnian to Early Famennian interval to date have failed. Global sea-level was at an all-time high for the Devonian, indicating there was no major build-up of glacial ice in this time interval (although apparently rapid oscillations in sea-level during the Late Frasnian and Early Famennian may indicate the formation of small, high-altitude alpine-type glaciers). Atmospheric carbon dioxide concentrations were six times higher than at the present day (Figure 2), and approximately twice as high as those present during the formation of the end-Devonian glacial ice-caps. Many argue that these facts, particularly the rapidity of the temperature drops during the Late Devonian biodiversity crisis, indicate a substantially different triggering mechanism than that seen for the end-Devonian extinctions.

The 'volcanic winter hypothesis' proposes that an interval of catastrophic flood-basalt volcanism occurred during the Late Frasnian. One of the climatic effects of such extensive volcanism is hypothesized to have been rapid global cooling, due to the vast amount of debris, ash, and gasses injected into the Earth's atmosphere. A volcanic-produced global dust and gas cloud would have blocked light from the sun, from reaching the Earth's surface, triggering planet-wide lethally cold temperatures even at the equator.

The catastrophic volcanism scenario is based upon the recognition that there have been other flood-basalt episodes in Earth history, during which enormous amounts of lava, gasses, and volcanic dust have been produced in volcanic eruptions of almost unimaginable magnitude. These flood-basalt fissure eruptions are produced by gigantic plumes of molten rock that originate deep in the Earth's mantle, which then

slowly rise to produce paroxysms of volcanic eruptions over huge geographic areas when they intersect the Earth's surface. Several flood-basalt episodes are known to have occurred at other times of biotic crisis, such as the eruption of the Siberian flood basalts during the Permo-Triassic mass extinction and the Deccan flood basalts during the Cretaceous–Tertiary mass extinction.

Vast regions of the bottoms of the Earth's oceans were depleted in oxygen during the Late Devonian. It has been argued that the great geographic extent of these anoxic water masses were produced in part by extensive submarine volcanism, and hence might be evidence for catastrophic volcanic episodes during the Late Devonian. In addition, a major continental rift-system is now known to have been active in the Ukraine region of Europe during the Late Devonian (the Pripyat–Dnieper–Donet rift), and many of the Earth's flood-basalt fissure eruptions are associated with rifting and spreading of the Earth's tectonic plates.

However, the volume of volcanic material erupted in the Pripyat–Dnieper–Donet rift appears to be relatively small (less than 10 000 cubic kilometres), and thus the intensity of the volcanism associated with the rift was not near the magnitude associated with the Siberian or Deccan flood basalt fissure eruptions (both of which produced well over a million cubic kilometres of volcanic material). Likewise, the extensive spread of anoxic bottom waters in the Late Devonian seas, and the characteristic black-shale deposits within these seas, has been argued to have been due more likely to greatly enhanced organic productivity in the phytoplankton. The greatly increased influx of nutrients into the oceans, produced by the effects of extensive land plant cover on the land (**Figure 1**), is believed to have produced widespread eutrophication in Devonian shallow seas. Bacterial degradation of phytoplankton rain and burial of the massive amounts of organic carbon fixed by eutrophication is a more probable cause of the Late Devonian black-shale deposits than submarine volcanism.

Another hypothetical way to produce a rapid drop in global temperature would be to impact the Earth with a large asteroid or comet, in essence to produce an 'impact winter' instead of a 'volcanic winter'. As in the case of the hypothesised Late Frasnian glaciations, extensive searches for geologic evidence of major impact events in the Late Frasnian have produced very few hard data. In contrast, considerable evidence exists for several impact events in the Early Frasnian, but about three million years before the biodiversity crisis in the Late Frasnian. In particular, three impact events are currently dated to have occurred between 369 to 367 million years ago: the Alamo impactor, which produced ejecta debris that covers over 19 000 square kilometres of southern Nevada (USA) and which is estimated to have produced a crater 70 kilometres in diameter, the Siljan impactor, which produced a 52-kilometre-diameter crater in Sweden, and the Flynn Creek impactor, which produced a 3.5-kilometre-diameter crater in Tennessee (USA). These impacts all occurred on the Earth's continents; however, an unknown number of additional impacts may also have occurred in the Earth's oceans, for which we have no geologic record.

The 'lag-time multiple impacts hypothesis' proposes that these Early Frasnian impacts produced an abrupt increase in global temperature rather than a decrease. The Alamo impactor in particular struck carbonate target rock, and would have produced a massive injection of carbon dioxide into the atmosphere. The climatic effect of these known Early Frasnian impactors, and of other impacts as yet poorly dated but known to have occurred during the span of the Late Devonian, is argued to have produced an anomalous greenhouse interval that interrupted the Givetian to Carboniferous gradual decline in global temperatures (**Figure 5**). The collapse of this anomalous greenhouse interval, and the rapid drop in global temperatures produced by the resumption of the pre-existing global cooling trend, is proposed to have produced the observed rapidity of temperature fall seen during the Late Devonian biodiversity crisis (**Figure 5**). This hypothesis would also account for

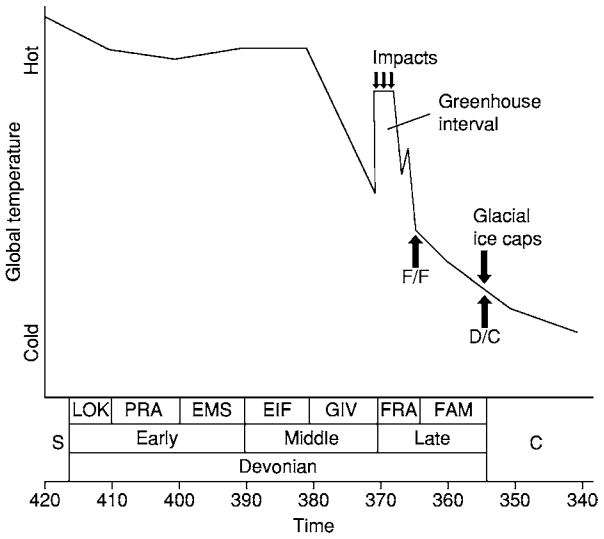

Figure 5 A proposed temperature curve for the Late Devonian, based upon the lag time multiple impacts hypothesis. Several known impacts that occurred in the Early Frasnian are proposed to have produced an anomalous greenhouse interval, interrupting the gradual cooling trend from the Givetian to the Carboniferous. Positions of the Late Devonian (F/F) and end Devonian (D/C) biodiversity crises are marked with arrows.

the apparent anomaly of hot Frasnian climates immediately preceding cold Famennian ones, indicated by the palaeobotanical evidence, whereas a gradual cooling trend produced by gradually decreasing atmospheric carbon dioxide levels (**Figure 2**) would predict Late Frasnian climates only slightly warmer, and different, from the Early Famennian.

The ultimate test of any of the proposed causal scenarios for the Late Devonian biodiversity crisis rests upon the construction of an accurate and detailed temperature curve for the entire Late Devonian period of time. Such a task will be laborious, but it is now technically feasible with oxygen-isotope analyses and laser-based sampling of conodont elements.

Carboniferous

A C Scott, Royal Holloway, University of London, Egham, UK

Introduction

The Carboniferous, spanning 60 Ma, was an important period in Earth history, with major changes in atmospheric composition (in terms of both oxygen and carbon dioxide), the development of an icehouse world, the formation of vast tropical peat (coal) deposits, and the radiation of plants and animals on land. In particular, vertebrates got a major foothold on land and the air was conquered by the insects. The vast supercontinent of Pangaea was also formed during this period. The significance of the Carboniferous can be demonstrated by the fact that it was one of the first geological periods to be recognized. Despite this and the fact that Carboniferous rocks and fossils

have been amongst the most widely studied, very few formal definitions of the units of the Carboniferous have been internationally ratified.

Historical Setting

The Carboniferous was named by William Conybeare and William Phillips in 1822, based upon their work in northern England. From their studies, particularly in Yorkshire, they recognized a distinctive coal-bearing sequence, which had an important limestone sequence below. The frequent coals, which were economically important, are reflected in the name. The lower limestone unit became known as the Mountain Limestone, and the coal series became known as the Coal Measures.

This sequence of rocks was found across much of Western Europe, and the Carboniferous was divided into the Lower Carboniferous, comprising predominantly marine limestones, and the Upper Carboniferous, comprising clastic and coal-bearing strata. In continental Europe these two major divisions were termed the Dinantian and Silesian. In North America, however, whilst a similar sequence of limestones and coals was found, the divisions were named the Mississippian by Winchell and the Pennsylvanian by Williams. Unfortunately, the boundary between them did not coincide with the boundary defined in western Europe. To complicate matters even further, a three-fold division of the Carboniferous was recognized in Russia.

Chronostratigraphy and Biostratigraphy

Through the Heerlen congresses, and later the International Carboniferous Congress, held in Europe, North America, South America, and China through the twentieth century, a number of attempts to divide the Carboniferous into stages and to correlate local stages worldwide were made. Local stages were erected with formal boundary stratotypes, but there is often confusion as to usage in the literature. Currently, whilst the Carboniferous stage nomenclature has been agreed, few boundaries have yet been defined by the International Commission on Stratigraphy (ICS) (Figure 1).

Devonian–Carboniferous Boundary

The base of the Carboniferous System (also the base of the Tournaisian Stage) has now been formally defined as the first appearance of the conodont *Siphonodella sulcata* within the evolutionary lineage from *Siphonodella praesulcata* to *Siphonodella sulcata*.

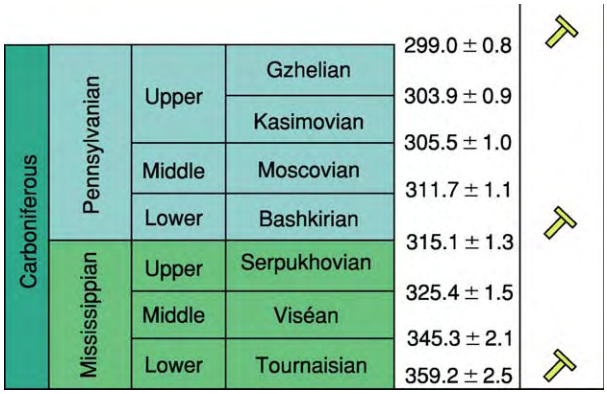

Figure 1 Current statigraphical nomenclature for the Carboniferous. Reproduced from the International Commission on Stratigraphy. Taken from ICS website.

The Global Standard Section and Point is at the base of Bed 89 in Trench E′ at La Serre in southern France. The rocks in the La Serre sequence are marine, belonging to the 'klippen of cabrières', comprising biodetrital oolitic limestones within a pelagic matrix of shale and cephalopod-bearing calcilutites. The fauna is varied and includes trilobites.

Carboniferous–Permian Boundary

The base of the Permian System (and hence the top of the Carboniferous System) is defined as the first occurrence of the 'isolated-nodular' morphotype of *Streptognathodus* '*wabaunsensis*' conodont chronocline, 27 m above the base of Bed 19, Aidarabsh Creek, northern Kazakhstan, which is in the southern Ural Mountains. The strata comprise hemipelagic silt and clay, with occasional lenses of sand and very course sand. The marine fauna, in addition to conodonts, includes ammonoids and fusilinid benthic foraminifera.

Mississippian–Pennsylvanian Boundary

Following considerable debate, the division of the Carboniferous System into two subsystems has been agreed. These two subsystems have been named the Mississippian and Pennsylvanian, although their usage may not always correspond with previous usage. The mid-Carboniferous boundary does not coincide with the boundary between either the Lower and Upper Carboniferous or the Dinantian and Silesian of previous schemes. In Europe the boundary is within the Namurian of older usage (Figure 2).

The base of the Pennsylvanian is also the base of the Bashkirian stage. The Global Standard Section and Point has been located at the lowest occurrence of the conodont *Declinognathodus nodiliferus* s.l., 82.9 m above the top of Battleship Wash Formation, Arrow Canyon, southern Nevada, USA.

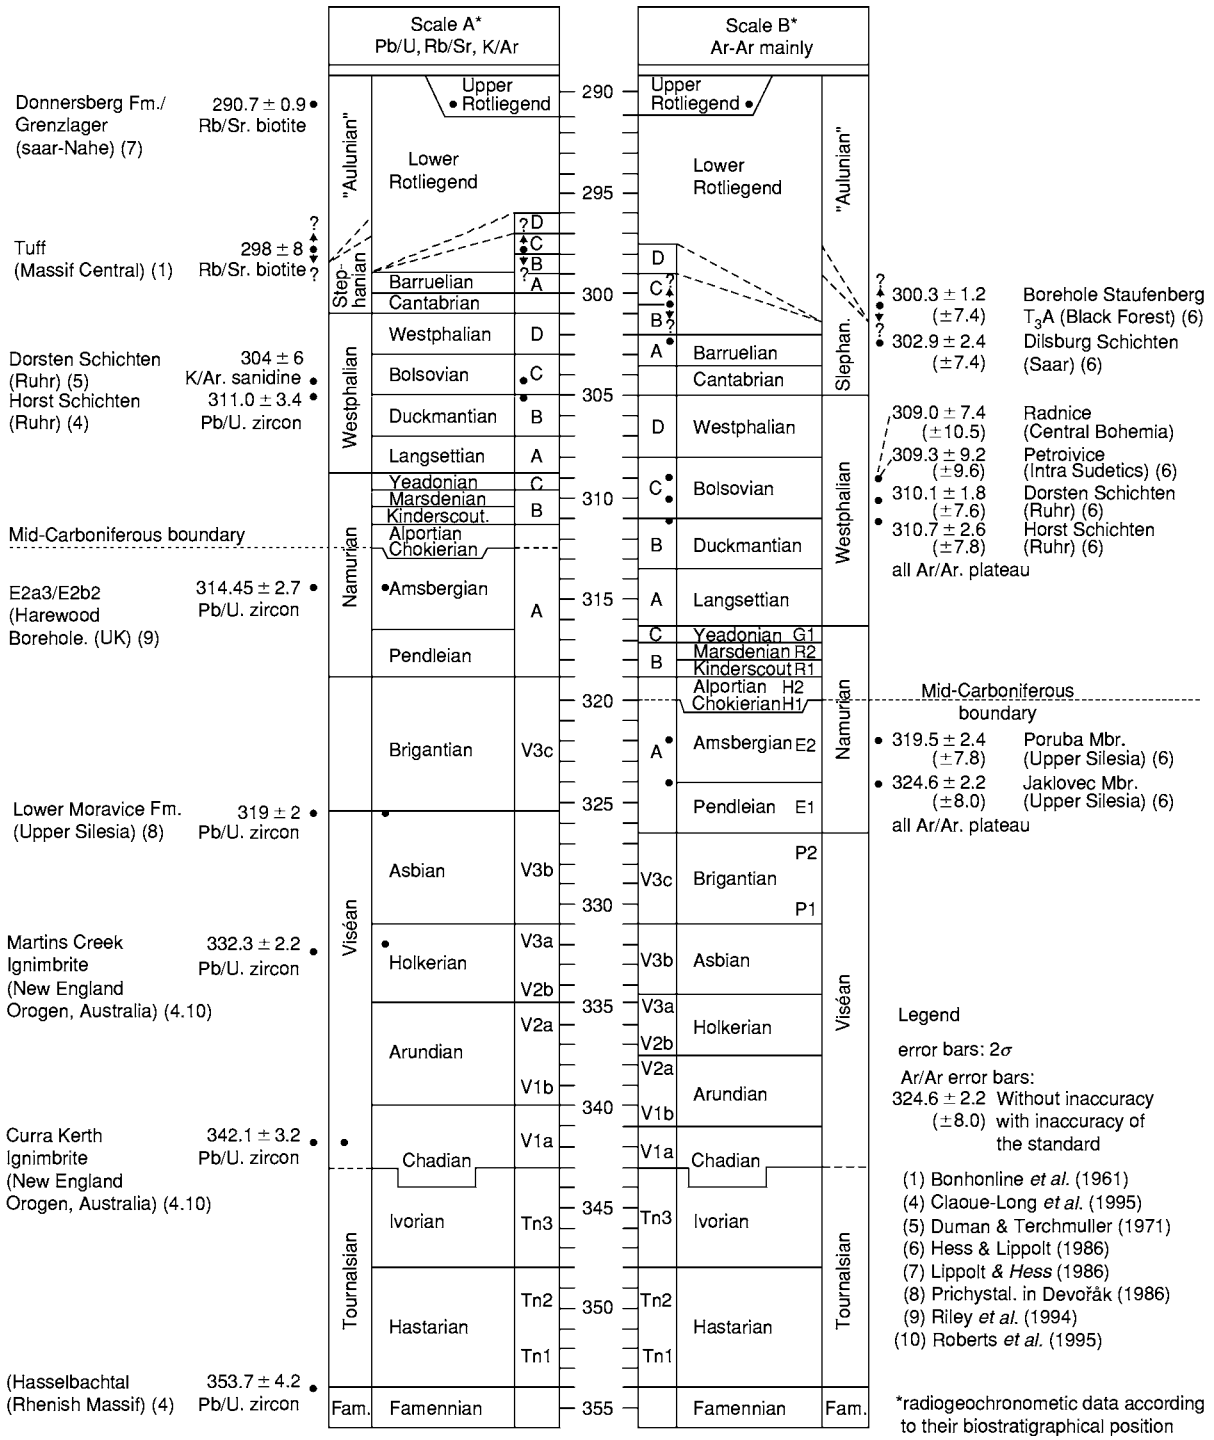

Figure 2 Absolute ages of Carboniferous strata obtained using different dating techniques and using a traditional Carboniferous chronostratigraphical nomenclature. Reproduced from Menning M, Weyer G, Drozdzewski G, Van Amerom HWJ, and Wendt I (2000) A Carboniferous time scale 2000: discussion and use of geological parameters as time indicators from central and western Europe. *Geologische Jahrbuch*, Hannover, A 156: 3 44.

Carboniferous Subdivisions

The Mississippian is now formally divided into three Stages (although these may become Series): Tournaisian, Viséan, and Serpukhovian. The Tournaisian–Viséan and Serpukhovian–Viséan boundaries have still to be formally placed. The Pennsylvanian is now formally divided into four: Bashkirian, Moscovian, Kasimovian, and Gzhelian. The Bashkirian–Moscovian,

Moscovian–Kasimovian, and Kasimovian–Gzhelian boundaries have yet to be decided. The division of the Carboniferous into formally internationally agreed series and stages may take a considerable time.

Absolute Ages

There is currently considerable debate over the absolute ages of Carboniferous sequences. Traditionally, most dates have been obtained from tonsteins (volcanic ash deposits) within coal seams. The ICS currently provide a number of dates. The base of the Carboniferous is stated by the ICS as 359 Ma and the top of the Carboniferous as 299 Ma, making the Carboniferous 60 Ma long. The mid-Carboniferous boundary is given as 318 Ma, making the Mississippian 41 Ma and the Pennsylvanian 19 Ma long. Menning, in his review of Carboniferous absolute time-scales, showed that there is a significant discrepancy between different radiometric-dating techniques (Figure 2). Traditional dates using uranium–lead dating techniques are in conflict with those obtained using argon–argon techniques. In scale A of Figure 2 the dates are from a series of techniques using uranium–lead, rubidium–strontium, and potassium–argon. A number of these involve the use of uranium–lead dates of zircons. Here the mid-Carboniferous boundary is placed at approximately 313.5 Ma. In contrast, scale B uses mainly argon–argon dates and the mid-Carboniferous boundary is placed at 320 Ma. The current trend is to place more reliance on the argon–argon dates, but it must be made clear that there are relatively few data points.

Biostratigraphy

Many groups of fossils have been used for biostratigraphical zonation and correlation. In the predominantly marine strata of the Mississippian, corals and brachiopods were widely used in Europe. Goniatites (cephalopods) have also been extensively used, particularly in North America. On land both vascular plants and non-marine bivalves have been widely used since the end of the nineteenth century. Advances in micropalaeontology in the mid-twentieth century brought the use of microfossils to the fore. Both foraminifera and conodonts became widely used in the later part of the twentieth century. Conodonts have, in marine strata, become the zonal fossils of choice, being used to define major chronostratigraphical boundaries. On land macrofossil plants and, more recently, pollen and spores (palynomorphs) have been widely used. Palynomorphs were first used to help correlate Pennsylvanian coal seams, and subsequent work on their distribution in clastic sediments has allowed them to be used to establish zones that can be correlated across continents. The use of pollen and spores for zonation and correlation was extended into the Mississippian, and they have the advantage not only of being found in non-marine strata but also of being washed or blown into marine rocks. This has allowed correlation between marine and non-marine sequences.

Lithologies and Environments

Within the Carboniferous equatorial belt, warm shallow-water carbonates dominate Mississippian sequences. This is what Derek Ager termed the 'persistence of facies.' Mississippian facies differ markedly in temperate and higher latitudes. Carboniferous sequences in South America, Australia, and South Africa are characterized by cold-water and often glacial deposits. In Europe, later Mississippian and Early Pennsylvanian deposits are commonly clastic shales and sandstones, which were lain down in thick deltaic sequences. By the later part of the Mississippian, commercial coals are found, such as in the Viséan of the Moscow Basin.

Widespread regression, possibly related to the onset of a major glaciation, allowed extensive mires to form throughout the tropics (Europe and North America) (Figure 3). Later Carboniferous deposits in Euramerica are characterized in many places by coal-bearing sequences. It was during the Pennsylvanian that many of the world's economic bituminous coals were formed. Some of these seams are several metres thick, taking tens of thousands of years to form. Many of the larger coal basins show evidence of regular marine influxes. The resulting marine bands, often containing goniatites, have been widely used for basinal and even intercontinental correlation. The regular sequences of non-marine rocks, in some cases with associated marine bands, have, on various scales, been called cyclothems and mesothems. The regular transgressive–regressive cycles, so well displayed in the mid-west of the USA, are thought to be the result of eustatic changes caused by the waxing and waning of the southern ice-sheet.

The later part of the Pennsylvanian is characterized by increasing aridity. Coal-forming mires shrank and peat-forming plants became extinct. In China, however, some of these environments and vegetation continued into the Permian. The drier environments supported very different vegetation from that which characterized the wet lowland habitats. Interbasin correlation, therefore, becomes difficult in some of these areas.

The Carboniferous World

Plate Reconstructions

The Carboniferous saw the gradual accretion of many continental landmasses. At the beginning of the Mississippian, two or three major continents had formed (Figure 4A). Europe and North America had collided to form Euramerica, which has also been termed Laurussia or Laurasia. Accretion was still active, with collision and uplift of the Appalachian mountain belt, which may have been a response to the northward migration of Africa. The Rheic Ocean, south of Britain, continued to close. The far-east Asian plate assemblies were more complex. Siberia was in the temperate northern hemisphere and is also known as Angara. China, comprising a northern block and a southern block, was also north of the equator, but there is dispute as to whether these two blocks had collided by the Carboniferous. This area is known as Cathaysia.

Many of the southern continents formed the supercontinent of Gondwana (*see* **Gondwanaland and Gondwana**). In the Carboniferous there continued to be continental accretion, for example in South America. Through the Carboniferous the northern and southern continents continued to amalgamate (Figure 4B) so that by the Permian the giant supercontinent of Pangaea (*see* **Pangaea**) had formed.

Palaeobiogeography

There have been several recent attempts to assess the palaeobiogeography of early Carboniferous vegetation using data from either macrofossils or pollen and spores. Taking the Mississippian as a whole, it is generally considered that the world's floras were predominantly cosmopolitan, characterized by assemblages including the lycopod genus *Lepidodendropsis* (Figure 5A), which was a widespread arborescent form that did not shed its leaves. The only regionally separate flora that has been recognized is the Angaran flora, which comprises mainly endemic genera. However, an additional temperate floral belt has recently been suggested. A larger number of regional floras have been recognized using mathematical techniques, but these analyses suffer from many problems, not least concerning the identity and age of the plants in question, some of which were first studied in the nineteenth century. These attempts of course have taken into consideration only compression plant genera, and there has been much recent work on anatomically preserved taxa, which can rarely be correlated with compression taxa. In addition, as might be expected, within any given region floras may vary because of ecological or preservational controls.

By the end of the Carboniferous, clear regional floras can be recognized (Figure 5B). The best-studied flora is that of Euramerica. This region comprised Europe (including eastern Europe) and North America and was, during this period, equatorial with a warm humid climate. The floras comprise diverse taxa typified by the species preserved in the Pennsylvanian Coal Measures, in particular the lycopods *Lepidodendron*, *Sigillaria*, and *Lepidophloios*, the sphenopsid *Calamites*, the ferns *Corynepteris*, *Renaultia*, and *Pecopteris*, the seed-ferns *Neuropteris*, *Alethopteris*, and *Mariopteris*, the cordiate *Cordaites*, and the conifer *Lebachia* (*Walchia*).

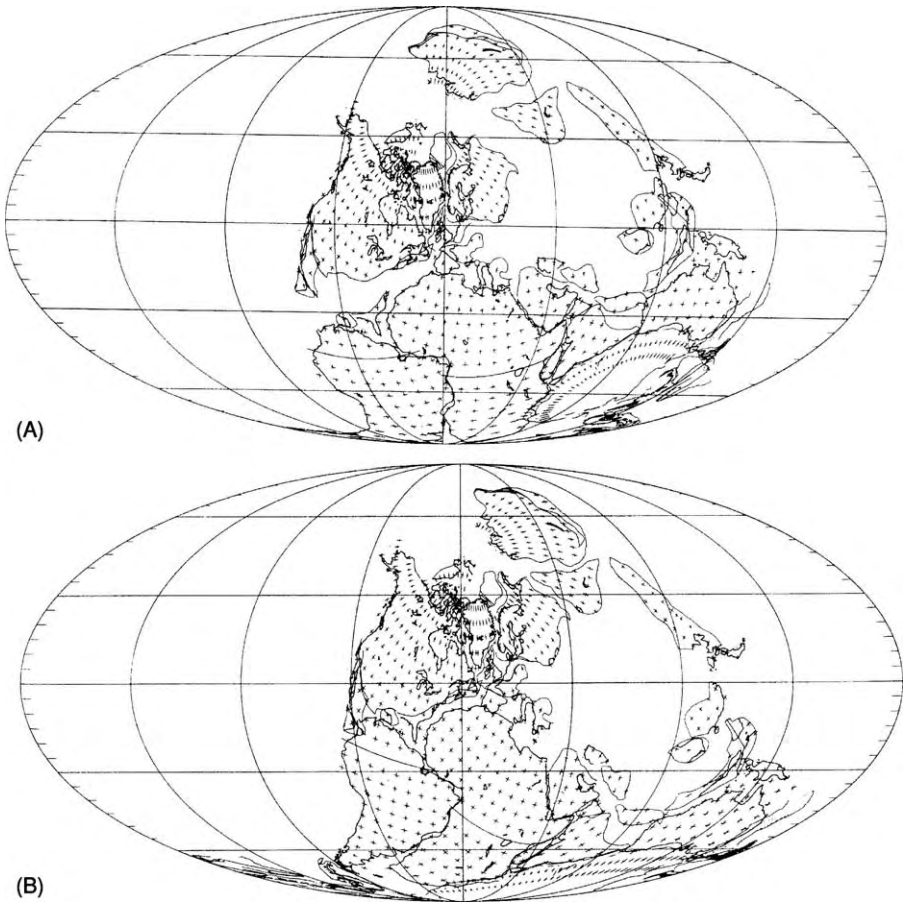

Figure 4 Plate reconstructions for (A) the Mississippian (Viséan) and (B) the Pennsylvanian (Moscovian). Reproduced from Scotese CR and McKerrow WS (1990) Revised world maps and introduction. In: McKerrow WS and Scotese CR (eds.) *Palaeozoic Palaeogeography and Biogeography*, pp. 1 21. Memoir 12. London: Geological Society.

The Gondwanan flora, characterized by the seed-fern *Glossopteris* and its relatives, is found during the Early Permian in Australia, Brazil, Africa, Antarctica, and India.

The Late Carboniferous flora from Australia is problematic. It comprises several genera with fern-like foliage, which have been linked to Early Carboniferous northern genera. There are two possible explanations for these occurrences: either they represent a relict population, which migrated southwards during the Carboniferous and survived in Australia after becoming extinct elsewhere, or, more likely, they belong to different plants with a similar leaf morphology. These plants include *Rhacopteris* and *Triphyllopteris*.

This regionalization of floras may partly reflect latitude – the *Glossopteris* flora is found in the high-latitude southern hemisphere, the Euramerican flora is found in equatorial areas, and the Angaran flora is found at high latitudes in the northern hemisphere – and may also reflect different climatic regimes (Figure 5C). This is supported by the fact that strata bearing the *Glossopteris* flora of Gondwana often overlie tillite horizons. The Cathaysian flora is also problematic, with the main regionalization in China occurring in the Permian.

The Carboniferous Atmosphere

The atmospheric composition changed markedly through the Carboniferous, and this period was one of the most unusual in Phanerozoic history (Figure 6).

Models of atmospheric oxygen for the Carboniferous by Berner and others show that the present atmospheric level of oxygen, 21%, was probably reached by the end of the Devonian. Oxygen levels are thought to have risen considerably during the Carboniferous, reaching a peak well above 30% by the Pennsylvanian. This rise in atmospheric oxygen may have been a result of the occurrence of

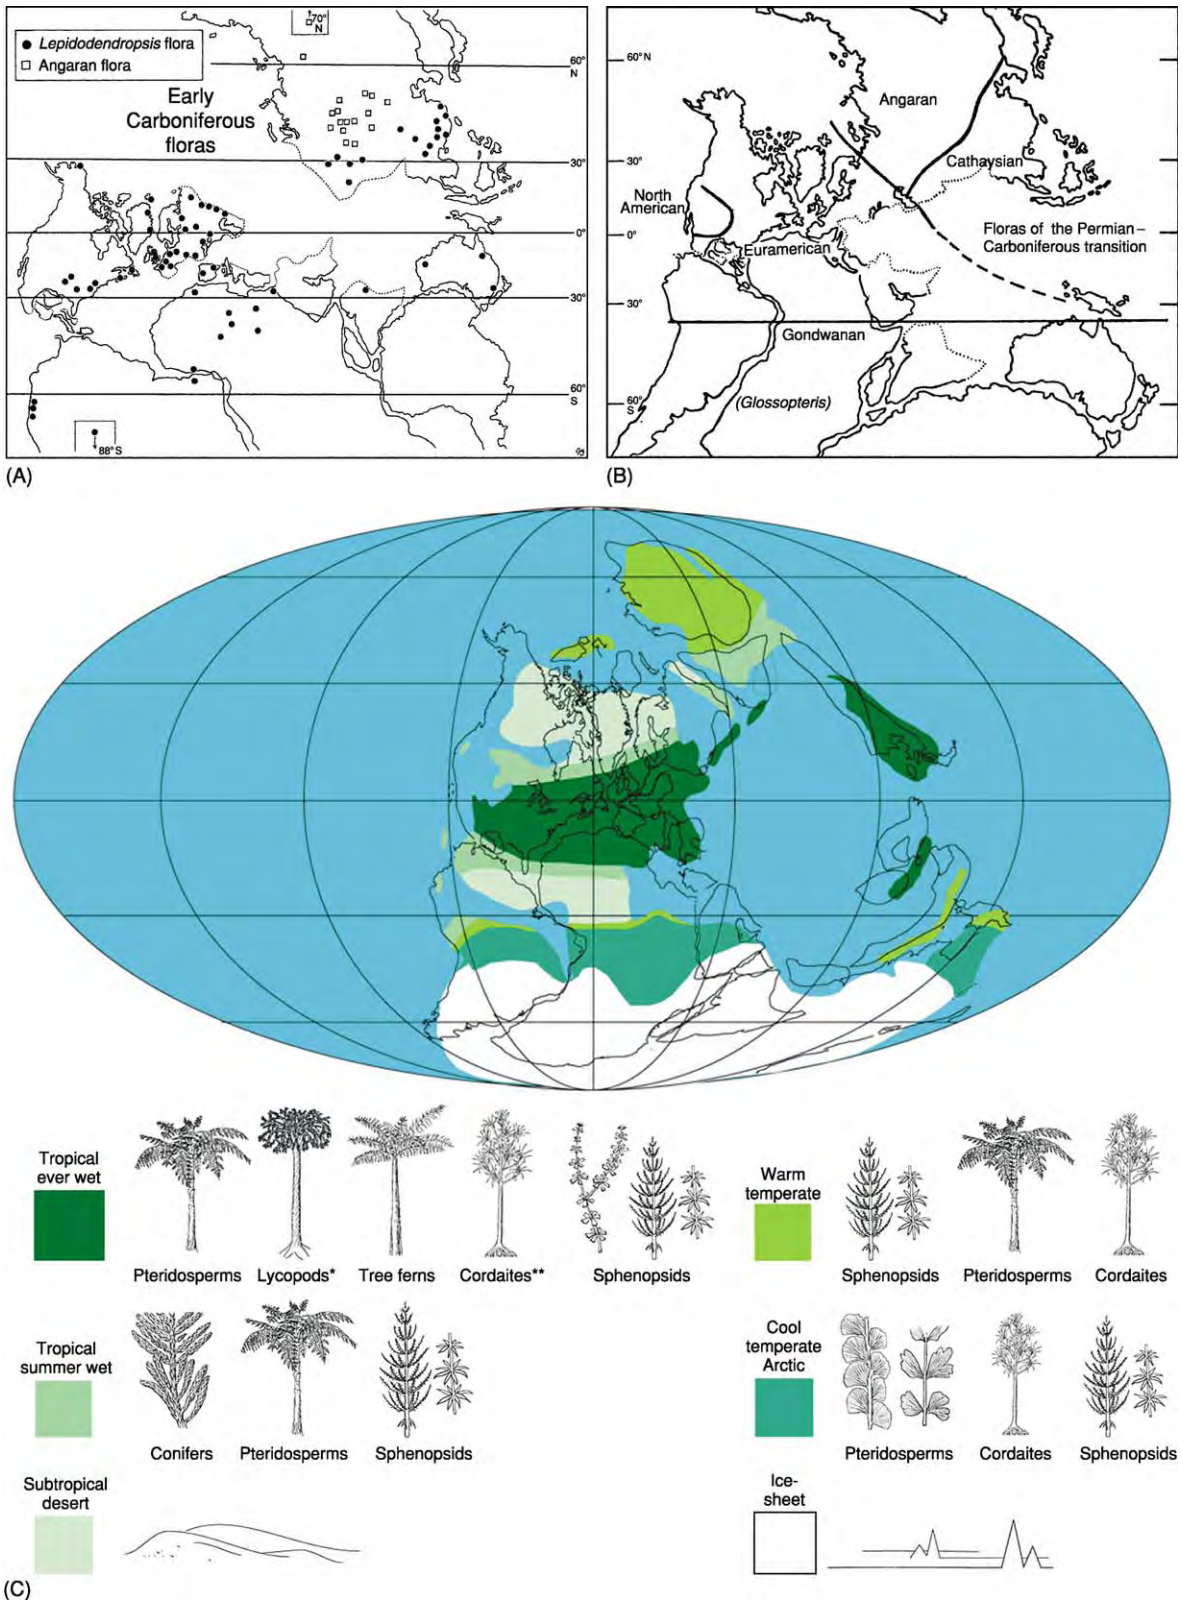

Figure 5 Palaeobiogeographical reconstructions of the Late Carboniferous showing (A) the floral provinces of the Mississippian (reproduced from Chaloner WG and Lacey WS (1973) *The Distribution of Late Palaeozoic Floras*. Special papers in Palaeontology 12. pp. 271 289), (B) the floral provinces of the Carboniferous Permian transition (adapted from Chaloner WG and Lacey WS (1973) *The Distribution of Late Palaeozoic Floras*. Special papers in Palaeontology 12. pp. 271 289.), and (C) Pennsylvanian biomes (reproduced from Willis KJ and McElwain JC (2002) *The Evolution of Plants*. Oxford: Oxford University Press).

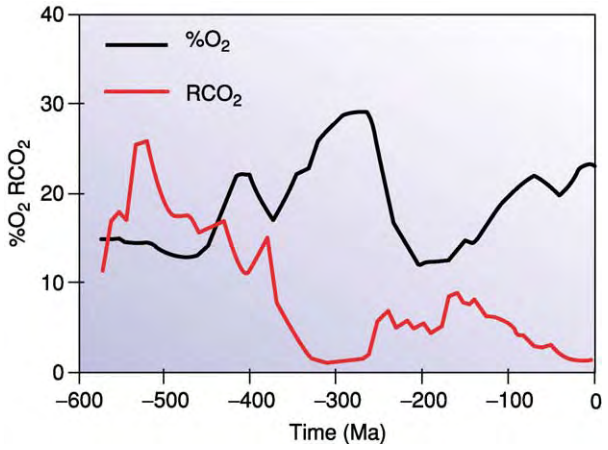

Figure 6 Changes in atmospheric composition over the Late Proterozoic and Phanerozoic, showing falling carbon dioxide and rising oxygen levels during the Carboniferous (360 300 Ma). Reproduced from Berner RA (2003) The long term carbon cycle, fossil fuels and atmospheric composition. *Nature* 426: 323 326.

widespread lowland tropical rainforest. The later postulated rapid fall in oxygen may have been a result of the demise of these extensive tropical coal-forming forests. The oxygen-rich atmosphere may have had a significant effect on animal evolution, allowing the growth of giant arthropods including insects. In addition, fires may have been more widespread and intense.

In contrast, levels of carbon dioxide fell rapidly at the end of the Devonian and during the Early Carboniferous. This coincided both with the evolution and initial spread of trees and with the onset of extensive peat formation and, hence, burial of carbon, in addition to the burial of extensive shallow-water carbonates. All of these factors combined to cause a major drawdown of carbon dioxide. The major climatic changes in the Late Carboniferous–Early Permian may be linked to increasing levels of carbon dioxide. The impact of these low levels of carbon dioxide on the Carboniferous world was severe, plunging it into a major icehouse phase, as evidenced by the spread of the polar ice-cap in the southern continents.

The Carboniferous Climate: Icehouse Conditions

One of the major glaciations in Phanerozoic history occurred in the Late Palaeozoic, beginning in the Carboniferous and ending in the Permian (Figure 7). The world, therefore, went from greenhouse conditions to icehouse conditions and back to greenhouse conditions. Striated pavements and glacial tillites both indicate the presence of a southern polar ice-cap across the Gondwanan continents (Figure 8). All other aspects of this glacial episode, however, are open to at least some debate.

- Onset. The onset of glacial conditions has been difficult to date. Palynological dating of South African sequences suggests that glaciation may have begun as early as the Devonian–Carboniferous boundary. Unequivocal evidence from tillites and inferences from carbon isotope excursions indicate that a significant ice-cap existed by Late Mississippian times. It is believed that the earliest glacial deposits are those of South America.
- Spread and extent. It has been shown that the onset of glaciation spread to South Africa and Antarctica and thence to Australia and India. Typically glacial tillites (e.g. Dwyka of South Africa) overlie striated pavements and are overlain by temperate coal-bearing strata. Whilst on palaeogeographical maps a large polar ice-cap is often shown across much of southern Gondwana, it is not clear whether this was the case or whether a smaller ice-sheet moved as the continents moved.
- Demise. Just as the bases of the glacial deposits across Gondwana are diachronous, so too are the overlying non-glacial deposits. Remnant ice-caps may have been present in upland areas, but Permian coal-bearing strata are found in South America, South Africa, Antartica, India, and Australia. The cessation of glaciation also appears to be diachronous, being older in South America and younger in Australia.
- Causes. Whilst a number of key facts about the Gondwanan glaciation and the Carboniferous world have been established, there is little agreement about cause and effect.

Climate change can be seen over several different time-scales, all of which have been well documented for the Carboniferous. The longest cycle, causing a change from greenhouse to icehouse cycles, may have been caused by the combination of plate movements, atmospheric change, orbital cycles, and the evolution of land plants. These factors continued to act throughout the Carboniferous. There are changes in both local and global climate through the Carboniferous. The occurrence of evaporates in some Mississippian deposits indicates a drier environment than that seen in the Pennsylvanian. Widespread wetland systems occurred in tropical regions during the Pennsylvanian (Figure 9).

Orbital-eccentricity cycles and axial-tilt and precession cycles have intermediate- and short-term climatic effects. However, these effects may be modified by local tectonic or orographic conditions. Studies of coals and vegetation show major wet–dry cycles

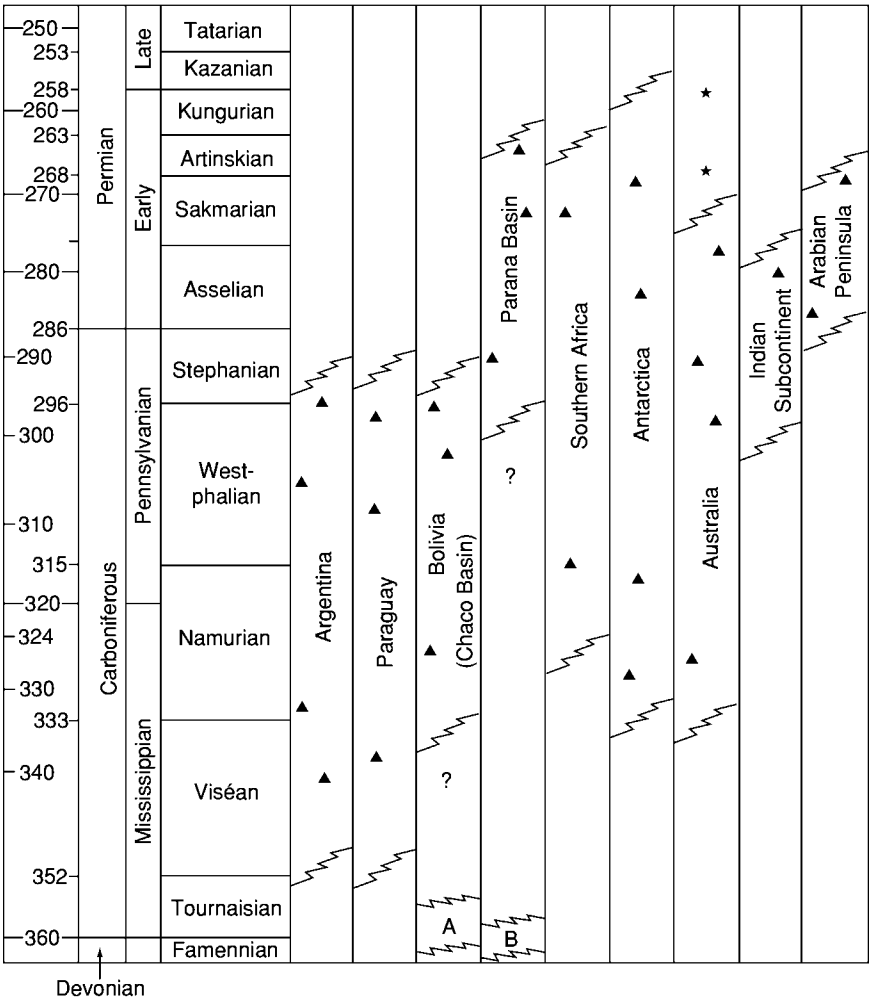

Figure 7 Timing of glaciation in the Late Palaeozoic across Gondwana. Reproduced from Eyles N (1993) Earth's glacial record and its tectonic setting. *Earth Science Reviews* 35: 1 248.

during the Pennsylvanian of Illinois. These changes in rainfall had a dramatic effect on vegetation and on peat (coal) formation. In particular, a major drying phase at the Westphalian–Stephanian boundary caused the extinction of a number of peat-forming lycophytes (Figure 9). Increasing aridity towards the end of the Carboniferous is also widely documented. The broad wet–dry cycles seen in Illinois are not always seen in other Euramerican basins, although the broad picture is confirmed (Figure 10).

Milankovitch cycles have been proposed to have caused waxing and waning of the ice-sheet over the southern continents, leading to rises and falls in sea-level (*see* **Earth:** Orbital Variation (Including Milankovitch Cycles)). It has been suggested that these sea-level changes may have been responsible for the cyclothemic and mesothemic units that are seen particularly well in the Pennsylvanian.

The Nature and Influence of Fire in Carboniferous Ecosystems

Fires may range from commonly seasonal to rare and catastrophic. Climate may play a significant role in controlling the frequency of fires. It is possible that, in addition to large-scale climatic changes, smaller-scale changes in climate may play a significant role in the occurrence of fires. It is possible that in some ever-wet environments fires are unusual. Disturbance of the normal climatic regime (e.g. El Niño events) may cause temporary changes in the rainfall pattern, for example, leading to a dry period when a catastrophic fire may occur. This may be the reason for the Great Fire of Borneo in 1982–1983. Small fluctuations in rainfall pattern may allow frequent small fires in a mire-forming environment. Storms may follow a major fire, and the increased erosion may give rise to the transportation and deposition of a sediment–charcoal mix at several sites. The occurrence of fusain (fossil charcoal) layers in the fossil record may be used to distinguish between events of different timescales.

The effects of large-scale fires are illustrated by the Lower Carboniferous marginal-marine fusain deposits at Shalwy Point, Donegal, Ireland. Here, there is no doubt that the fire was catastrophic. The widespread nature of the fire not only yielded significant amounts of charcoal but also would have led directly to increased soil erosion, which in turn would have led to a major increase in bed load in the alluvial system.

Life on Land

There were many major changes in the terrestrial biota during the Carboniferous.

Plants

The Early Carboniferous saw a major radiation in many groups of vascular land plants. Amongst spore-bearing plants, lycopsids underwent a major radiation into several new ecological niches. Extensive peat mires were developed for the first time. At this time sphenopsids also became abundant, with forms such as *Archaeocalamites* being particularly widespread. There was a dramatic diversification of ferns during the Mississippian, with zygopterid ferns being particularly abundant. It has been proposed that these plants were the primary colonizers of volcanic terrains throughout Europe.

The most important plant radiation at this time was in the seed plants. In particular, pteridosperms

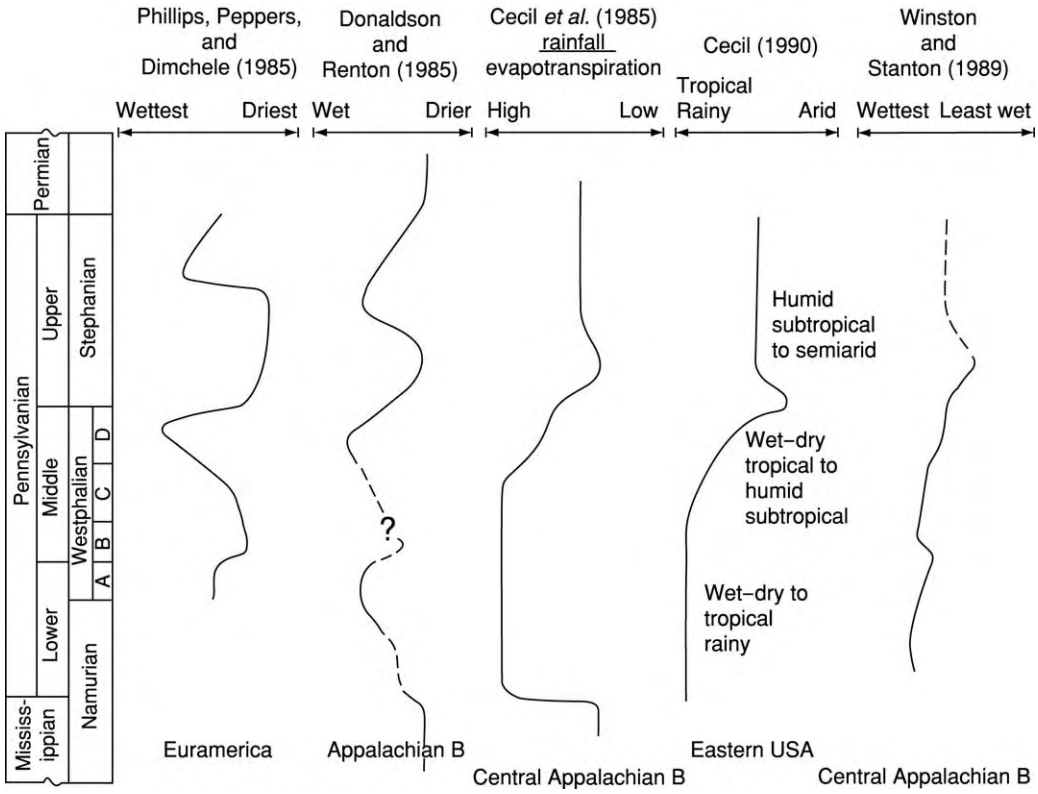

Figure 10 Interpreted palaeoclimatic trends for the Euramerican coal basins during the Pennsylvanian. Reproduced from Calder JH and Gibling MR (1994) The Euramerican Coal Province: controls on Late Paleozoic peat accumulation. *Palaeogeography, Palaeoclimatology, Palaeoecology* 106: 1 21.

underwent a rapid radiation into a variety of lowland habitats. The abundance of anatomically preserved specimens in the Mississippian of Scotland has allowed detailed phylogenetic studies of these plants.

Several plant groups diversified during the Pennsylvanian. The lycopods are the main coal-forming plants of the Carboniferous. They are also known as club mosses but are, of course, true vascular plants. Today only a few genera of herbaceous forms survive, but in the Carboniferous they showed a vast array of life habits from small herbaceous forms to large arboresent (tree) forms. Much of our recent data on these important plants has come from the study of coal balls – anatomically preserved fossils where the internal anatomy can be elucidated. As with the lycopods, Carboniferous sphenopsids are represented by both arborescent and herbaceous forms.

Ferns are plants with well-developed megaphyllous leaves. All the Carboniferous forms are homosporous. Fern-like foliage is abundant in the Pennsylvanian Coal Measures but most belongs to the pteridosperms (seed-ferns). The identification of true ferns in the compression fossil record requires fertile specimens. The Carboniferous was once known as the age of ferns because of the abundance of fern-like foliage amongst the compression fossils. It was shown, however, that most of this foliage belongs to an extinct group of plants that bore seeds and pollen organs, known as the pteridosperms or seed-ferns. Three major families are known from the Upper Carboniferous: Lyginopteridales, Medullosales, and Callistophytales. These were either shrubs or climbers in the vegetation.

The most advanced plants of the late Carboniferous were the closely related cordaites and conifers. It is still unclear whether the cordaites gave rise to the conifers or whether they had a common ancestor. Both, however, are gymnospermous and are represented by both trees and shrubs. The conifers were probably major elements in drier upland floras.

Terrestrial Invertebrates

The East Kirkton terrestrial Mississippian Lagerstätten has opened a major window on a terrestrial ecosystem. Several invertebrate groups are first found here or there is evidence of their terrestrial nature. The fauna includes eurypterids, scorpions, myriapods, and a spider, in addition to aquatic arthropods such as ostracods. The eurypterids were large and

include *Hibbertopterus*. The scorpions show unequivocal evidence of terrestrial adaptations and specimens over 30 cm long have been found; they may have reached up to 1 m in length and been a top predator. Other arthropods include millipedes and an opilionid or Harvestman spider.

No fossil insects are known from East Kirkton; the first unequivocal evidence of true insects (Hexapoda: Pterygota) does not occur until the Early Pennsylvanian, although there are recent claims of early Devonian insects. Insects of the Pennsylvanian had wings.

The terrestrial fauna of the Pennsylvanian Coal Measure forests included many carnivorous animals. Centipedes (Myriapoda: Chilopoda) were common, especially in the Mazon Creek fauna of Illinois, as were many spiders (Arachnida: Aranae), some of which had inward-striking (dianial) fangs, indicating an ability to kill insects and other groups of spiders that possessed downward-striking (paraxial) jaws for attacking prey on a firm substrate, either on the ground or on tree trunks.

The first insects, which make an appearance in the Namurian, were members of the extinct order Palaeodictyoptera. Together with five other orders they comprise the Palaeoptera, and all have their origins in the Pennsylvanian. Two orders, the Ephemeroptera (mayflies) and Odonata (dragonflies and damselflies) are extant.

The other Carboniferous orders are, like the Palaeodictyoptera, extinct, surviving only until the end of the Permian. The Protodonata were very similar to the first dragonflies except for a variation in wing venation and their great size. The Megasecoptera and Diaphanopterodea were very similar to the Palaeodictyoptera.

Five orders of exopterygote neopteran insects also appear in the Pennsylvanian. Three of these orders became extinct at the end of the Palaeozoic. These were the Protorthoptera, which was the most diverse of all the extinct orders, the Caloneurodea, which some workers place in the Endopterygota, and the Miomoptera, which were very small insects, perhaps related to the Protorthoptera. The other two orders, the Blattodea (cockroaches) and Orthoptera (grasshoppers, katydids, and crickets), are extant. The Blattodea were apparently the commonest group of insects during the Pennsylvanian. There is increasing evidence of plant–insect interactions in the Carboniferous.

Vertebrates

The Carboniferous saw the diversification and spread of vertebrates onto land. Earliest Mississippian deposits contain relatively few tetrapod fossils. Some late Tournasian deposits in Scotland and Canada have yielded a few isolated fragments. The later Viséan rocks, mainly of Scotland, have yielded many important new skeletons. A single small specimen of tetrapod, named *Casineria kiddi*, has been described from mid-Viséan deposits in eastern Scotland. The anatomical features of the specimen indicate that it was fully terrestrial. The most spectacular finds in recent years have come from the Late Viséan deposits of East Kirkton. Amongst a wide range of taxa, all less than 1 m long, are the temnospondyls. Other forms include early anthrocosaurs. This group is better known from Pennsylvanian strata. *Westlothiana lizziae* (Lizzie the lizard) is a species of particular note as it shows many of the characteristics of reptiles.

Several tetrapod groups show evidence of major diversification in the late Mississippian and early Pennsylvanian (*see* **Fossil Vertebrates:** Palaeozoic Non-Amniote Tetrapods). Most of the important tetrapod sites are found in tropical Euramerica and include the North American sites of Linton (Ohio), Mazon Creek (Illinois), and Joggins (Nova Scotia), several British and Irish sites, including Jarrow and Newsham, and continental European sites, such as Nyrany (Czech Republic).

The temnospondyls underwent a major radiation in the early Pennsylvanian and were the largest group of 'amphibians.' The most important of these was the small *Dendrerpeton*, which was first found in the tree stumps at Joggins. Amongst the temnospondyls were several aquatic forms. The anthracosaurs were another important group of tetrapods, also with a Mississippian origin. They included the crocodile-like embolomeres such as *Eoherpeton*. The most fearsome predator in this group was *Anthracosaurus*, which is known only from its skull.

Microsaurs also have a Mississippian origin; they include several important genera and have been confused with true amniotes. Other related groups include the lysorophids and aiistopods. Amniotes (including the reptiles for some authors) are first found in the Mississippian but radiated in the Pennsylvanian. Whilst several reptiles are known from the Pennsylvanian, it is clear that terrestrial tetrapod faunas were dominated by amphibians. It is significant to note that, with the possible exception of *Scincosaurus*, all the major Upper Carboniferous tetrapods were probably carnivores or insectivores.

The first true amniote (as opposed to ancestral group) was also found at Joggins. *Hylonomus* was amongst the animals found within the Joggins tree stumps. Other forms include *Captorhinus*, but it was not until the latest Carboniferous that herbivory evolved in larger forms, such as *Edaphosaurus*. In the Early Permian of Gondwana there is evidence of the

first aquatic amniote, *Mesosaurus*, which is found on several continents. It is in the Permian that the first major radiation of amniotes occurred.

Life in the Sea

Much of our knowledge about Carboniferous marine life comes from the extensive tropical shallow-water carbonates of the Mississippian. These warm shallow seas supported a rich benthos dominated by filter-feeding brachiopods and crinoids. Plankton diversity appears, however, to have been low, with the fauna dominated by only a few groups of acritarchs (marine aquatic algae). In some areas reefs dominated by rugose and tabulate corals together with sponges, bryozoans, and calcareous algae were important. Fusiline foraminifera became important for the first time. Nektonic animals included goniatites and such vertebrates as conodonts, which are important for biostratigraphical correlation. Undisputed conodont animals were discovered in the Mississippian rocks of Eastern Scotland associated with various aquatic arthropods. Fishes are also found in many marine and non-marine environments. A variety of sharks are known from Carboniferous deposits, and some of the best examples (such as *Stethacanthus* from Bearsden in Scotland) are from brackish marine deposits. Ray-finned and lobe-finned fishes also diversified in the oceans at this time.

The structure of Pennsylvanian marine communities was similar to that in the Mississippian. However, Pennsylvanian marine strata are not as widespread. In Europe the spread of marine facies across low-lying mires is well documented. The marine rocks are predominantly muddy and yield goniatites, bivalves, and conodonts, in contrast to the limestones that yield corals and brachiopods in addition to the goniatites and conodonts known from North America and Ukraine. Fusiline foraminifera became increasingly abundant through the Pennsylvanian in these carbonate environments.

The End of the Carboniferous and Mass Extinctions

Major changes took place at the end of the Carboniferous. Plate movements resulted in the continued collision of Laurasia and Gondwana to form the supercontinent Pangaea. The formation of Pangaea led to major climatic change, with tropical drying and the spread of continental red beds. The decrease in rainfall prevented peat formation in more tropical areas and was accompanied by the apparent extinctions of many terrestrial plant and animal groups. The floras of dryer upland habitats began to spread towards the lowlands. These floras were dominated by the newly evolved conifers. In the southern latitudes, the floras that had been typical of the Carboniferous, composed of progymnosperms, pteridosperms, spenopsids, and dwarf lycopsids, gave way to the glossopterid-dominated floras of the Permian. Recent research in China has shown that many of the extinctions in Euramerica at the end of the Carboniferous were local and not global. Several Carboniferous plant and animal groups are found in the Permian of China and become extinct only at the end of the Permian.

In the oceans there was continued faunal turnover, with some groups becoming extinct and others, such as the fusiline foraminifera, diversifying and becoming more important and widespread – they are particularly useful for defining the base of the Permian and for correlating subsequent Permian stages. There is no evidence, however, of a mass extinction at the end of the Carboniferous.

Permian

P B Wignall, University of Leeds, Leeds, UK

Introduction

The Permian Period, spanning the 43 Ma interval between 294 Ma and 251 Ma, witnessed several major turning points in Earth's history. Pangaea, the greatest supercontinent of all time, finally amalgamated in the Permian, and began to break up again almost immediately in a prolonged disintegration that would finally finish in the Cretaceous. Climate also changed markedly: the extensive southern-hemisphere glaciation that had begun in the Carboniferous concluded in the Middle Permian, to be replaced by a warming trend that was to peak in the earliest Triassic with some of the warmest conditions the world has ever experienced. The Permian was also a time of extremes in the fortunes of plants and animals. The Early to Middle Permian was generally a successful time for life, with low extinction rates and the evolution of the first large land animals and of plant communities that invaded the continental interiors. In contrast, the end of the Middle Permian was marked by an extinction crisis that primarily affected the inhabitants of shallow tropical seas. This was the first such crisis since the end of the Devonian, 100 Ma previously, and it brought to an end one of the most benign intervals of Earth history. Much worse was to follow with the end-Permian mass extinction, by far the biggest disaster in the history of life.

Subdivisions of Permian Time

Dividing the Permian into smaller time units has always proved surprisingly controversial. Whereas the subdivision of other intervals, such as the Jurassic and Cretaceous, has been stable and established for many decades, the current chronostratigraphical scheme for the Permian (Table 1) is only a few years old, and numerous other schemes can be found in the older literature. The problem stems principally from the lack of useful fossils available to correlate Permian strata in different regions of the world. In contrast, Ordovician stratigraphers can easily subdivide time using a succession of extremely widespread graptolite fossils, and Jurassic stratigraphers similarly use ammonites for subdivision and global correlation. For a long time Permian stratigraphers used ammonoids to define biozones, but these tend to be restricted to specific regions and in many areas are absent altogether. For example, there are extensive exposures of Permian rocks in western and Arctic Canada, but ammonoids are extremely rare in these deposits. In particular, since there are no ammonoids diagnostic of Late Permian time in this region, it was thought that Late Permian rocks were not present there. It now appears more likely that such rocks are present but the diagnostic fossils are not – a crucial distinction. Much Permian correlation is now achieved using conodonts (*see* **Microfossils:** Conodonts), a group of microfossils that are widespread in marine sediments of this age and therefore more useful than the ammonoids in establishing global time units.

Despite recent advances, there are still problems with correlating Permian rocks, primarily because different intervals of time are defined in different regions. Thus, the Early Permian (Cisuralian) is based on sections from Russia, the country where the period was originally defined; the Middle Permian (Guadalupian) is based on US sections, mostly in Texas; and the Upper Permian (Lopingian) is based on excellent marine sections in South China. Two Russian names, the Dzhulfian and the Dorashamian, were commonly used for the Late Permian interval, but these proved very difficult to identify outside the region, once again because of problems with the localized occurrences of ammonoids. As a result, the Dorashamian Stage – identified using ammonoids – was thought to be absent in most regions, but the essentially equivalent Changxingian Stage – identified using conodonts – is known to be widespread.

Tectonics

For nearly 200 Ma, from the Ordovician to the Permian, the Earth's continents gradually coalesced until eventually most continental crust had been amalgamated to form the supercontinent of Pangaea (Figure 1) (*see* **Pangaea**). The final stage of closure occurred during the Permian with collision of the Siberian continent with the Laurussian portion of northern Pangaea, the Eurasian Orogeny. This produced the Urals, a narrow and very long mountain belt that extends from the Volga region of southern Russia to Novaya Zemlya in the Arctic Ocean. During the Permian this newly forming mountain range shed vast quantities of sediment to the west of the advancing deformation front, into a deep-water basin in the eastern Barents Sea area, to the north of Norway, and into a series of terrestrial molasse

basins: the Volga-Urals and Timan-Pechora basins. To the east of the Urals the vast West Siberian Basin was also receiving large quantities of sediment and for much of the Late Permian sediment influx and subsidence kept pace so that the region remained around sea-level. In the latest Permian this area was the site of eruption of one of the largest volcanic provinces ever to form: the Siberian Traps. Subsidence rates continued to be high and the region remained around sea-level despite the eruption of several kilometres thickness of lava.

By the Middle Permian the areal extent of Pangaea was at its zenith, and it stretched in a giant arcuate shape from the north pole, which lay in eastern Siberia, to the south pole, which then, as now, lay in Antarctica (Figure 1). Pangaea was narrow at its waist owing to the presence of Tethys, an equatorially centred ocean that separated the northern and southern arms of the supercontinent. The eastern opening of Tethys was partially closed by the presence of some of the few continental masses that were not incorporated in Pangaea, notably South China and several smaller continents that are now part of southeast Asia. On the other side of the world from Tethys a vast ocean, called Panthalassa, stretched across 220° of longitude, making it 20% larger than the modern Pacific. Viewed from space in the Permian one side of the world would have looked entirely blue!

The break up of Pangaea began even as the Siberia–Laurussia collision was nearing completion, with the rifting of several small continents from the southern margin of Tethys, known as the Perigondwanan margin, in the Middle Permian (Figure 1). As these drifted northwards they opened up a narrow ocean behind them, known as Neotethys; the older Tethys to their north is often known as Palaeotethys. These slivers of continents included the present-day regions of Antalaya (Turkey), Armenia, parts of Iran and Afghanistan, and central Tibet; they are often depicted as forming an elongate narrow continent called Cimmeria. However, it is uncertain whether these ever formed a continuous continent. The Tibetan Block in particular seems to have begun its drift somewhat later than the other continents and to have lagged behind them during their northern passage. The Middle Permian rifting activity was accompanied by some voluminous volcanic episodes, notably that which formed the Panjal volcanics of Kashmir, India. This formerly extensive province of basaltic lavas was subsequently much deformed and metamorphosed during the formation of the Himalayas. However, the biggest Permian volcanic province is in the Emeishan region of south-western China and seems to have occurred during a poorly understood rifting episode around the Middle Permian–Late Permian boundary. Extensive sheets of basalt dominate the Emeishan

Table 1 Subdivisions of Permian time (names in brackets are those formerly used to describe Late Permian intervals)

Series	*Stages*
Lopingian base 262 Ma, top, 251 Ma (Tatarian)	Changxingian (Dorashamian) Wuchiapingian (Dzhulfian)
Guadalupian base 272 Ma	Capitanian Wordian Roadian
Cisuralian base 294 Ma	Kungurian Artinskian Sakmarian Asselian

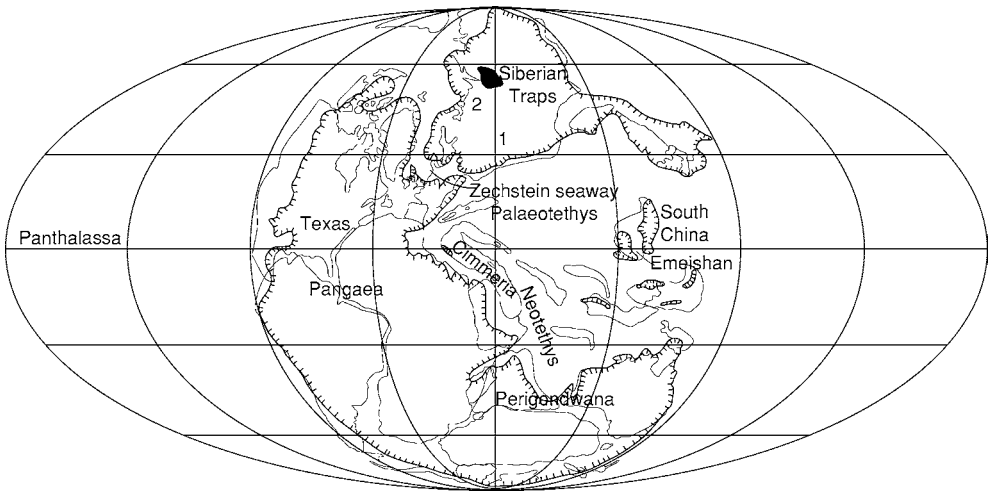

Figure 1 Global palaeogeography of the Late Permian showing the supercontinent of Pangaea. 1, Volga Urals Basin; 2, Timan Pechora Basin.

volcanic pile, and they may exceed a million cubic kilometres in volume. This basalt was extruded quietly from long fissures, but, during the later stages of the volcanism, these eruptions were replaced by explosive eruptions that produced more acidic lavas.

One consequence of supercontinent formation is that the area of fringing shallow shelf seas becomes minimal. This was indeed the case in the Permian, when the area of shallow-marine deposition was probably at its lowest level of the past 600 Ma. Truly extensive shallow seas were restricted to the continents that were not part of Pangaea, notably South China. However, several major marine embayments pierced the coast of Pangaea and brought shallow seas into the heart of the supercontinent. Two of these embayments were associated with the development of rift systems that would eventually contribute to the break up of Pangaea. Thus, down the east coast of Greenland and along the east coast of Africa (west coast of Madagascar) two long and narrow seaways developed.

A major invasion of the sea also occurred in the western and southern USA. In this region one of the most spectacular reef systems of all time developed. This is now superbly exposed in the Guadalupe Mountains of Texas. Much of the original topography of this reef system has been re-exposed, and it is possible to walk from the reef flat down the steep reef front to the deep basinal setting in front of the reefs – now a desert floor in front of a mountain escarpment. The other major area of Permian marine deposition in the USA occurs in the Idaho–Wyoming–Utah region. Here the rocks are of a very different character from the Texan rocks: dark shales and phosphates dominate the succession. Phosphates form today where cold deep waters upwell on western-facing continental margins, and a similar origin appears likely for the Permian phosphates.

At low to intermediate latitudes the deep interior of Pangaea was very arid (see below) and so it is not surprising that many of the seaways that penetrated into the supercontinent were subject to intense evaporation. The biggest of these evaporitic basins occurred in the north-west European area, where the Zechstein Sea was gradually infilled with a vast thickness of sea salts – one of the thickest evaporite deposits in the geological record.

Climate

Vast areas in the centre of Pangaea were a long way from any seaway and so it is not surprising that arid conditions were common over many areas of the continent. This was particularly true in the northern hemisphere, where much of Europe and North America lay in the rain shadow of the Appalachian–Variscan mountain chain (**Figure 1**). Many geologists live in these regions today and so a general impression of the Permian as a time of aridity has tended to enter the literature. However, the view from the Permian polar regions is rather different, and extensive coal deposits – testimony to humid climates – are known from the Permian of Siberia and Antarctica. Many of these coals formed in forested areas that were at latitudes of over 65° (e.g. eastern Australia, Antarctica, and eastern Siberia). These deposits indicate substantial rainfall and a lack of permanent snow cover at the Permian poles, conditions that were very different from those encountered in polar areas today.

The 43 Ma duration of the Permian also saw substantial changes in climate, the most important of which was the waning of the southern-hemisphere glaciation that had begun in the Early Carboniferous. At the beginning of the Permian extensive ice-sheets covered large areas of Antarctica and South Africa and deposited a jumble of boulders and clays known as the Dwyka Tillite. Ice also advanced as far north as southern Australia and parts of South America, at palaeolatitudes of approximately 45° S, before gradually shrinking back. By the end of the Middle Permian there is no evidence of permanent ice anywhere. The reason for the termination of this major glacial interval, known as the Permo-Carboniferous glaciation, is not understood but it may relate to the drift of southern Pangaea away from the south pole. At the start of the Permian the pole lay within Antarctica but by the Late Permian it was within the southernmost Panthalassa Ocean.

Marine Fossils

Life in the Permian seas and oceans was remarkably similar to that in the preceding Carboniferous. In the tropical carbonate seas of equatorial latitudes the bottom-dwelling fauna was diverse and consisted of brachiopods, stalked echinoderms (especially crinoids), bryozoans, corals, lesser numbers of molluscs, and the occasional rare trilobite. Foraminifera (single-celled organisms that secrete a tiny calcareous skeleton) were also common and they produced a group of 'giants' in the Permian – the fusulinids – that reached up to a centimetre in diameter. These are abundant and highly diverse in some Permian limestones. Reefs were common in equatorial locations and included the magnificent examples from the Guadalupe Mountains (mentioned above) and many others from Tethyan settings. Calcareous sponges and calcareous algae (especially a form known as *Tubiphytes*) were the principal constructors of these

reefs, although the associated fauna was diverse. This included a bizarre group of brachiopods known as the richthofenids, which evolved a conical valve with a lid-like upper valve. In gross morphology they resembled the contemporaneous rugose corals, and they were undoubtedly pursuing a similar life strategy.

Land Animals

Prior to the Late Carboniferous–Early Permian it is probable that very few land animals ever strayed far from water, but this changed dramatically during the Permian with the colonization of the continental interiors, a major ecological breakthrough that was almost certainly triggered by the evolution of eggs that did not have to be laid in water. The majority of Permian tetrapods (four-legged land dwellers) belong to two major groups, the synapsids, a group that ultimately gave rise to mammals (but not in the Permian), and the diapsids, a group that gave rise to reptiles and later (in the Triassic) to the dinosaurs.

Unlike the relatively stable Permian marine invertebrate faunas, the Permian tetrapod faunas underwent several phases of turnover. The initial radiation was dominated by the pelycosaurs, a synapsid group that included the large sail-backed predator *Dimetrodon*, one of the few 'famous' Permian tetrapods. The pelycosaurs included both herbivores and carnivores of a broad range of sizes although all had a characteristic sprawling pose and dragged long tails. They would have undoubtedly looked clumsy compared with many modern mammals. In the later Permian the pelycosaurs gave way to an even more diverse group of synapsids known as the therapsids. These included the dicynodonts, which were large (up to 3 m long) powerfully built herbivores, the cynodonts, which were smaller herbivores with distinctive tusks in their upper jaws, and the rather fearsome-looking gorgonopsids, which were predators of around a metre in length. The diapsids contributed the pareiasaurs, a group of large powerful herbivores, to the impressively diverse Late Permian tetrapod communities.

Land Plants

Just as the conquest of the land by animals was probably facilitated by the evolution of eggs, so the parallel conquest by plants was probably driven by the evolution of seed-bearing plants. Thus, the Permian saw the decline of tree ferns, which dominated Carboniferous floras, and the rise of several groups of seed plants (particularly cycads and ginkgos) and seed ferns (glossopterids). Four floral realms, with a clear climate-controlled distribution, are readily distinguished in the Permian. The flora of the Angaran Realm, centred on Siberia, was adapted to the cool-to-cold climates of this region. Cordaites, a primitive group of seed ferns, and the fern-like sphenopsids dominated the flora as they had done in this region in the preceding Late Carboniferous. These two groups were also common, together with ginkgos, in the Euramerican flora, which occupied the semiarid and possibly monsoonal locations of some low northerly palaeolatitudes. The Cathaysian flora, centred on northern China, was adapted to the warm ever-wet climate of this equatorial part of the world. It was similar in composition to the tree fern-dominated flora of the preceding Carboniferous, although with the addition of the large-leaved gigantopterids, another group of seed ferns. The most distinctive Permian flora occurred in the Gondwanan realm, where deciduous glossopterid tree fern forests were extensive (Figure 2). These thrived in the cool temperate conditions that developed in high-latitude locations such as Australia and South Africa after the melting of the ice-caps in the Early Permian. Most of the coal reserves of these countries, together with the less exploitable coals of Antarctica, formed at this time.

Extinction

For a long time the end-Permian mass extinction (*see* **Palaeozoic:** End Permian Extinctions) was thought to be a protracted affair that had begun well before the end of the Permian. However, recent work has demonstrated that there were in fact two separate extinction events in the latter part of the Permian, separated by a phase of radiation and recovery in the Late Permian. The end-Middle Permian extinction, sometimes known as the end-Guadalupian event, is poorly understood, primarily because it has only recently been discovered and has been little studied, but also because there are few complete successions recording the transition from Middle Permian to Upper Permian strata. The effects of this crisis are best known from equatorial sections, particularly in southern China where many species of fusulinid and brachiopod went extinct. Reef development also ceased in many areas of the world, including the Guadalupe reefs of Texas, at around this time. What is far from clear is whether this extinction event can be detected at higher latitudes and whether there were any corresponding extinctions on land. The plant record does not appear to show any major change around this time.

Despite its recent discovery, several theories have already been proposed to explain the end-Guadalupian mass extinction. As noted above, complete sections spanning the Middle Permian–Upper Permian boundary are rare. This is because of a major fall in sea-level

Figure 2 Slab of rock from the Permian of Antarctica, showing abundant fronds of the tree fern *Glossopteris*.

at this time, possibly to one of the lowest levels of the past 600 Ma. The result was that shallow-marine habitats became very limited, with drastic consequences for the inhabitants of such environments. Climate change triggered by volcanic activity is also a possible factor in this extinction event (and in many other extinction events). The Emeishan volcanic traps of southern China are roughly contemporaneous with the extinction event, raising the possibility that the emissions of volcanic gas associated with the lava eruptions may have changed the climate. However, precise synchronicity of the eruptions and the extinction has yet to be demonstrated. Recently, a Middle Permian–Late Permian succession was discovered in a limestone succession that formed on a small island that was formerly within the Panthalassa Ocean (the rocks have now been accreted to Japan). Remarkably, an acidic volcanic ash is developed at the boundary. This is a product of the kind of explosive volcanism normally characteristic of continental rather than oceanic locations. A huge volcanic eruption in a continental location (perhaps Emeishan) may have blown ash out into the far reaches of the Panthalassa Ocean. If ash could reach this distant location, then it is possible that it could also have triggered drastic climate change. Only further study will demonstrate the veracity of the currently proposed mechanisms of the end-Guadalupian extinction.

End Permian Extinctions

R J Twitchett, University of Plymouth, Plymouth, UK

Introduction

The extinction event at the close of the Permian period was the largest of the Phanerozoic. Understanding this event is crucial to understanding the history of life on Earth, yet it is only since the late 1980s that scientists have begun to study this event in detail. This is partly because of the discovery of many new geological sections spanning the time of the extinction crisis, partly because of a renewed public and scientific interest in extinction, and partly because of increasing dialogue, travel, and exchanges between geologists and palaeontologists from the West (Europe and America) and those from Russia and China. Over the years, a bewildering number of hypotheses have been suggested to explain the end-Permian extinction crisis, and new data are constantly appearing. There is currently no consensus as to the precise cause, and the current leading contenders are considered below.

Definition and Dating

The Permian–Triassic boundary is now defined as the point at which a specific species of fossil conodont (an extinct type of primitive vertebrate) called *Hindeodus parvus* first appears in a geological section at Meishan in South China (Figure 1). This definition was accepted only after many years of debate: its significance is immense. Palaeontologists from around the world are now able to correlate their local sections with this single reference section, thus unifying a confusing plethora of names that geologists working independently, in different countries, had erected to describe rocks of the same age. It also confirmed that the main extinction event occurred in the latest Permian, before the Permian–Triassic boundary (i.e. before the appearance of *H. parvus*), in the Changhsingian Stage (Figure 2).

The presence of layers of volcanic ash interbedded with the fossiliferous sediments at Meishan have also allowed absolute dating of the boundary interval through the precise measurement of radiogenic elements, such as ^{206}Pb and ^{238}U, in minerals such as zircons. In 1991, Claoue-Long and colleagues dated the Permian–Triassic boundary at 251.2 ± 3.4 Ma. Seven years later, Sam Bowring and his group reanalysed the same beds and arrived at a date of 251.4 ± 0.3 Ma, confirming the earlier result but with far higher resolution and cementing 251 Ma in the subsequent literature.

However, accurate dating is notoriously difficult, and the further back in time one goes the worse the resolution becomes and the greater is the potential error. In 2001, Roland Mundil and colleagues confirmed that there were problems with the Bowring dates. Mundil's group reassigned the ash bed above the Permian–Triassic boundary an (older) age of 252.7 ± 0.4 Ma. However, the ash bed below the Permian–Triassic boundary, approximating to the level of the mass extinction, proved far more difficult to date: that it is probably older than 254 Ma was the best that the geochronologists could achieve.

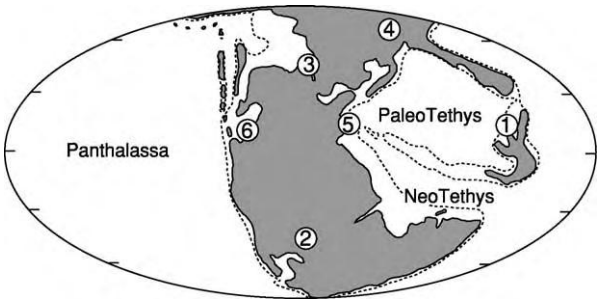

Figure 1 Sketch of Permian Triassic palaeogeography, showing the major regions discussed in the text: 1, South China; 2, Karoo Basin, South Africa; 3, eastern Greenland; 4, Siberia; 5, northern Italy; and 6, western USA.

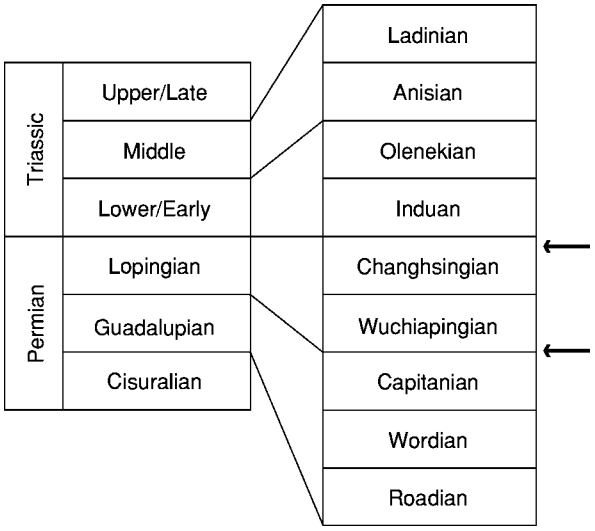

Figure 2 Permian and Triassic stratigraphy. Arrows indicate the stratigraphical positions of the extinction events discussed in the text.

Is this change in date and loss of resolution important? For many Permian–Triassic studies it is largely irrelevant. Correlation between marine sections relies on well-established methods of biostratigraphy and is unaffected by such results: the relative sequence of events can be deduced regardless. However, it is a significant blow for correlation between fossiliferous marine sediments and distant terrestrial sections, and for the hypothesis that the Siberian flood basalts were responsible for the extinction crisis (see below). It also means that absolute rates of change, both faunal and environmental, cannot be determined.

What Went Extinct?

Estimating the severity of past extinction events is not easy. Owing to the vagaries of preservation and fossil recovery and the difficulty of recognizing biological species from fossils, palaeontologists investigating extinctions tend to work at higher taxonomic levels. Thus, estimates of extinction magnitude are derived from large databases of family-level diversity through time, which show that 49% of marine invertebrate families disappeared during the Permian–Triassic interval.

Extinction at the species level is then estimated, rather than directly measured, using a statistical technique called reverse rarefaction. From this method, the often-quoted figure of a 96% loss of marine species is derived. However, such a calculation makes a number of assumptions, including, for example, the assumption that species extinction was random, with no selectivity against certain groups. The balance of evidence indicates that this assumption is incorrect, and, thus, the true magnitude of species loss may be closer to 80%. However, this still makes the end-Permian extinction event the most severe crisis of the Phanerozoic!

Marine Extinctions

Despite these shortcomings, it is clear that several groups were severely diminished in number in the Late Permian, some groups went completely extinct, and not all groups were affected equally. For example, the diverse and successful fusulinid foraminifera disappear suddenly during the Changhsingian stage with the loss of some 18 families, whereas other benthic foraminifera suffered much lower levels of extinction. The diversity of the stenolaemate bryozoans also decreased markedly through the latter half of the Permian, but only the Order Fenestrata became extinct. By contrast, other bryozoan groups, such as the gymnolaemate order Ctenostomata, maintained their diversity at the family level.

A pattern of gradual decline throughout the Permian, particularly during the latter half, followed by final extinction of the last few remaining taxa in the Changhsingian, is typical of many groups. Examples include the Palaeozoic corals (Rugosa and Tabulata), trilobites, and goniatites, all of which became extinct, and the articulate brachiopods, which were reduced to a handful of surviving genera. This pattern implies that longer-term (possibly climate driven) changes in the marine realm may have been largely to blame for the loss of diversity.

A few groups, such as the echinoderms, suffered dramatic losses prior to the end-Permian. All of the extant echinoderm groups experienced severe bottlenecks during the Permian–Triassic interval: only a couple of lineages of crinoids and echinoids survived into the Mesozoic. However, the major crisis interval appears to have been in the Late Guadalupian, when crinoids experienced over 90% loss and other groups of echinoderms, such as the Blastoidea, became extinct.

Terrestrial Extinctions

The extinction on land was just as severe as in the oceans, with some 77% of vertebrate families becoming extinct. In the Karoo Basin of South Africa (**Figure 1**), only seven out of 44 tetrapod genera (16%) cross the Permian–Triassic boundary. When all fossil terrestrial organisms are considered together, the Permian–Triassic event is the single largest extinction episode in the otherwise exponential rise of terrestrial diversity through the Phanerozoic.

A long-term (more than 20 Ma) change in terrestrial vegetation occurred during the Permian–Triassic interval. Termed the Palaeophytic–Mesophytic transition, it probably reflects gradual shifts in climate and palaeogeography. However, superimposed on this longer-term trend is a catastrophic collapse of the dominant gymnosperm forests in the latest Permian, as evidenced by the disappearance of pollen taxa such as *Vittatina*, *Weylandites*, and *Lueckisporites*. Studies in eastern Greenland (**Figure 1**) have shown that this ecological crisis occurred simultaneously with the marine extinction event.

Some workers have suggested that a peak in the abundance of *Reduviasporonites* (also called *Tympanicysta*), observed in some sections, marks the sudden destruction of these forests. They have interpreted this taxon as a saprophytic fungus, which thrived on the piles of dead and dying vegetation. Unfortunately, this attractive scenario must now be rejected. Recent geochemical, structural, and biomarker studies have shown that *Reduviasporonites* is definitely not a fungus and is probably a photosynthetic alga.

One Event or Two?

Early databases of global marine biodiversity recorded a broad peak of elevated extinction rates spanning the entire Late Permian. As the data improved, two distinct peaks were resolved: one in the latest Permian (the major event) and one at the end of the Guadalupian. This latter event marks the point at which many diverse groups (such as sponges and stenolaemate bryozoans) begin to decline in diversity. For the brachiopods and echinoderms, especially the crinoids, it marks the main episode of diversity loss.

While there is some evidence of climate change at this time, there are also good reasons why the end-Guadalupian event might not be a 'real' biotic extinction event. The Middle Permian was a time of incredible biodiversity, but the majority of the fossil taxa are endemic to the comprehensively monographed and exquisitely preserved silicified faunas of the Guadalupian reef belts of the southern USA, particularly western Texas. At the close of the Guadalupian, sea-level fell across that region, and the overlying sediments are unfossiliferous evaporites. The disappearance of the fossils is therefore a result of facies change and not real extinction.

Globally, Upper Permian fossiliferous marine rocks are relatively poorly known, and the quality (i.e. completeness) of the Late Permian fossil record is correspondingly poor. Many taxa that were common in the Guadalupian have not been found in Upper Permian rocks but must have been living at that time because they reappear in the Triassic. These missing taxa are called Lazarus taxa. The presence of many Lazarus taxa indicates that the completeness of the fossil record is low (Figure 3).

The reality of the end-Guadalupian event is still debated. If it is simply the result of bias in the rock record, then newly described sections should contain many of the taxa previously supposed to have become extinct. Certainly this is true of the brachiopods: newly described Upper Permian sections from Tibet contain some taxa that were thought to have vanished earlier. Further detailed analysis of this interval is clearly needed.

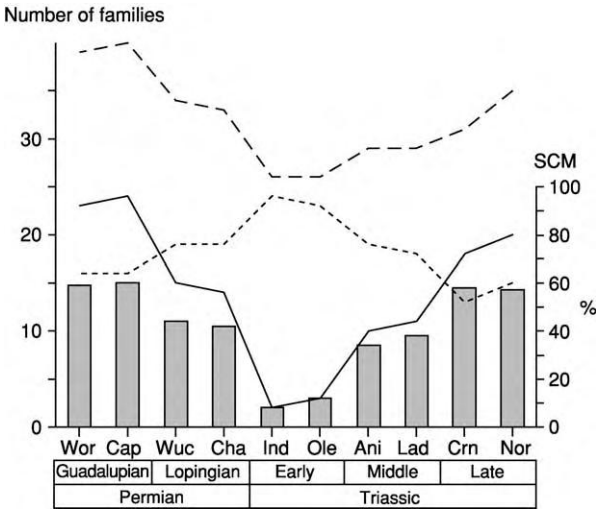

Figure 3 Fluctuations in fossil diversity and the quality of the fossil record of marine sponges through the Permian Triassic extinction and recovery interval: solid line, families of sponges represented by actual fossils; dotted line, number of Lazarus taxa; dashed line, total diversity (sum of fossil taxa and Lazarus taxa). Grey bars show the simple completeness metric (SCM), which is the number of actual fossil taxa as a percentage of the total diversity. The SCM gives an estimate of the completeness of the fossil record. Note that, as diversity declines after the Guadalupian, the number of Lazarus taxa increases and so the completeness of the fossil record decreases. Stratigraphy from Figure 2. Data from *The Fossil Record 2* (Benton, 1993).

Possible Causes

Extraterrestrial Impact

Initial attempts to find evidence of a Permian–Triassic impact were made in the early 1980s, following the proposal that a massive meteorite impact had caused the end-Cretaceous extinction event (*see* **Mesozoic:** End Cretaceous Extinctions). Three pieces of evidence are considered crucial in identifying a meteorite impact event: a crater, an enrichment ('spike') of the rare metallic element iridium, and a layer of impact debris containing shocked quartz and tektites. However, the few reports of these pieces of evidence in latest Permian rocks are considered to be, at best, equivocal. Certainly, there is no Permian–Triassic iridium spike comparable to that found at the Cretaceous–Tertiary boundary, no widespread impact layer, and no large crater that can be accurately correlated with the extinction horizon. For an impact event to be a possible cause of the extinction crisis, it must also be demonstrated that the extinctions were unequivocally instantaneous and coincident with the impact itself.

In 2001, Luann Becker and colleagues reported the presence of helium and argon trapped in the cage-like molecular structure of fullerenes from the Permian–Triassic boundary in China and Japan. Isotopic profiles indicated that the helium and argon, and hence the fullerenes, had to have come from an extraterrestrial source. However, there are persistent problems with the acceptance of Becker's data, as other scientists have consistently failed to replicate her results, despite using samples from exactly the same sites and exactly the same laboratory procedures. A Japanese expert, Yukio Isozaki, has also argued that the Permian–Triassic boundary is missing from the Japanese section studied by Becker and colleagues

and that their samples came from below the extinction level.

Later in 2001, Kaiho and colleagues described Permian–Triassic sediment grains that were supposedly formed by impact, as well as geochemical shifts that they interpreted as indicative of a huge impact. However, their data are far from conclusive and were rapidly and severely criticized by other geochemists. In 2003, Asish Basu and colleagues revived interest by claiming to have found 40 tiny (50–400 μm) unaltered fragments of meteorite in a sediment sample from a terrestrial Permian–Triassic boundary section in Antarctica. Although Basu and colleagues were quick to dismiss contamination as a source of these grains, meteorite experts were immediately sceptical of the findings, as meteoritic metals are highly reactive and, in terrestrial settings, oxidize extremely quickly.

Doubtless scientists will continue to produce evidence of extraterrestrial impact at or near the Permian–Triassic boundary, if only because such hypotheses readily appeal to the wider public and journal editors alike. However, current data are highly controversial and lack the key criteria of major impact that have been recorded time and again in Cretaceous–Tertiary sections the world over. Independent replication of results is crucial for scientific acceptance, especially when the data are unusual and controversial. So far, all the evidence proposed for an impact at the Permian–Triassic boundary has failed this necessary test.

Eruption

The largest outpouring of continental flood basalts in the Phanerozoic occurred in Siberia during the Permian–Triassic interval. Including both the Siberian Platform basalts and the newly discovered coeval deposits buried in the West Siberia Basin, described by Marc Reichow and colleagues, the flood basalts covered an area of $1.6 \times 10^6\,km^2$ to maximum depths of 3.5 km (Figure 1). If all other igneous rocks, such as pyroclastic flows, are included, then this coverage increases to $3.9 \times 10^6\,km^2$. Dating the top and bottom of the lava pile shows that the eruptions occurred over a relatively short period of time, maybe just 600 000 years. Was this huge volcanic event a cause of the Permian–Triassic extinction crisis?

Radiometric dating is the only way to answer this question because no fossils have yet been collected from sediments interbedded with the basalts that provide correlation with other regions. Early efforts at dating the Siberian Traps produced an array of ages, from 160 Ma to 280 Ma. By contrast, more recent results, by different scientists using a variety of methods, cluster around 250 ± 1 Ma. In the late 1990s, this was considered to be exactly the date required, and the flood basalts were thought to be the primary trigger for the catastrophic extinction. However, the recent redating of the Meishan beds now implies that the Permian–Triassic event occurred before 253 Ma, and the Siberian Traps are therefore several million years too young.

On a Phanerozoic time-scale, the excellent correlation between extinction episodes and flood-basalt provinces means that it is difficult to accept the possibility that the Siberian Traps played no role in the end-Permian extinction event. There is still a chance. The oldest date that Reichow's team have for the onset of volcanic activity (dating the emplacement of intrusive gabbros) is 253.4 ± 0.8 Ma.

Another intriguing consequence of the 253 Ma age for the Permian–Triassic boundary is that the Emeishan flood basalts of western South China now need to be considered. Dating by Ching-Hua Lo and colleagues (published in 2002) shows that the main eruptions, which were largely marginal marine events, occurred around 251–253 Ma, with an initial phase of activity at around 255 Ma; thus, they predate the Siberian Traps and are dated close to the new dates for the Permian–Triassic crisis. Interestingly, Ching-Hua Lo's new dates preclude the possibility that the Emeishan flood basalts played a role in the end-Guadalupian crisis (at about 256–259 Ma; see above). Mei-Fu Zhou and colleagues had championed this particular correlation following their dating of the Emeishan basalts to 259 ± 3 Ma, which was published just a few months before Ching-Hua Lo's results in the same journal! Absolute dating is a difficult business (*see* **Analytical Methods:** Geochronological Techniques).

Global Warming

Animals and plants do not curl up and die just because a volcano is erupting on the other side of the world. Species become extinct when their population falls below viable levels. Population decline in natural systems is a response to local changes, such as loss of habitat, drought, and temperature change, many of which are ultimately driven by climate. What climate changes are recorded around the extinction interval and how might they be related to the flood-basalt volcanism?

Global cooling was proposed early on as a cause of the Permian–Triassic event; this largely hinged on the identification of latest-Permian glacial deposits in Siberia and eastern Australia. However, reanalysis of the biostratigraphy proved that these deposits are,

in fact, Middle Permian in age. With evidence of extensive ice sheets confined to the Early Permian and the last vestiges of glaciation now dated as Middle Permian, it is evident that the Permian as a whole records a warming trend.

At the culmination of this long-term warming trend, there is also evidence for an additional rapid greenhouse episode at the time of the extinction crisis. A large drop in the proportion of heavy oxygen isotopes (^{18}O) in carbonates from the Gartnerkofel-1 core of southern Austria has been interpreted as representing an increase in temperature of 6°C. However, interpretation of the oxygen isotope record is problematic as it is very sensitive to alteration during burial and diagenesis. The limestones of Gartnerkofel-1 have been largely recrystallized, especially around the boundary interval, and thus the oxygen isotope data are surely suspect.

However, there is growing independent support for global warming at the boundary. Gregory Retallack has demonstrated, from studies of the stomatal index of fossil leaves, that peaks in atmospheric CO_2 (a proven greenhouse gas) occur at both the end-Permian and end-Guadalupian boundaries. His studies of fossil soils also indicate a change to humid greenhouse conditions in the Early Triassic. Finally, there is a large (usually 3–6‰) increase in the proportion of light ^{12}C, relative to heavier ^{13}C, in carbonates deposited at this time. This shift is interpreted by most geochemists to be the result of methane (CH_4) release, as this is the only mechanism currently known that could rapidly deliver the required amount of light ^{12}C to the atmosphere and oceans. This methane, which is also a potent greenhouse gas, is assumed to have been produced by the melting of methane hydrate deposits in shallow marine shelves and polar tundra. Thus, a runaway greenhouse scenario is envisaged, whereby warming led to melting of gas hydrates and release of methane, which fuelled further warming and further methane release, in a positive-feedback loop that presumably continued until the reserves of gas hydrate were depleted (Figure 4).

Flood basalts are assigned a triggering role in this runaway greenhouse model, by venting enough initial CO_2 to drive temperatures above the threshold for gas-hydrate breakdown. However, volcanic eruptions also reduce global temperatures by releasing particulates and SO_2. Some authors have incorporated a cooling episode into their extinction models, but regard it as a brief event, which was subsequently eclipsed by the later warming. There is currently no geological evidence to support an episode of global cooling at the onset of the Permian–Triassic extinction crisis.

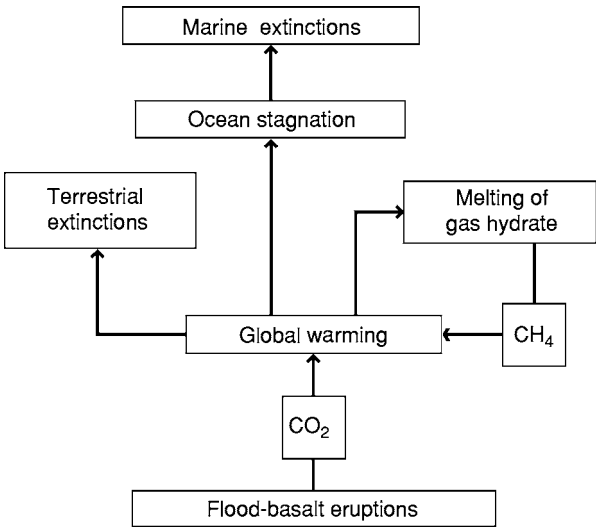

Figure 4 The runaway greenhouse model for the end Permian extinction event. See text for details.

Post-Extinction Recovery

Douglas Erwin has remarked that the duration of the post-Permian recovery interval is the greatest of any Phanerozoic mass extinction and is proportionally longer than would be expected given the magnitude of the species loss. Certainly, a literal reading of the fossil record shows that it took some 100 Ma (until the mid-Jurassic) for marine biodiversity at the family level to return to pre-extinction levels. However, ecological recovery was somewhat quicker, with complex communities such as reefs being re-established some 10 Ma after the Permian–Triassic boundary. Thus, how one views the duration of the recovery interval, measured on a local or global scale, depends on how one defines 'recovery'.

Details of the marine recovery are best known from the low palaeolatitudes of Panthalassa (the present-day western USA) and Palaeotethys (e.g. northern Italy) (Figure 1). Epifaunal benthic communities in the immediate aftermath of the event (the Early Induan) comprise low-diversity assemblages of small suspension feeders (typified by the bivalves *Promyalina* and *Claraia* and often the inarticulate brachiopod *Lingula*). Bedding planes are dominated by a single taxon, which may occur in prodigious numbers. These taxa are considered by many, with varying degrees of evidence, to be pioneering r-selected opportunists (i.e. animals that mature early and produce many offspring). Stromatolites and other microbial mats are commonly encountered and may have provided grazing opportunities for the depauperate microgastropod community. Occasional horizons of mm-diameter *Planolites* burrows attest to temporary colonization events by a scarce infauna

of small deposit feeders living just 1–2 cm below the sediment surface. In the higher palaeolatitude regions of the Boreal Ocean (Greenland, Spitsbergen) and NeoTethys (Madagascar, western Australia) a fairly diverse but small-sized nekton of fishes and ammonoids is recorded.

Sedimentary and geochemical data indicate that environmental conditions were particularly harsh. Most recent palaeoenvironmental studies have concluded that the Early Triassic oceans contained very low concentrations of dissolved oxygen and may have been anoxic or even euxinic for considerable periods of time. Low oxygen levels were probably the result of a combination of factors. First, levels of atmospheric oxygen had fallen steadily from 30% in the Early Permian to approximately 15% (i.e. 70% of present-day values) by the Permian–Triassic boundary. Second, global warming in the latest Permian (see above) would have increased sea-surface temperatures, and warm water holds less dissolved oxygen than cool water. Finally, climate models indicate that global warming would also lead to a reduction in the temperature gradient between the poles and the equator, thus slowing down thermohaline circulation. In present-day oceans, the temperature difference between the warm equator and the cold poles drives a relatively vigorous thermohaline circulation, which maintains oxygenation of the ocean floors. In the sluggish earliest Triassic oceans, oxygen would have been used up faster than it could be replaced, resulting in stagnation and anoxia.

The ecology of the post-extinction survivors and the long interval of low diversity are interpreted as being the result of this anoxic event. In the few places where the oceans were well-oxygenated in the immediate aftermath of the extinction (e.g. Oman), a far more diverse benthic community, comprising upwards of 20 genera, was soon established. Unfortunately, these localized experiments in rapid post-extinction recovery were snuffed out by the arrival of anoxia in the later Induan.

With the disappearance of benthic oxygen restriction later in the Early Triassic, larger organisms and more diverse communities reappeared. The ecological complexity of infaunal communities began to increase with the reappearance of deeper-burrowing suspension feeders (producing *Arenicolites*, *Skolithos*, and *Diplocraterion* burrows). Burrowing crustaceans (producing traces such as *Thalassinoides*) are the last significant component of the infauna to reappear. In the palaeotropics, *Thalassinoides* first reappears in the Middle Triassic. In higher palaeolatitudes (East Greenland, Spitsbergen), small *Thalassinoides* reappear in the later Induan, suggesting faster recovery in the Boreal Realm.

In most parts of the world, epifaunal complexity did not significantly recover until the Late Olenekian, with an increase in tiering (vertical stratification of organisms above the sediment surface) as crinoids and bryozoans returned. However, the most complex ecological structures – metazoan reefs – do not return until the Middle Triassic, accompanied by a significant increase in faunal diversity and the reappearance of many Lazarus taxa.

Our understanding of the recovery of terrestrial ecosystems is less refined, with most data deriving from the Karoo Basin of South Africa. Like the marine survivors, terrestrial vertebrate survivors tended to be small: in the Karoo Basin five small carnivorous therocephalians and one small anapsid (*Procolophon*) survived the Permian–Triassic crisis. The other survivor, and the dominant terrestrial vertebrate for several million years, was the herbivore *Lystrosaurus*, which, like *Claraia*, was globally widespread.

More is known of the recovery of the terrestrial vegetation. The most detailed studies are those of Cindy Looy and colleagues, who have analysed fossil spores and pollen from Europe and eastern Greenland. Following the collapse of the Late Permian gymnosperm forests, open herbaceous vegetation rapidly took over, with short-lived blooms of pioneering opportunistic lycopsids, ferns, and bryophytes – stress-tolerant forms that were subordinate members of the pre-crisis vegetation. Pollen from woody gymnosperms seems to indicate that a few surviving elements of the Permian forests lingered on for a while, but equally these records could just represent reworking of the pollen. Certainly, by the earliest Triassic no tree-like gymnosperms remained, and a stable low-diversity open-shrubland vegetation of cycads and lycopsids was established. Complex and diverse forest communities did not reappear, at least in Europe, until the latest Olenekian and early Middle Triassic. Thus, the return of ecological complexity on land closely mirrors that in epifaunal marine communities.

Conclusions

The greatest mass-extinction event of the Phanerozoic is receiving an unprecedented level of scientific interest. New sections are being discovered and described, allowing new hypotheses of causes and consequences to be tested and old ones to be modified or rejected. The 1990s witnessed a number of major advances, culminating in the acceptance of Meishan, China, as the appropriate locality to define the Permian–Triassic boundary and the subsequent formalization of Permian–Triassic stratigraphy. The

picture presented here is a current (2004) view of this crisis: a snapshot that doubtless will be refined in the decade to come.

PANGAEA

S G Lucas, New Mexico Museum of Natural History, Albuquerque, NM, USA

Introduction

Geologists apply the term Pangaea (from the Greek words meaning 'all Earth', and usually pronounced pan-JEE-uh) to the supercontinent that existed during the Late Palaeozoic and Early Mesozoic, about 300–200 Ma ago. Pangaea was an amalgamation of continental blocks that were the precursors of the existing continents, though much of eastern Asia was an archipelago of islands loosely connected to eastern Pangaea.

Components of Pangaea

Pangaea (Figure 1) was accreted from continental blocks that differed from today's continents. The southern supercontinent of Gondwana (also called Gondwanaland) (*see* **Gondwanaland and Gondwana**) was the Palaeozoic amalgamation of South America, Africa, Antarctica, Australia, and the Indo-Pakistani subcontinent, as well as several smaller terranes. The northern supercontinent of Laurussia (or Laurasia) consisted of North America and most of Europe.

Asia, however, did not exist as a single block. The continental nucleus of present-day Asia was the Siberian block, but other blocks included Kazakhstan, Tarim, and a loose archipelago of blocks that were to become much of China and South-east Asia. Many of these eastern Asian blocks originated as slivers of northern Gondwana and drifted northwards during the Late Palaeozoic and earliest Mesozoic to accrete to the larger Asian blocks during the Late Triassic–Jurassic.

Pangaea was surrounded by a universal ocean called Panthalassa (from the Greek words meaning 'all sea'), which was the ancestor of today's Pacific Ocean. The Atlantic Ocean did not exist even in ancestral form, because of the fusions of North America to Europe and of South America to Africa.

An arm of Panthalassa formed a deep east–west embayment in the eastern edge of Pangaea (Figure 1). This was the Tethys Sea, which is named after the sister and consort of Oceanus in Greek mythology. Tethys was the ancestor of the present Mediterranean Sea. Successive ocean basins within it are termed Palaeotethys (Devonian–Permian) and Neotethys; the latter opened during the Late Permian as a result of rifting between Gondwana and the smaller central and southern Asian terranes.

Late Carboniferous Accretion of Pangaea

The Pangaean supercontinent came together (accreted) at the end of the Carboniferous (*see* **Palaeozoic:** Carboniferous), when Laurussia and Gondwana were sutured along what has been termed the Hercynian megasuture. Very old mountain ranges mark the

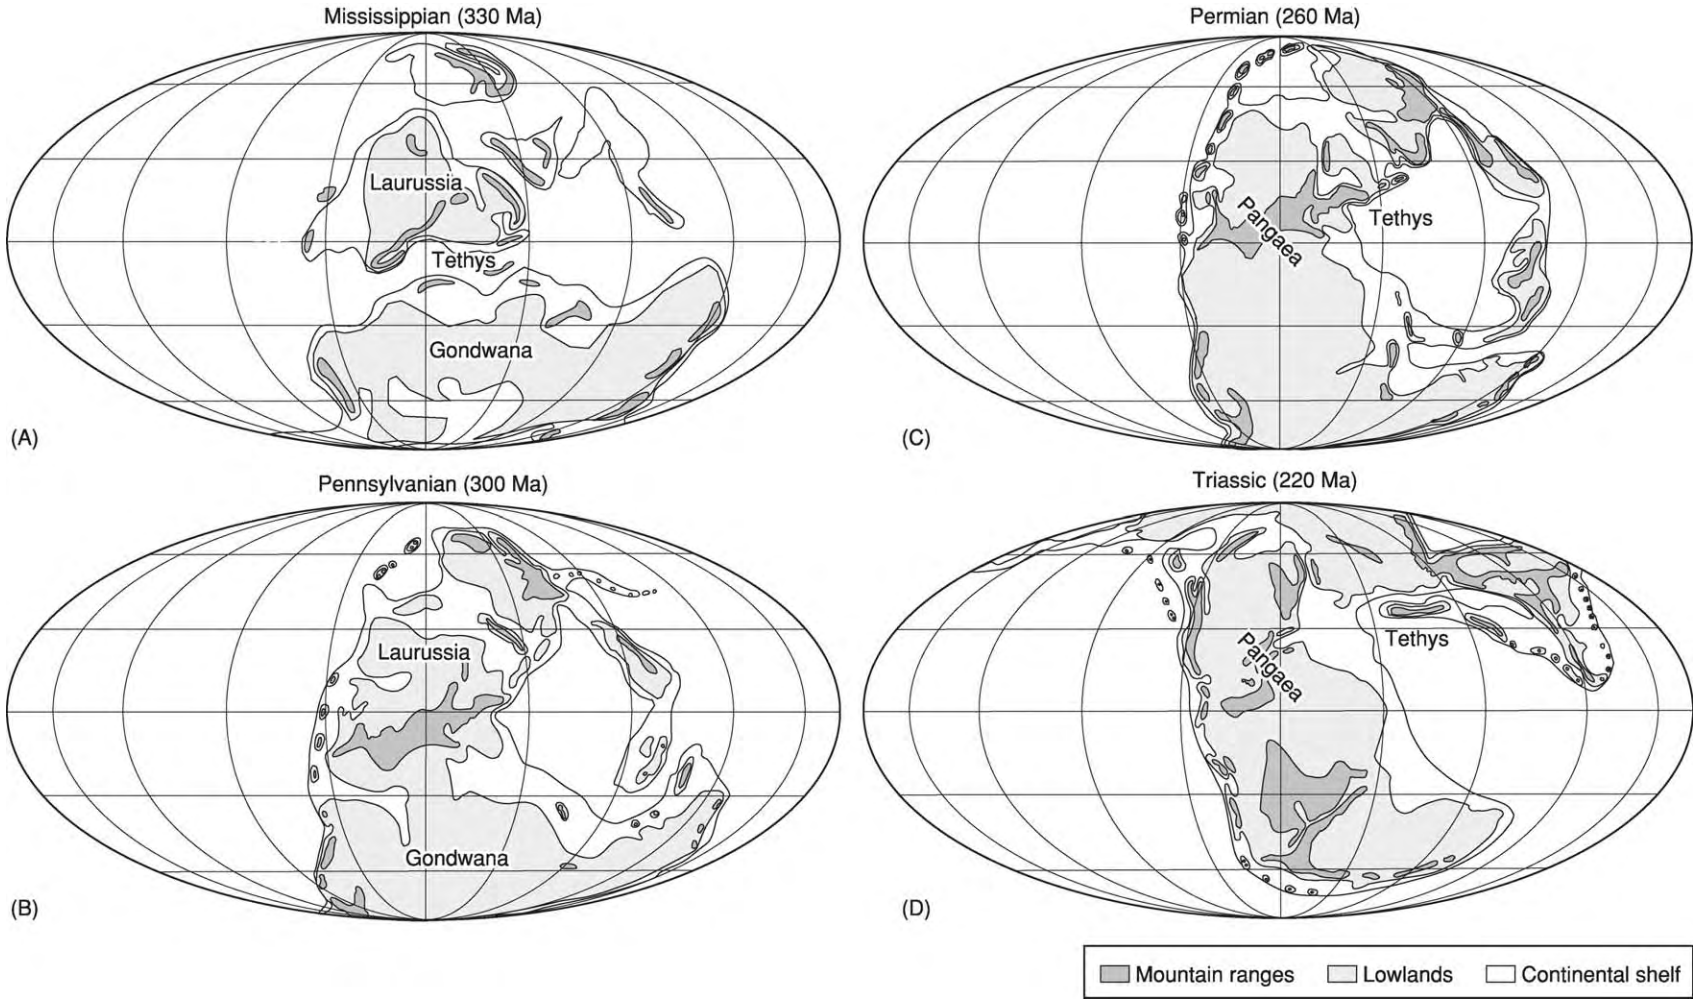

Figure 1 Palaeogeographical maps. (A,B) In the Carboniferous, Pangaea was accreted by the suturing of Gondwana and Laurussia near the palaeoequator (A) Early Carboniferous (Mississippian), and (B) Late Carboniferous (Pennsylvanian). Pangaea was fully united during (C) the Permian and (D) throughout much of the Triassic.

collisional boundaries of the Pangaean blocks. These are the Appalachian Mountains of eastern North America (*see* **North America:** Northern Appalachians; Southern and Central Appalachians), the Ural Mountains of European Russia (*see* **Europe:** The Urals), and the Hercynian Mountain ranges of southern Europe and parts of North Africa.

The Late Carboniferous was a time of vast coal swamps in the tropical latitudes. There was a steep temperature gradient during the Late Carboniferous, from icy poles to hot tropics, which was more similar to today's world than perhaps at any other time in Earth history. In Gondwana, ice ages pushed glacial ice to within 30° of the palaeoequator.

Permian Pangaea

Once assembled, at the beginning of the Permian, Pangaea stretched from pole to pole in a single hemisphere (Figure 1C). The ocean of Panthalassa covered the other hemisphere.

Permian Pangaea was a relatively diverse place in terms of climate and topography. Permian glacial deposits found in South America, Africa, India, and Australia provide evidence of continuing glacial ages in southern Gondwana during the Early Permian. Along the sutures of Pangaea, huge mountain ranges towered over vast tropical lowlands. Interior areas were dry deserts where dune sands accumulated. Evaporites (particularly gypsum and halite), deposited in the south-western USA and northern Europe, resulted from the evaporation of hot shallow seas and form the most extensive salt deposits in the geological record. Perhaps the best testimony to the diversity of Permian Pangaea are its fossil plants, which identify several floral provinces across the vast supercontinent.

The coastlines of the Pangaean tropics were warm, and the waters were teeming with life. The cold offshore waters of the poleward portions of Pangaea had a very different and less diverse biota. The biotic extinctions (turnover) at the end of the Permian were the largest of the entire Phanerozoic (*see* **Palaeozoic:** End Permian Extinctions); they were undoubtedly influenced by the vast volcanic outpourings in Russia (the Siberian traps) and South China (the Emeishan traps).

Triassic Pangaea

At the beginning of the Triassic, the Pangaean supercontinent still sat in a single hemisphere surrounded by the enormous Panthalassan Ocean. Subduction zones that dipped beneath the continents nearly encircled Pangaea, and elevations were relatively high owing to regional uplift across Pangaea during the Late Permian and Triassic. Intense mountain building and foreland-basin deformation took place around the Pangaean margins during the Late Permian and earliest Triassic. The maximum accretion (integration) of Pangaea occurred at about the end of the Middle Triassic, approximately 230 Ma ago.

Early–Middle Triassic Pangaea was a much more cosmopolitan world than Permian Pangaea. Triassic fossil plants indicate only two vast provinces, north and south of the palaeoequator. However, some land animals, such as the mammal-like reptile *Lystrosaurus* (Figure 2), roamed across much of Pangaea. Indeed, recognition during the 1970s of the widespread nature of Early Triassic fossils of *Lystrosaurus* (which are found in Russia, China, India, Africa, and Antarctica), a land animal, provided compelling evidence of the unity of Pangaea.

During the Triassic, the vast Pangaean supercontinent drifted northwards and rotated counterclockwise. The landmass was nearly symmetrical about the palaeoequator. However, no sooner had the maximum integration of Pangaea occurred, than the supercontinent began to fragment.

Thus, by the Late Triassic, separation of Laurussia and Gondwana had begun, with the onset of rifting in the Gulf of Mexico basin. Indeed, the breakup of Pangaea began in the western Tethys and severed the supercontinent into two pieces, north and south, by the Jurassic. The east–west rifting that opened up the Atlantic Ocean basin was not really achieved until the Cretaceous. However, around the nascent North Atlantic basin, a huge basaltic volcanic province, called the

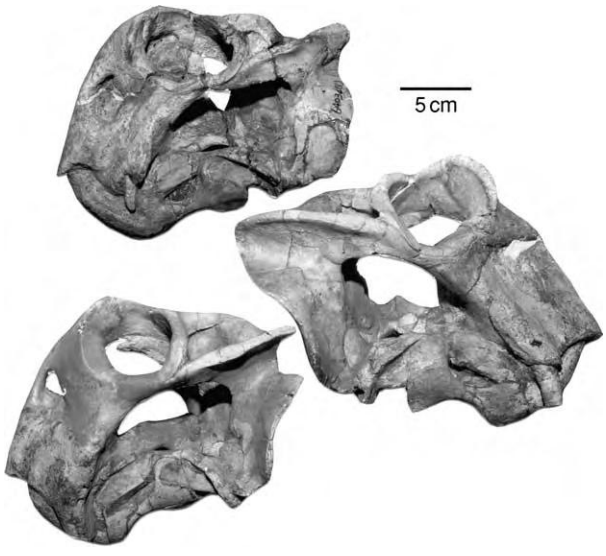

Figure 2 Skulls of the Early Triassic mammal like reptile *Lystrosaurus* from northern China. Fossils of *Lystrosaurus* are also known from Russia, India, Africa, and Antarctica, providing strong evidence of the unity of Pangaea.

circum-Atlantic magmatic province, appeared at about the beginning of the Jurassic, as lavas poured forth along fractures that formed as Pangaea rifted apart.

An important aspect of Triassic Pangaea was the large number of microplates (also called displaced or suspect terranes) that were to accrete to the Pangaean nucleus during the Late Triassic and Jurassic. These microplates were of variable size and can be identified by the sharp contrasts between their rocks and fossils and those of adjacent rocks. They are fragments of other continents, island arcs, or pieces of oceanic crust that moved long distances to be accreted to continents. More than 100 such terranes have been identified in the Cordilleran belt of western North America. Numerous terranes in the Panthalassa Ocean moved eastwards to join the western ends of the Americas. In eastern Tethys, as noted above, rifted slivers of northern Gondwana moved northwards to accrete to and form much of eastern and South-east Asia during the Late Triassic–Jurassic.

PETROLEUM GEOLOGY

Contents

Overview

J Gluyas, Acorn Oil and Gas Ltd., Staines, UK

Introduction

Petroleum geoscience is defined as the disciplines of geology and geophysics applied to the understanding of the origin, distribution, and properties of petroleum and petroleum-bearing rocks.

Petroleum geoscience can be described as the study and understanding of five key components: source, seal, trap, reservoir, and timing (of petroleum migration). These are sometimes known as the 'magic five ingredients' without which a basin cannot become a petroleum province (Figure 1). This article examines each of these components.

Source Rock

Petroleum (oil and gas) forms from organic matter: dead plants and animals. Burial, and thus heating of such organic matter induces reactions leading to the generation of gas, then oil and gas, and, finally, gas alone as the temperature and residence time at high temperature increase. Continued burial and heating turn the residual organic matter into pyrobitumen and eventually into graphite (*see* **Petroleum Geology:** The Petroleum System).

Seal

Oil and gas are less dense than water and, following expulsion from the source rock, they rise towards the Earth's surface unless movement is arrested by a seal. Seals tend to be fine-grained or crystalline, low-permeability rocks, such as mudstone/shale, cemented limestones, cherts, anhydrite, and salt (halite). Seals can also develop along fault planes, faulted zones, and fractures.

The presence of seals is critical for the development of petroleum pools. In the absence of seals, petroleum will rise to the Earth's surface and be destroyed. Although seals are critical for the development of petroleum pools, none are perfect. All leak. Combinations of regionally extensive seals and underlying reservoir complexes are commonly referred to as 'plays', and the areas within which the quality of seals and reservoirs is such that petroleum accumulations could occur (given an appropriate trapping configuration) are commonly referred to as 'play fairways'.

The most common subdivision of seals distinguishes between seals in which petroleum is unable to force its way through the largest pores (membrane seals) and seals in which petroleum can escape only by creating fractures (hydraulic seals). Attributes which favour a rock as a seal include a small pore size, high ductility, large thickness, and wide lateral extent. The physical properties of the water and petroleum are also important. Water salinity, petroleum density, and interfacial tension between petroleum and water are the most important, and these properties will change according to changing pressure and temperature conditions.

The most common lithology that forms a petroleum seal is mudrock. Mudrocks are composed of either carbonate or siliciclastic minerals (or both), and mudrock sequences are often thick (>50 m) and laterally continuous (>1.0 km^2). Examples of mudrock seals are found in all deltaic settings (including the Gulf of Mexico, Niger, and Nile Delta petroleum

provinces) and many interior, rift, and passive continental margin basins (including north-west Australian shelf, north-west Europe, North Sea, and south-east Asia). Halite can form a more effective seal, but is a relatively rare lithology found only where conditions of high evaporation of seawater have taken place. The Upper Permian rocks of north-west Europe contain Zechstein halite that is known to have trapped gas for long periods of geological time. Halite forms part of the sealing lithology in many of the large Middle East petroleum accumulations.

Membrane Seal

When petroleum is trapped beneath a seal, there is a buoyancy pressure (P_b). The magnitude of the buoyancy pressure is a function of the contrast in density between the water (ρ_w) and petroleum (ρ_p), and its height (h) above the free water level where both are in equilibrium (normally close to the petroleum–water contact). The relationship can be written as

$$P_b = (\rho_w - \rho_p)h$$

where P_b is expressed in units of pressure (e.g., bar, psi, MPa) and the fluid densities are expressed as pressure gradients (e.g., bar m ^{1}, psi ft ^{1}, Pa m ^{1}) (Figure 2). The maximum petroleum column is controlled by the capillary entry pressure of the petroleum into the largest pores in the seal. The capillary entry pressure (P_d) of a water-wet rock is given by the equation

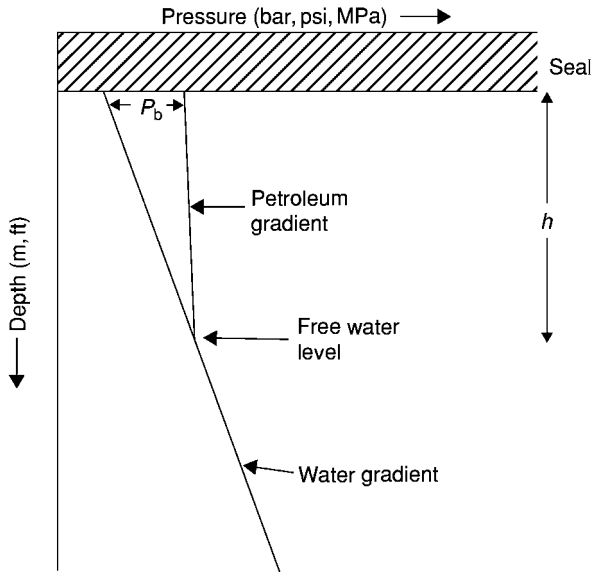

Figure 2 A pressure vs. depth plot, illustrating a typical water gradient (aquifer) supporting a petroleum column, whose steeper gradients lead to a pressure difference (P_b) at its maximum beneath the seal. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

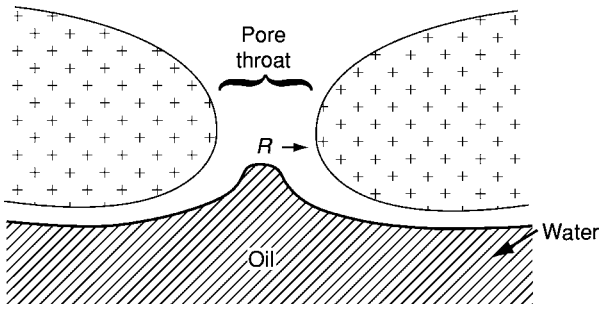

Figure 3 A schematic illustration of a pore throat between two grains. The radius of the pore throat and the buoyancy pressure, plus the interfacial angle and surface tension between oil and water, determine whether oil can migrate through the pore throat or remain trapped beneath. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

$$P_d = 2\gamma \cos\theta / R$$

where γ is the interfacial tension between the water and the petroleum, θ is the contact angle, and R is the radius of the largest pore (Figure 3). The interfacial tension and contact angle change with increasing temperature and pressure and are related to fluid type and density. These properties are routinely established from laboratory experiments on rocks. The seal capacity determines the height of a petroleum column that can be trapped beneath it, and the seal will be breached when the buoyancy pressure (P_b) exceeds the seal capillary entry pressure (P_d).

Hydraulic Seal

When the capillary entry pressure of the rock is extremely high, for example in evaporites, the failure of the seal is controlled by the strength of the rock that, if exceeded, creates natural tension fractures (*see* **Tectonics:** Faults; Fractures (Including Joints)). The rock will fracture when the pore pressure is greater than both the minimum stress and the tensile strength of the rock. Structural geologists describe the stresses in rock in terms of three orthogonal components of stress (Figure 4), one oriented vertically (S_v) and the other two oriented horizontally (S_{hmin} and S_{hmax}). In relaxed sedimentary rocks found in an extensional basin or a young delta, S_v is usually greater than both S_{hmin} and S_{hmax}, and so the minimum stress (σ_3) is horizontal. Under these conditions, the rock will fracture by creating vertically oriented fractures which will propagate horizontally. In rocks under horizontal push, or compression, the vertical stress (S_v) is the minimum stress (σ_3), and the rock will fail by the opening of horizontal fractures.

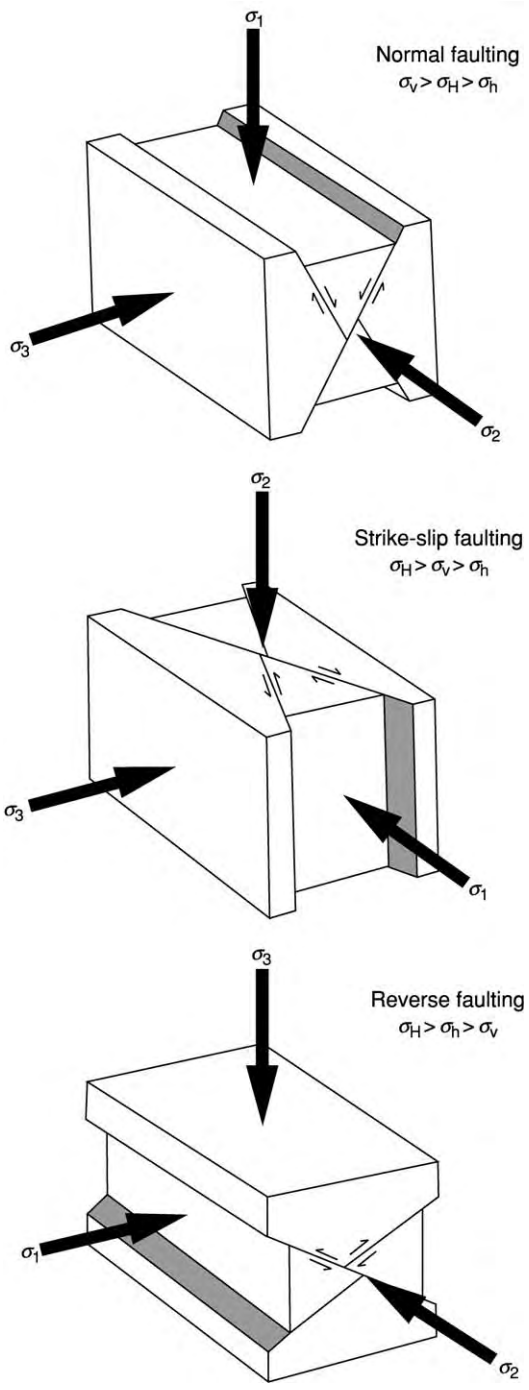

Figure 4 The relative magnitudes of the three principal stresses, one vertical (v) and two horizontal (H, h), acting in a rock mass, and the associated direction of shear, for normal strike slip and reverse faulting regimes. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

Fault

Faults can act as both conduits (migration pathways) and seals, depending on the hydraulic conditions, the rock properties of the faults, and the properties of the

rocks juxtaposed across the faults. The consideration of faults as seals follows the same reasoning as for cap-rock seals above, i.e. the sealing capacity of a fault relates to its membrane strength and hydraulic strength. Membrane fault seals fail when the pressure of the petroleum can exceed the entry pressure of the largest pores along the fault plane. Hydraulic fault seals fail when the fault is opened mechanically by high pore pressure which exceeds the minimum stress.

Reservoir

For a rock to be a petroleum reservoir, it need only be porous, i.e., capable of holding petroleum, and permeable, i.e., able to flow petroleum.

Intrinsic Properties

The following properties must be known or estimated in order for the petroleum volume to be calculated.

1. Net to gross.
2. Porosity.
3. Permeability.
4. Petroleum saturation.

The question regarding whether any discovered petroleum will flow from its reservoir into the well bore is only partially addressed in exploration. This is commonly because permeability estimations are rarely accurate.

Net to gross Net to gross is a measure of the potentially productive part of a reservoir, commonly expressed as the percentage of producible (net) reservoir within the overall (gross) reservoir package (Figure 5). The percentage net reservoir can vary from just a few per cent to 100%. Net pay is used to describe the petroleum-bearing net reservoir.

It is common to define net sand (or limestone) using a permeability cut-off (typically 1 mD for gas and 10 mD for light oil). Such information on permeability is only available when the reservoir has been cored or a petroleum flow test completed. For uncored intervals and uncored wells, a combination of data on lithology and porosity from wireline logs is used. These data are calibrated to permeability data in a cored interval (*see* **Petroleum Geology: Exploration**).

Porosity Porosity is the void space in a rock (Figure 6). It is commonly measured as a volume percentage (*see* **Sedimentary Rocks:** Sandstones, Diagenesis and Porosity Evolution). In the subsurface, this volume may be filled with petroleum, water, a range of non-hydrocarbon gases (CO_2, H_2S, N_2), or some combination of these. Most reservoirs have porosities in the range 20–30%.

Not all pores are alike; there are big pores and little pores, pores with simple shapes, and others with highly complex three-dimensional morphologies. A knowledge of the size and shape of the pores and the way in which they are interconnected is

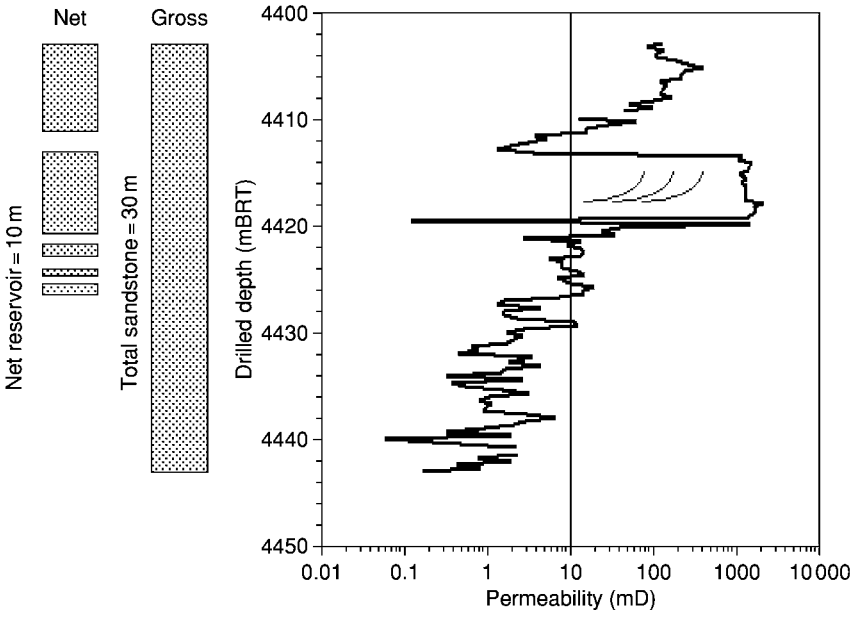

Figure 5 Net to gross is the ratio between reservoir rock capable of flowing petroleum and the gross reservoir interval. It is commonly defined using a single permeability cut off. The example here is a Jurassic oil bearing sandstone from the North Sea. Thirty metres of sandstone was cut in one core, but only 19 m had a permeability greater than the 10 mD cut off chosen, a net to gross of 63%. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

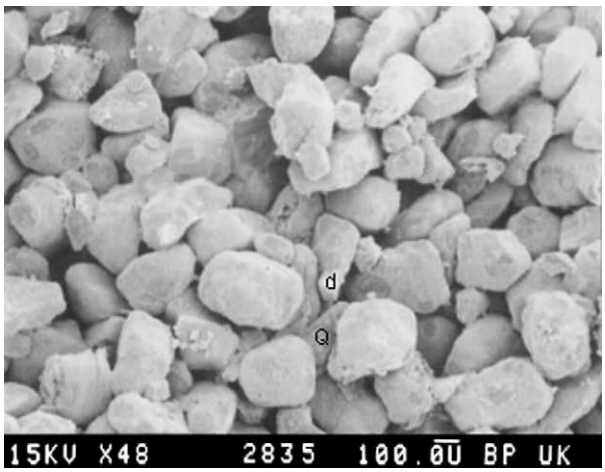

Figure 6 Scanning electron photomicrograph of a porous (28%) and permeable (2200 mD) Permian, Rotliegend reservoir sandstone, southern North Sea. Field of view, 2.7 mm × 1.8 mm. Photograph by A. J. Leonard, reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

important, because it is these factors that determine the permeability of the rock.

For sands and sandstones, a threefold description of porosity is used: intergranular, intragranular, and microporosity (Figure 7). Intergranular porosity occurs between grains. Individual pores in clean sand will occupy approximately 40% of the total volume. For coarse sands, the pores are larger than in fine sands. In most sandstones, the intergranular porosity is primary, a residuum of that imparted at deposition. Some intergranular porosity may be created in sandstones by the dissolution of mineral cements. Most intragranular porosity is secondary in origin, created on partial dissolution of grains. Microporosity simply means small pores, those associated with depositional or diagenetic clay or other microcrystalline cements.

Porosity development in limestones and dolomites is much more variable than that for sandstones. Both rock types are much more prone to mineral dissolution and precipitation than sandstones. This, coupled with the often varied suite of shell and other bioclastic material in the carbonates, makes for a wealth of pore types (Figure 8): intergranular, intragranular, intercrystalline, intracrystalline, biomouldic, vuggy, fracture, cavernous. The size range for pores is also much greater for limestones than for sandstones: from micropores (a few micrometres) in individual oolite grains to giant cave systems.

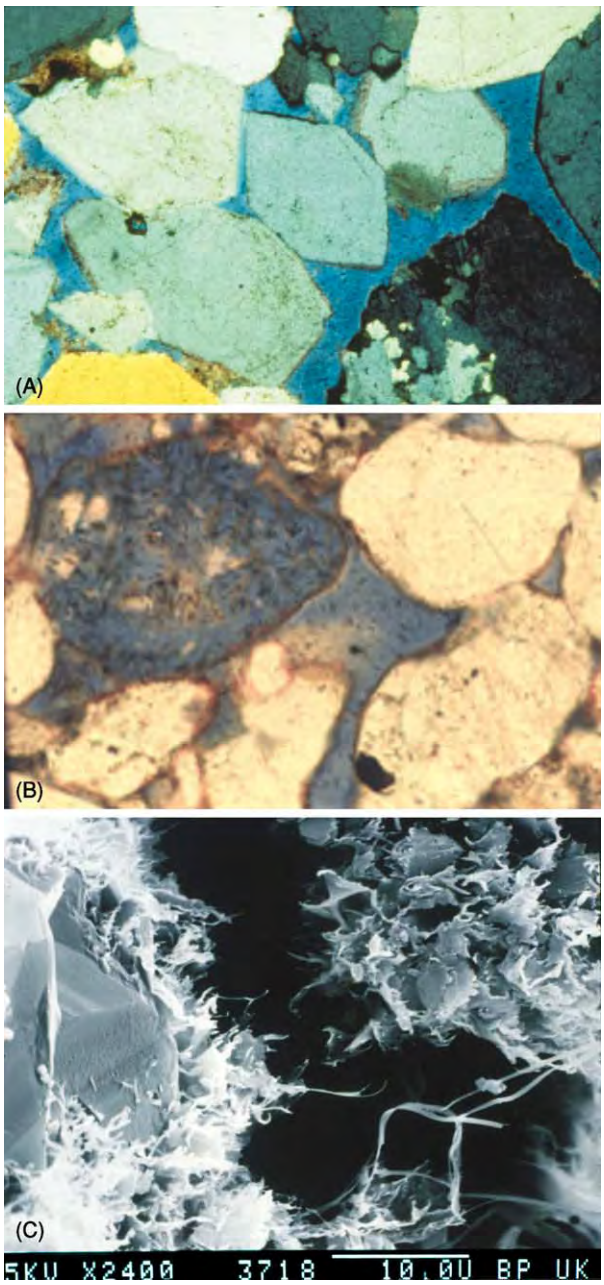

Figure 7 Porosity in sandstones. (A) Intergranular porosity (arrowed) between quartz grains with quartz overgrowths, Jurassic Brent sandstone, northern North Sea. Field of view, 1.3 mm × 0.9 mm. (B) Intragranular porosity within partially dissolved feldspar, Permian Rotliegend sandstone, southern North Sea. Field of view, 650 μm × 450 μm. (C) Microporosity (arrowed) between illitized kaolinite plates, Jurassic Brent sandstone, northern North Sea. Photographs by J. G. Gluyas.

Permeability Permeability is an intrinsic property of a material that determines how easily a fluid can pass through it. In the petroleum industry, the darcy (D) is the standard unit of permeability, but millidarcies (mD) ($1\,\text{mD} = 10^{-3}\,\text{D}$) are more commonly used. A darcy is defined as a flow rate of $10^{-2}\,\text{m s}^{-1}$ for a fluid of 1 cP (centipoise) under a pressure of $10^{-4}\,\text{atm m}^{-2}$. Permeability in reservoir rocks may range from 0.1 mD to more than 10 D. Permeability

G. Gluyas.

measurements made at the Earth's surface are commonly greater than those in the subsurface, and a pressure correction must be made to restore the value of permeability to reservoir conditions. This intrinsic rock property is called the absolute permeability when the rock is 100% saturated with one fluid phase.

Water, oil, and gas saturation It is rare in nature to find a reservoir entirely oil (or gas) saturated. More commonly, the pore system contains both oil and water. The proportions of each phase are commonly expressed as percentages linked to the abbreviations: S_w for water, S_o for oil, and S_g for gas. Water and petroleum saturations are not constant across a reservoir. They vary in response to the position in the oil column, the permeability of the rock, and the mineralogy of the rock. Oil and water saturations will also change as petroleum is produced.

Reservoir Lithologies

Sandstone and limestone (including dolomite) are the most common reservoir lithologies. Sandstones dominate as important reservoirs in the USA (including Alaska), South America, Europe, Russian Asia, north Africa, and Australia. Limestones form the dominant reservoirs in the Middle East. They are also important in the Far East, western Canada, and some of the former Soviet states.

Sandstones, limestones, and dolomites of any age can make fine reservoirs. However, most of the best reservoirs in the world are relatively young. Petroleum fields are more common in Cenozoic and Mesozoic sediments than in Palaeozoic reservoirs. Precambrian age reservoirs are rare. There is no intrinsic reason why old rocks are more or less likely to be reservoirs than younger ones; it is simply that older reservoirs have had greater chance to be involved in tectonism or cementation, so destroying their porosity or permeability.

In addition to sandstone and limestone, fractured rock of any type can form a reservoir. The fractures alone may form the total pore volume of the reservoir. Alternatively, the fractures may help drain petroleum from the intervening lower permeability rock.

Reservoir; sandstone depositional systems Sediments, including those which may one day form a petroleum reservoir; can accumulate in many environments on the Earth's surface (*see* **Sedimentary Environments:** Depositional Systems and Facies). This includes sands deposited both on land and beneath the sea (Table 1). The overall architecture and internal

Table 1 Clastic reservoirs

Depositional system	*Architectural elements*	*Size range*	*Reservoir properties*	*Example oil/gas field(s) or province*
Alluvial fan	Low angle half cones, linear and sheet sand bodies	1 10 km diameter	Heterogeneous, poorly sorted	Quiriquire Field, Pliocene E. Venezuela, 750 mmbbl
Aeolian deposit	Dune, sand sheet	100s km^2	Dune well sorted porous sands high quality sandsheet moderate quality	Permian Rotliegend, Europe; Jurassic Norphlet, US Gulf Coast
Lake deposit	Half cone (fan)	Few km diameter	Poor to good, function of sediment input	Thailand & China
Fluvial system	Channel fill, crevasse splay	Channel belts 10s km × few km, crevasse splay few km diameter	Channel fills in braided and meandering systems commonly good; braided net to gross > meandering net to gross	Prudhoe Bay Field, Triassic Alaska, >10 bn bbl; Wytch Farm Field, Triassic UK onshore, 300 mmbbl
Delta and coastline	Channel mouthbar, shoreface, beach	**Figure 9**	Commonly good in reworked sandstones, variable net to gross	Niger Delta, W. Africa; Brent system, North Sea; Mahakan Delta, Indonesia; multiple billion barrels fields
Shallow marine	Shoreface to offshore sandstone bars	**Figure 9**	Good to excellent, high net to gross	Shannon Sandstone, Cretaceous USA; Fulmar/Ula Sandstones, Jurassic UK and Norwegian North Sea; Toro Sandstone, Jurassic/Cretaceous Papua New Guinea
Deep marine	Fan lobe, fan channel	10 100s km long, 10s km across	Depends upon sediment source area	Tertiary formations, North Sea; Plio Pleistocene US Gulf Coast; Tertiary Congo Fan

geometry of the sand bodies (**Figure 9**) control the performance of a reservoir during petroleum production (*see* **Petroleum Geology:** Production).

Reservoir; carbonate depositional systems Limestones and dolomites form some of the largest petroleum reservoirs in the world. Many of the largest occur in the Middle East. Other areas in which carbonate reservoirs deliver large quantities of oil and gas are western Canada, Mexico, Texas (USA), Norway (central North Sea), Poland, Kazakhstan, western and south-eastern China, Iran, and Libya.

The sediment that forms most carbonate reservoirs accumulated in shallow marine environments (*see* **Sedimentary Environments:** Carbonate Shorelines and Shelves). The important exceptions are pelagic chalks (Ekofisk Complex of the North Sea) and deep-water resedimented carbonates of the Poza Rica Trend in Mexico.

Like their clastic counterparts, there is a clear link between the reservoir potential of a carbonate body and the environment in which the host sediment accumulated. High-energy ooid and shell shoals can make excellent reservoirs. Framework reef complexes are also prime reservoir targets. However, unlike siliciclastics, carbonates can undergo almost complete transformation on weathering and/or diagenesis to produce reservoirs from former seals and seals from former potential reservoirs.

Dolomite (*see* **Sedimentary Rocks:** Dolomites) Producing dolomites range in age from Precambrian to Tertiary. It is estimated that about 80% of the recoverable petroleum in carbonate-hosted reservoirs of the USA occurs in dolomite and only about 20% in limestone. The same ratio probably applies to the producible reservoirs in the Permian Zechstein of Europe, whilst older carbonate plays in Europe and Russian Asia are almost wholly dolomite. The dolomitization of limestones commonly leads to an increase in both porosity and permeability (**Figure 10**).

Karst (*see* **Sedimentary Processes:** Karst and Palaeokarst) Karstified limestones and dolomites represent the second major group of carbonate reservoirs not directly linked to depositional environments. Karst is a product of mineral dissolution (**Figure 11**). It develops where carbonates are exposed to meteoric water, often linked with episodes of sea-level fall. Karst features are well known to geologists and geographers alike: caves, collapse breccias, dissolution-enhanced joints and fractures, and vugs.

Fields producing from karstified limestones and dolomites include the Liuhua Field in the South China

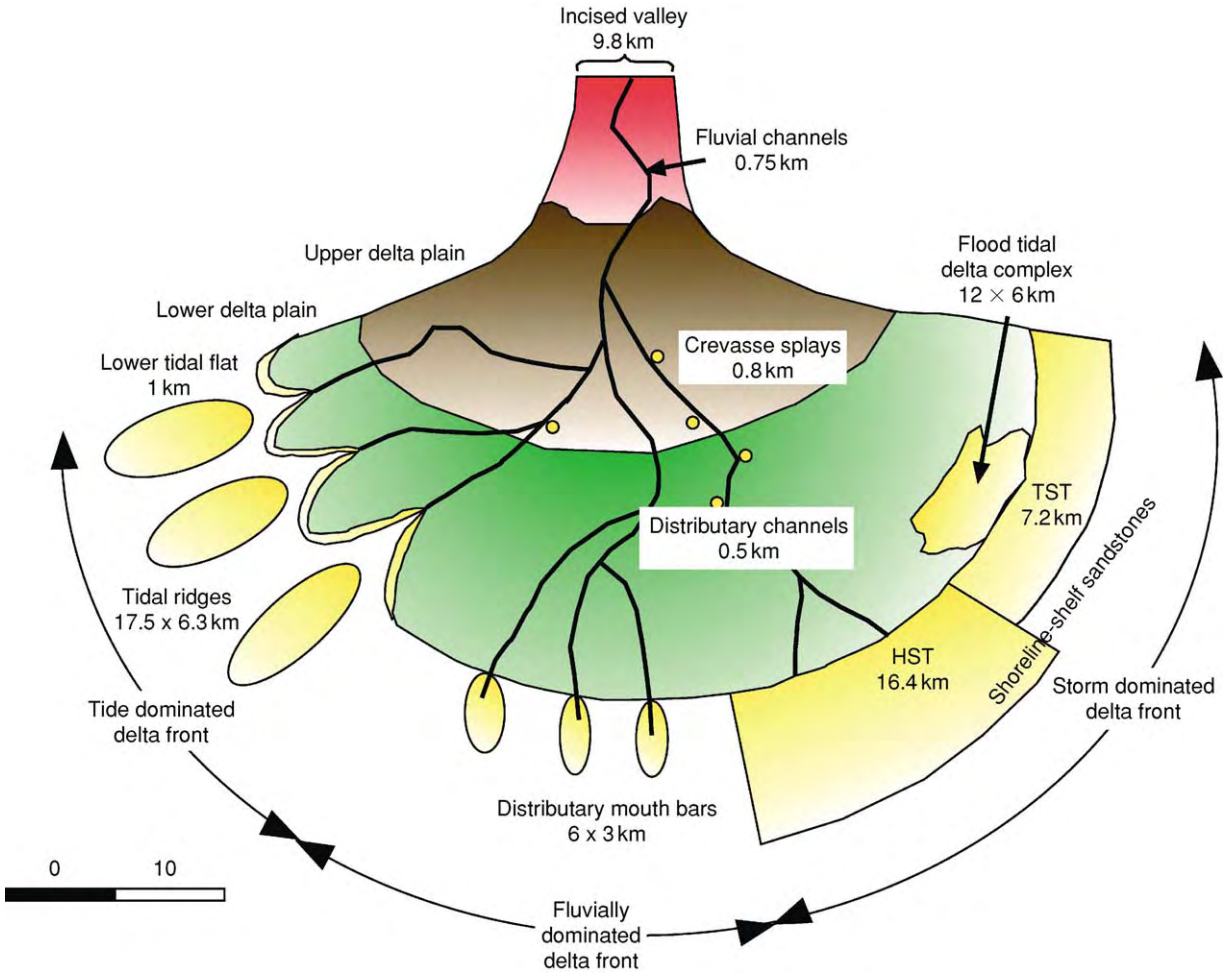

Figure 9 The average size, shape, and location of sand bodies in wave, tidal, and fluvially influenced reservoirs. Reproduced from Reynolds AD (1994) Sequence stratigraphy and the dimensions of paralic sandstone bodies. In: Johnson SD (ed.) *High Resolution Sequence Stratigraphy: Innovations and Applications*, pp. 69 72. Liverpool: Liverpool University.

Sea, the Permian reservoirs of Texas and New Mexico, and parts of the Upper Permian in the Zechstein Basin in Europe. Thermal karst, produced when hot fluids dissolve limestones at depth, may also become reservoirs. The Albion Scipio Field of Michigan is of this type.

Trap

Trap is the term to describe the body, bounded by seals and containing reservoir, in which petroleum can accumulate as it migrates from the source rock to the Earth's surface. There are many different trap geometries. These can be grouped into three categories: structural, stratigraphical, and hydrodynamic (Table 2). Structural traps are created by tectonic, diapiric, compactional, and gravitational processes (Figure 12). Almost the entire world's discovered petroleum is in traps that are largely structural. Stratigraphical traps are

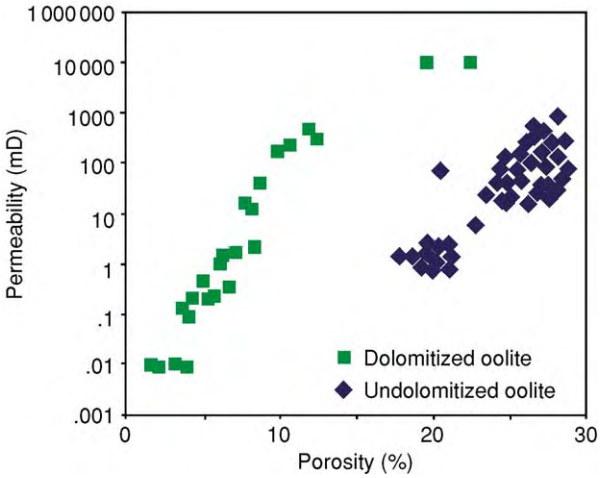

Figure 10 A comparison of porosity and permeability for dolomitized and undolomitized oolite, Cretaceous Middle East. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

formed by lithological variations or property variations generated by alteration of the sediment or fluid through diagenesis (Figure 13). Much of the world's remaining undiscovered petroleum will be found in stratigraphical traps. Purely hydrodynamic traps are rare. Such traps rely on the flow of water through the reservoir horizon to 'drag' the petroleum into a favourable trapping configuration, such as the plunging nose of a fold. The trapping mechanism for many fields is commonly a combination of structural and stratigraphical elements or, more rarely, structural elements and hydrodynamic conditions.

Figure 11 Tower karst containing fracture and cavernous porosity, Palaeozoic limestones, Zhaoquing, Guangdong Province, China. Photograph by J. G. Gluyas.

Structural Trap

Compressive tectonic regimes commonly lead to the development of large-scale contractional folds and thrusts. This is common at convergent plate boundaries and transpressional strike-slip plate boundaries (wrench systems). The El-Furrial Trend of eastern Venezuela is an example of such a system. The anticlinal traps of the trend were developed during convergence of the Caribbean and South American plates during the Neogene. Many of the traps are large ramp anticlines (Figure 14). They have oil columns of, on average, 400 m and reservoirs formed from high net to gross shallow marine sandstones.

In North America, thrust-linked rollover anticlines form the major trap type in the Wyoming–Utah thrust belt fields and the southern foothills of the Alberta Basin, Canada. Compressional anticlines also form giant traps within the Zagros fold belt of Iran.

Traps formed by extensional tectonics are common in rift basins. The East Shetland Basin of both the UK and Norwegian sectors of the North Sea contained about 15 billion barrels of recoverable oil. Much of this oil was trapped in tilted fault blocks formed during Late Jurassic rifting. In the pre-rift section, oil is reservoired in the sandstones of the Middle Jurassic Brent Group, together with other sandstones of both Jurassic and Triassic age (Figure 15). Traps formed through tectonic extension are also important in the Gulf of Suez, the Haltenbanken area, offshore mid-Norway, and in the pre-rift sections of the Gippsland Basin (Australia).

Traps can also be formed by diapiric processes. The specific gravity of salt (halite) is about 2.2 g cm ^{3} and that of fully consolidated rock is about 2.5–2.7 g cm ^{3}. Thus salt is buoyant relative to most other sediments

Table 2 Structural and stratigraphical traps

Structural	Tectonic	Extensional
		Compressional
	Diapiric	Salt movement
		Mud movement
	Compactional	Drape structures
	Gravitational	Listric fault movement
Stratigraphical	Depositional	Pinchouts (dunes, bars, reefs, channels, etc.)
		Unconformities (erosional, subcrop, karst, etc.)
	Diagenetic	Mineral precipitation
		Mineral dissolution (thermal karst, dolomitization)
		Tar mats
		Permafrost
		Gas hydrate crystallization

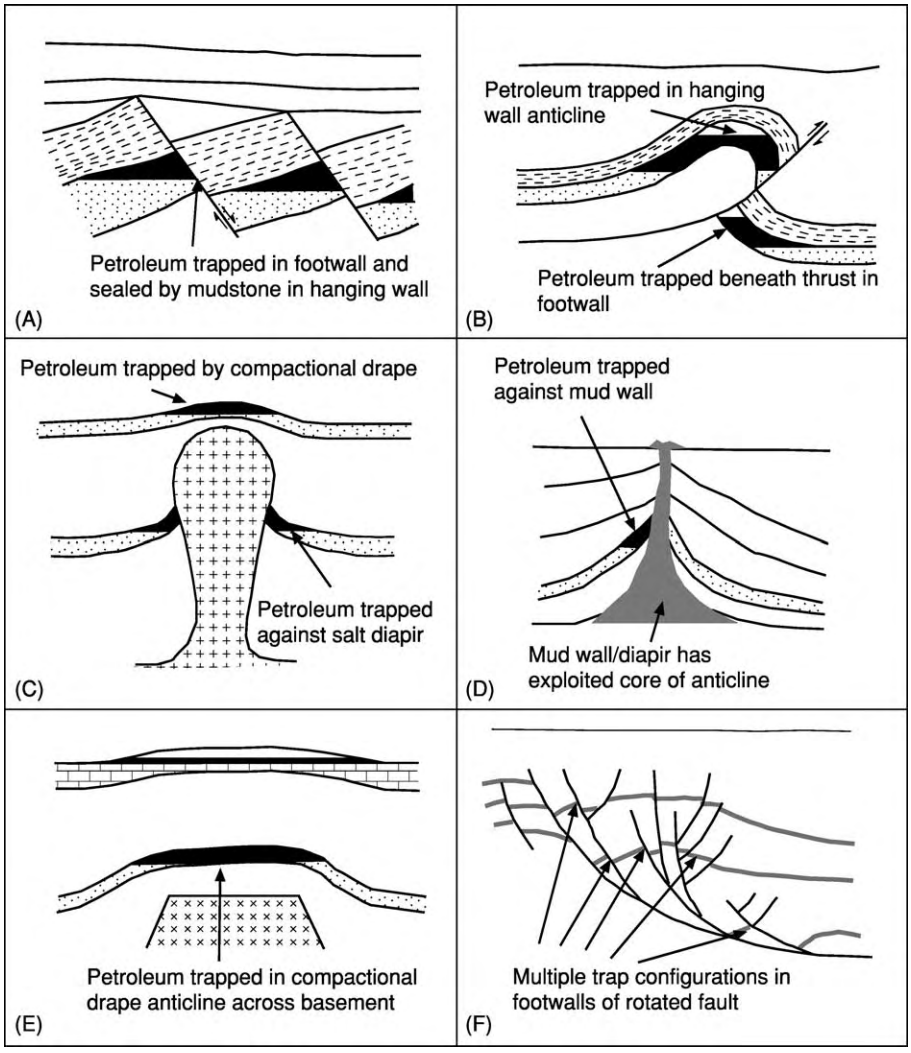

Figure 12 Structural traps. (A) Tilted fault blocks in an extensional regime. The seals are overlying mudstones and cross fault juxtaposition against mudstones. (B) Rollover anticline on thrust. Petroleum accumulations may occur on both the hanging wall and the footwall. The hanging wall accumulation is dependent on a subthrust fault seal, whereas at least part of the hanging wall trap is likely to be a simple, four way, dip closed structure. (C) Lateral seal of a trap against a salt diapir and compactional drape trap over the diapir crest. (D) Diapiric mudstone associated trap with lateral seal against mud wall. Diapiric mud associated traps share many common features with that of salt. In this diagram, the diapiric mud wall developed at the core of a compressional fold. (E) Compactional drape over a basement block commonly creates enormous low relief traps. (F) Gravity generated trapping commonly occurs in deltaic sequences. Sediment loading causes gravity driven failure and produces convex down (listric) faults. The hanging wall of the fault rotates, creating space for sediment accumulation adjacent to the fault planes. The marker beds (grey) illustrate the form of the structure that has many favourable sites for petroleum accumulation. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

and sedimentary rocks. Over geological time, salt deforms plastically. With loading caused by continued sedimentation, layers of salt may aggregate into swells and eventually pillows. Subsequently, a salt diapir may rise through the overburden. Very similar processes to those associated with salt diapirism can occur in association with muds. Rapidly deposited muds are commonly water rich, overpressured, and, in consequence, highly mobile. Mud lumps (Niger Delta), shale walls, diapirs, and mud volcanoes (Trinidad, Azerbaijan) are all products of mass mud movement.

Diapiric movement of both salt and mud can create anticlinal structures that could form petroleum traps. Trap configurations can also develop in the areas of salt withdrawal. The 'turtle' structure anticline develops via increased sedimentation in areas of salt withdrawal. Later, as salt continues to feed the diapir, the structure flounders and flips into an anticline.

Greater Burgan (Kuwait), the second largest oilfield in the world (>75 billion barrels of reserves), developed over a large, low-amplitude salt swell.

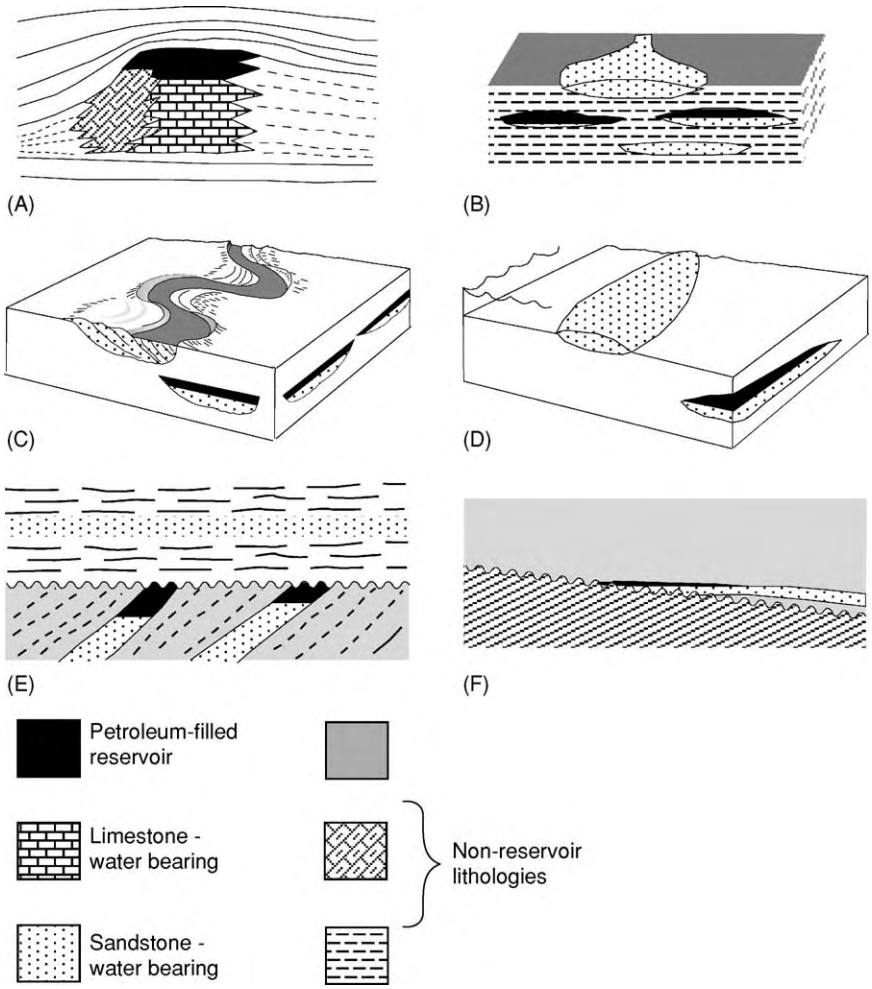

Figure 13 Stratigraphical traps. (A) 'Reef' oil is trapped in the core of the reef, with fore reef talus and back reef lagoonal muds acting as lateral seals and basinal mudstones as top seals. (B) Pinchout (sandstone) trap within stacked submarine fan sandstones. The upper surface of the diagram shows the plan geometry of a simple fan lobe. Lateral, bottom, and top seals are the surrounding basinal mudstones. (C) Channel fill sandstone trap. The oil occurs in ribbon shaped sandstone bodies. The top surface of the diagram shows the depositional geometry of the sandstone. Total seal may be provided by interdistributary mudstones or a combination of these and marine flooding surfaces. (D) Shallow marine sandstone bar completely encased in shallow marine mudstone. The upper surface of the diagram shows the prolate bar. (E) Subunconformity trap. The reservoir horizon is truncated at its up dip end by an unconformity and the sediments overlying the unconformity provide the top seal. Lateral and bottom seals, like the reservoir interval, pre date the unconformity. (F) Onlap trap. A basal or near basal sandstone onlaps a tilted unconformity. The sandstone pinches out on the unconformity and is overstepped by a top seal mudstone. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

Similar, simple anticlinal dome traps typify the Cretaceous Chalk fields of the Norwegian North Sea. As with the Middle East examples, the key controlling structures are the underlying salt pillows.

Traps associated with diapirs rather than swells tend to be much smaller in aerial extent than the giants described above. They also tend to be much more structurally complex, commonly containing both radial and concentric fault patterns. The Machar Field (STOOIP (standard barrels of oil originally in place) about 228 mmstb) of the North Sea is roughly circular in outline with a diameter of about 4 km (Figure 16).

Anticlinal traps created through compaction occur across basement highs, tilted fault blocks, carbonate shelf rims, reefs, or isolated sand bodies. Some of the simplest are also the largest. The world's biggest field, Ghawar in Saudia Arabia, is such a trap. Oil occurs in Jurassic carbonates draped over and compacted around a north–south-trending basement high.

Traps formed by gravity-driven processes are particularly important in large recent deltas. The best-described examples are from the US Gulf Coast and West African deltas (Niger, Congo). The gravity structures form independently of basement tectonics and owe their existence to shallow detachment along

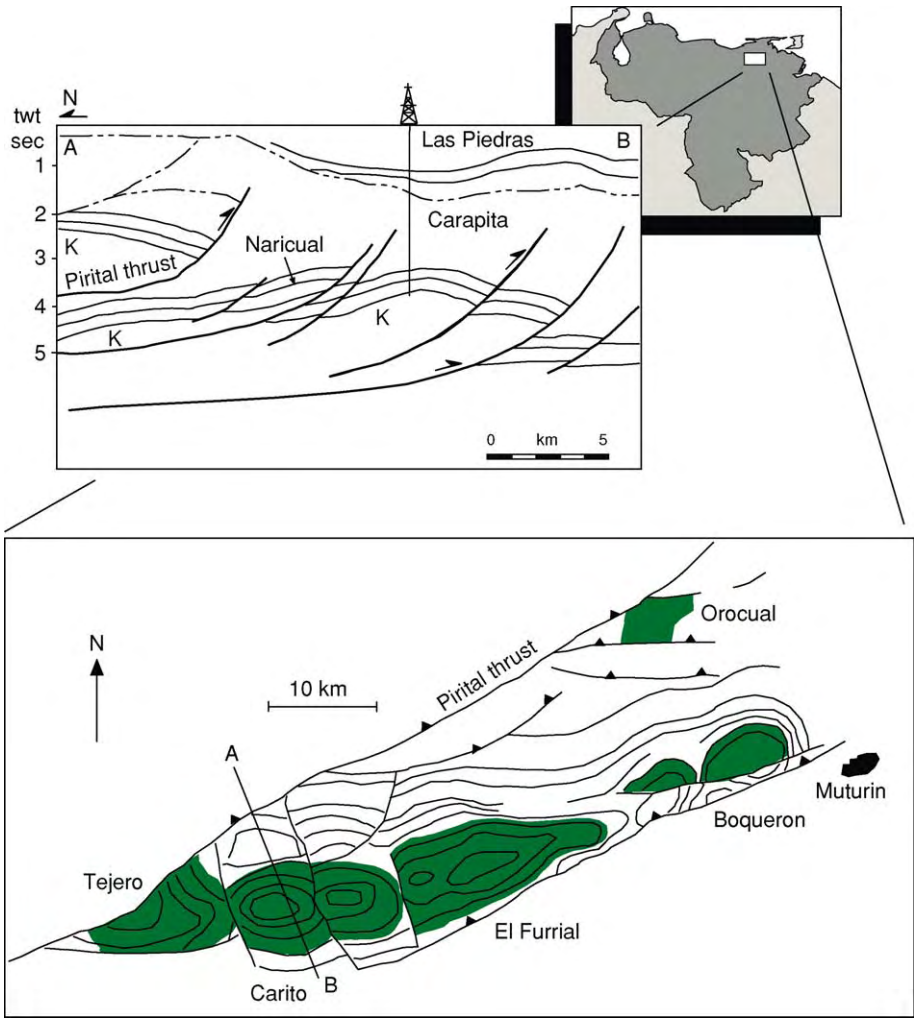

Figure 14 El Furrial Trend, eastern Venezuela. The petroleum traps are large rollover anticlines on the hanging walls of thrusts. Most are four way, dip closed structures, whilst some have a dependence on a fault component along their south eastern thrust margin. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

low-angle, basinward-dipping planes. The drive mechanism is provided by the weight of sediment deposited by the delta at the shelf–slope break or on the slope itself. In the Niger Delta, the detachment planes are highly mobile muds, whereas, in the Gulf Coast (Mississippi Delta), detachment occurs on both muds and the Louanne Salt (Jurassic). The key detachment surfaces are commonly listric, concave-up, and concave-basinward in plan view. The main faults are commonly large, being tens of kilometres tip to tip.

Stratigraphical Trap

From top to bottom of a systems tract, each depositional environment is capable of producing a juxtaposition of permeable and impermeable sediments which might one day form a stratigraphical trap for petroleum. In practice, the reservoir geometry becomes the trap geometry. Examples include aeolian dunes encased in lacustrine mudstone, sand-filled fluvial channels cut into mud-rich overbank deposits, shallow marine bar sandstones surrounded by marine shales, carbonate reefs isolated by enclosing marls, and submarine fan sands trapped within the domain of pelagic mud.

The Paradox Basin (Colorado and Utah, USA) contains a large array of small oil and gas fields in stratigraphical pinchout traps. Devonian reservoirs occur within shallow marine bar sandstones and Carboniferous reservoirs within carbonate mounds. The Paradox Basin traps are difficult to find, but have relatively simple shapes. Their geometries are either prolate bar forms or more equidimensional carbonate mounds. Pinchout traps formed in deltaic settings are often much more complex in outline and, because

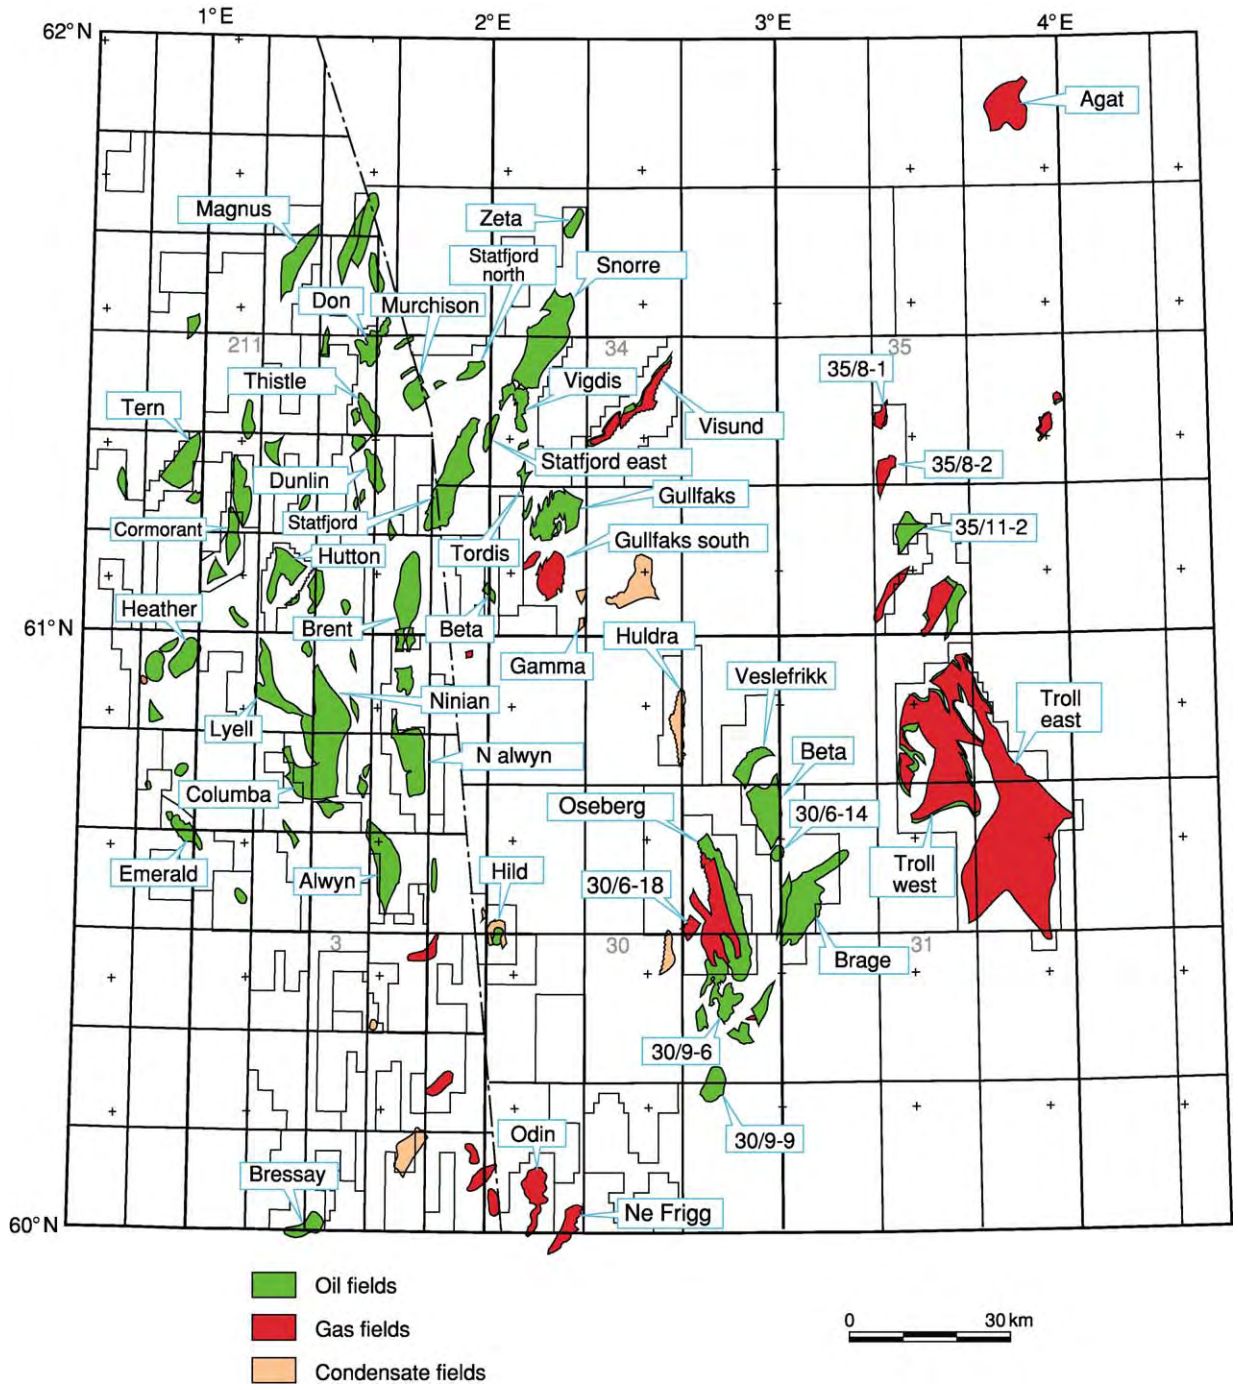

Figure 15 UK and Norwegian Brent Province. The elongate shapes reflect the geometry of the tilted fault blocks that form the traps. The reservoir is largely Middle Jurassic Brent sandstones together with Triassic and Upper Jurassic sandstones in some fields. The traps for neither Troll (Upper Jurassic reservoir in low relief anticline) nor Agat (Lower Cretaceous reservoir, stratigraphically trapped) are tilted fault blocks. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

potential reservoir sandstones are commonly discontinuous, multiple pools (clustered fields) are common (Figure 17).

Attenuation of the up-dip portions of a potential reservoir interval by an unconformity can create massive traps with enormous petroleum catchment (drainage) areas. The largest oilfield in North America, Alaska's Prudhoe Bay, is an unconformity trap. It has about 25 billion barrels of liquid and more than 20 trillion cubic feet of gas in place. East Texas, the

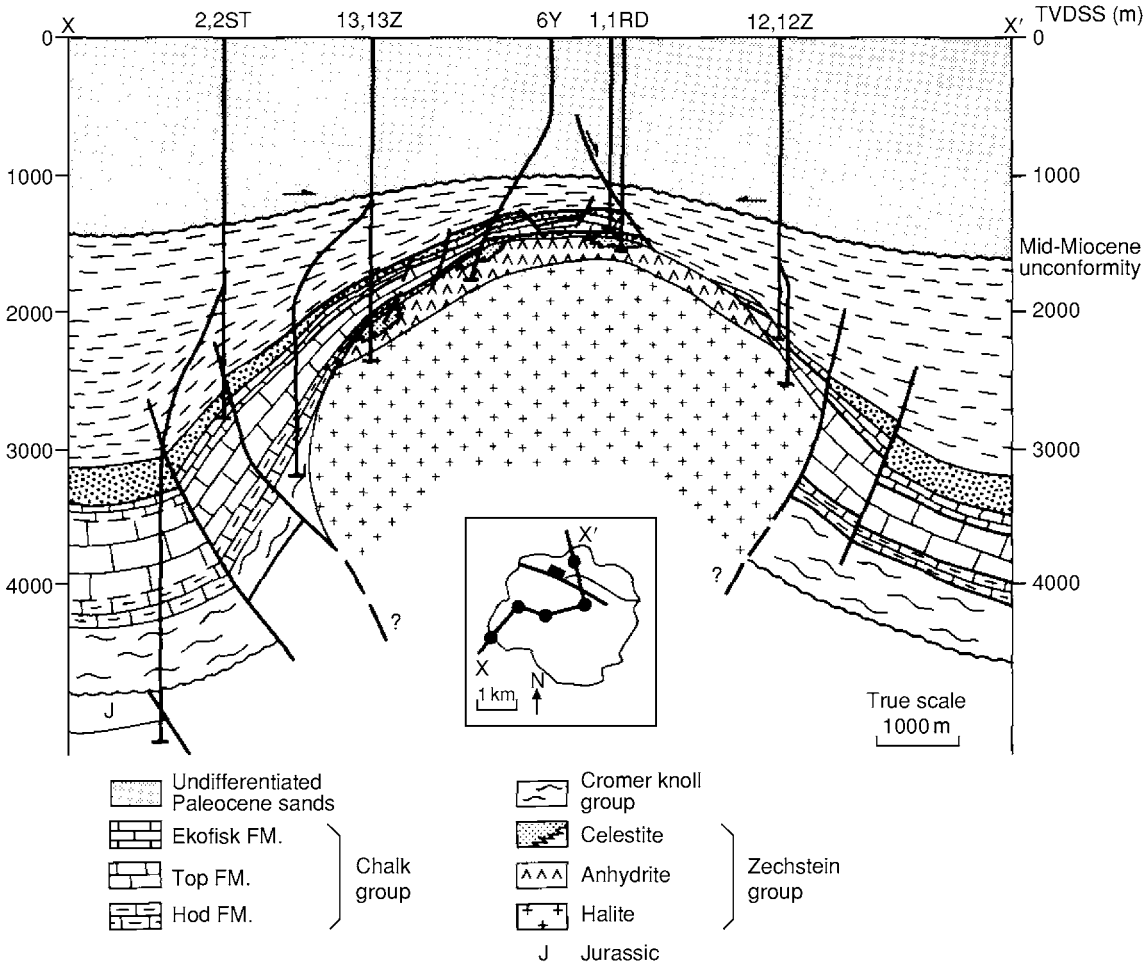

Figure 16 A structural cross section of the Machar Field, central North Sea, showing the circular outline of the field and the distribution of reservoirs around the head of the salt diapir. Reproduced from Foster PT and Rattey PR (1993) The evolution of a fractured chalk reservoir: Machar Oilfield, UK North Sea. largest oilfield in the USA Lower 48, is also a stratigraphical trap. The productive Woodbine Sandstone reservoir, with its initial reserves of about 6.8 billion barrels, is sandwiched between two unconformities. The sand rests upon the Washita Group mudstones and is itself truncated beneath the Austin Chalk. The field, some 40 miles long and 5 miles wide, is a simple homoclinal dip to the west.

Each of the unconformity traps described above relies on a combination of trapping mechanisms, which rely in large part on a planar or gently folded unconformity. Unconformities come in a variety of shapes. The most spectacular of the unconformity-bounded traps are those commonly referred to as 'buried hills'. Such hills are residual topography of a one-time land surface. Thus it is the unconformity surface that has the trapping geometry (Figure 18). Buried hill traps are most common in karstified areas, such as northern China.

Mineral cements are known to form top, lateral, and even bottom seals to reservoirs. Examples in carbonate systems are more numerous than those in clastic systems. In the Albion-Scipio Field of Michigan (USA), all surrounding rock to the trap is thoroughly cemented limestone and dolomite. A comparable situation exists for many of the carbonate-hosted oilfields of Abu Dhabi; porosity only exists where there is oil. Areas that at one time must have been the aquifers to the oilfields have been thoroughly cemented. For a few fields, such cementation has allowed trap integrity to be maintained despite tilting of the field after petroleum accumulated.

Tar mat seals are common in the shallow subsurface. They also act as cap rock for the largest single accumulation of heavy (viscous) oil in the world; the Faja of south-eastern Venezuela, which has about 1.2 trillion barrels of oil in place. Tar seals and tar sands

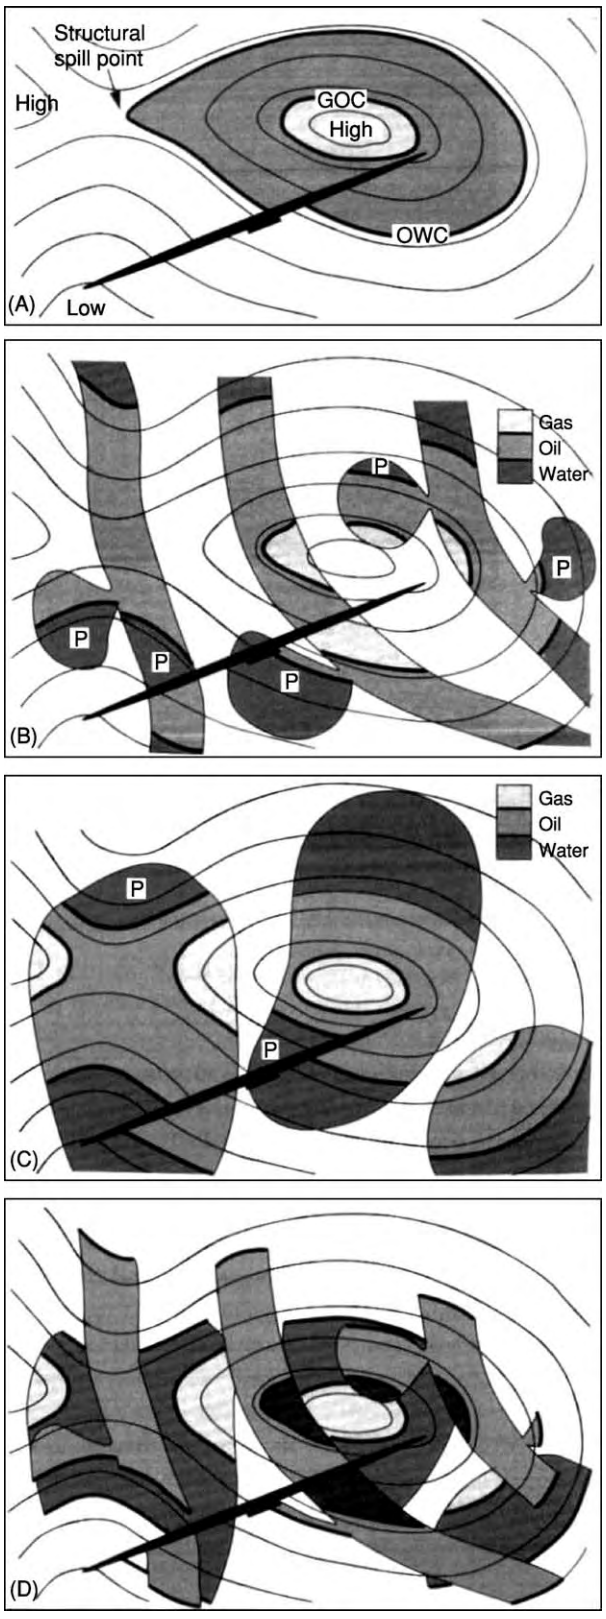

Figure 17 Paralic field outlines commonly have complex shapes because of the interaction between structure and sedi ment bodies. This complexity is multiplied because individual paralic sandstones tend to be stacked. The four examples show: (A) field shape on a simple faulted anticline for which the reservoir interval is much larger than the anticline; (B) the same structure as in (A), but with the reservoirs developed in channel and crevasse splay sandstones that are smaller in area than the structure; (C) the same structure as in (A), but with mouthbar sandstones which are also smaller than the structure; (D) a combination of channel and mouthbar sandstones at different levels. A. Reynolds, personal communication, 1994. Reproduced courtesy of BP.

are also common within the Western Canada Basin and Californian basins.

Gas trapped beneath permafrost forms large fields in the northern part of the West Siberia Basin, adjacent to the Kara Sea. In cold regions, gas (methane) is also trapped as gas hydrate.

Hydrodynamic Trap

The idea that moving water could and would control the distribution of both oil and gas traps was first advocated in 1909. The hypothesis had a number of supporters until the 1930s, when the number of publications on the topic dwindled and the anticlinal theory of petroleum accumulation reassumed its position as the only favoured theory. Twenty years later, the idea was resurrected, although it remains controversial.

Those traps with undoubted hydrodynamic credentials tend to be in foreland basins where subsurface reservoir units commonly crop out in adjacent mountain belts. The outcropping reservoir units are recharged with meteoric water and the hydraulic head drives the flow through the basin. Two of the best-documented examples are the Frannie Field of the Big Horn Basin, Wyoming, and the East Colinga Extension Field of San Joaquin Valley, California. In both instances, there is sufficient information to map the tilted oil–water contacts, rule out the possibility of significant permeability barriers in the systems, and explain the water flow in terms of the adjacent topography and subsurface structure.

Migration

Migration is the process (or processes) whereby petroleum moves from its place of origin, the source rock, to its destruction at the Earth's surface. Along the route, the petroleum's progress may be temporarily arrested and the petroleum may accumulate within a trap. The timing of trap formation relative to that of petroleum generation and migration is critical. The trap has to form at the same time or earlier than petroleum migration if it is to capture petroleum.

Migration may be divided into three stages (Figure 19).

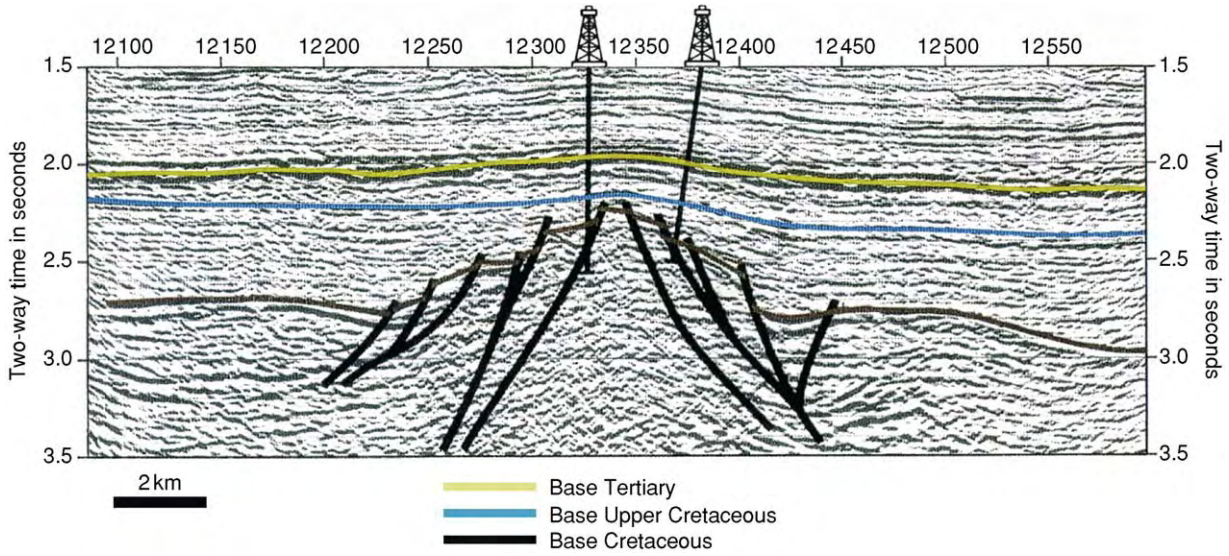

Figure 18 Subunconformity trap beneath the base Cretaceous unconformity, Buchan Field, UK North Sea (fractured Devonian sandstone reservoir). - Primary migration: expulsion of petroleum from the source rock.
- Secondary migration: the journey from source rock to trap.
- Tertiary migration: leakage and dissipation of the petroleum at the Earth's surface.

Primary Migration

There have been many hypotheses created to explain the migration of petroleum out of the source rock. Most researchers now favour processes whereby petroleum is expelled from the source rock as a separate phase within a water-wet rock matrix.

Analyses have been performed on a source rock (Kimmeridge Clay, North Sea) which is actively expelling petroleum. The aim was to elucidate the precise primary migration mechanisms. The analytical results could best be explained by invoking pressure-driven flow of a petroleum-rich phase as the main expulsion mechanism for source rocks. Specifically, it was demonstrated that petroleum was first expelled when the volume of generated petroleum approximately matched the volume of pore space within the mudstone. That is, the mudstone was almost fully saturated with petroleum before expulsion occurred. This supported earlier observations on lean source rocks. Those which yield less than 5 kg petroleum per tonne tend not to achieve sufficient saturation for expulsion to occur.

Gas expulsion may occur in a similar fashion to that of oil, albeit at higher temperatures. Clearly, the volume increase associated with gas generation is massive, be it directly from kerogen or from the thermal decomposition of previously formed oil. Pressure-driven expulsion will occur either through

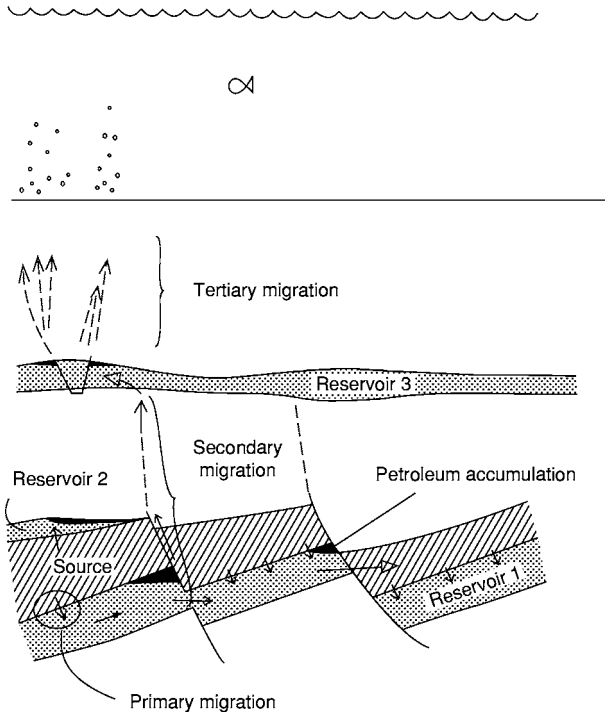

Figure 19 Diagram of the three stages of migration. Primary migration out of the source rock and into a trapped reservoir (reservoir 2) or a carrier bed (reservoir 1). Secondary migration in carrier reservoir 2 and up faults into reservoir 3. Tertiary migration (dissipation) from reservoir 3 to the surface. Reproduced from Gluyas JG and Swarbrick RE (2003) *Petroleum Geoscience*. Oxford: Blackwell Science.

the existing pore network or through induced fractures. During gas generation, previously generated, short-chain liquid hydrocarbons may become dissolved in the gas and expelled with it. This mechanism has been used to explain the production of condensate from Type III kerogen in overpressured mudstone.

Secondary Migration

Secondary migration takes petroleum from the source location to trap or traps via carrier beds. The defining aspect of secondary migration is that it concentrates or focuses the petroleum. On escape from the source rock, petroleum is dispersed over a large area. By the time petroleum reaches the relatively restricted area of a trap, it can occupy more than 90% of the pore volume in the reservoir. Secondary migration is temporarily arrested once the migrating petroleum enters a trap. Disruption of the trap or overfilling of the trap can lead to remigration of the petroleum to a higher structural level under the same secondary migration process. Such secondary migration ends when petroleum approaches the Earth's surface.

The medium through which the petroleum travels during secondary migration is also quite different from that of the source rock. The pore size and thus permeability in a carrier bed, be it a sandstone, carbonate, or fractured lithology, is much larger than that in a source rock. The driving mechanism for secondary migration is the density difference between the petroleum (less dense) and water (more dense). The density difference is expressed through the buoyancy force generated by the pressure difference between a point in a continuous petroleum column and the adjacent pore water.

The restricting force to petroleum migration is the capillary injection pressure. A slug of petroleum migrates from pore to pore in a carrier bed, squeezing through the intervening pore throats. The force required to move petroleum through a pore throat is a function of the radius of the pore throat, the interfacial tension between the petroleum and the water, and the wettability of the rock–petroleum–water system.

The buoyancy effect means that petroleum will tend to rise within the sediment column. The capillary effect dictates that, in the absence of other forces, petroleum will migrate from small pores to large pores. Furthermore, petroleum (and water) will attempt to equilibrate with respect to pressure. That is, flow can be induced by pressure differential (either overpressure or hydrodynamics).

It is possible to estimate the likely migration directions from source bed to reservoirs by mapping the orthocontours of the likely carrier systems (Figure 20). Orthocontours are simply lines constructed on a map at right angles to the contours. Instead of displaying areas of equal height (or depth), they depict lines of maximum dip. The buoyancy effect dictates that the rising petroleum will follow such orthocontours. Clearly, such an exercise must be attempted on the geometry of the carrier bed(s) as it was during the phase of petroleum migration. This clearly leads to attempts to reconstruct the basin history in terms of deposition, structuring, and source rock maturation.

The capillary effect controls how much of a carrier bed becomes petroleum saturated. Rarely are carrier beds of a uniform grain size distribution. Thus, petroleum will tend to migrate along the coarsest, high-permeability pathways (Figure 21). These may occupy 10% or less of any particular formation. Open fractures have the same effect as coarse beds. Petroleum will exploit them. Temporarily open fracture systems are commonly invoked as the mechanism whereby migrating petroleum 'jumps' upward in the stratigraphy of a particular basin.

The rate at which petroleum migrates can be calculated using Darcy's law

$$q = -(k/\mu)(\mathrm{d}\theta/\mathrm{d}z)$$

where q is the volume of flow rate ($m^3\,m^{-2}\,s^{-1}$), k is the permeability, μ is the viscosity (Pa s^{-1}), and $\mathrm{d}\theta/\mathrm{d}z$ is the fluid potential gradient.

Typical permeability values are: sandstones, 10^{-12}–$10^{-15}\,m^2$ (1 D to 1 mD); limestones, 10^{-14}–$10^{-17}\,m^2$ (10 mD to 10 μD).

From these data, it is possible to calculate that the migration rate for petroleum in sandstone will be 1–1000 km per million years and, in limestone, 0.01–10 km per million years.

Phase changes will occur in petroleum as a result of its migration upwards to regions of lower pressure and temperature. This is most important for high-temperature, high-pressure condensates, but any oil will exsolve some gas if the pressure in the formation drops below the bubble point. The residual petroleum and generated gas are then likely to behave differently with respect to subsequent migration.

At low temperatures (<70°C), and in regions in which there is significant water flow, petroleum may be degraded by bacterial action or by water washing. The bacterial process follows a systematic loss of the *n*-alkanes, branched alkanes, isoprenoids, alkylcyclohexanes, and polycyclic alkanes. This progressive destruction of the petroleum leads to increases in the pour point and viscosity of the oil and a lowering of the API (American Petroleum Institute) gravity.

Tertiary Migration

Tertiary migration includes leakage, seepage, dissipation, and alteration of petroleum as it reaches the Earth's surface. The products of seepage may be gas chimneys in the shallow sediment, gas hydrate layers and mounds, cemented pock marks and mud volcanoes, effects on vegetation, and live oil and gas seepage at the surface.

The physical processes that drive tertiary migration are the same as those that operate during secondary migration. Buoyancy drives the petroleum to the surface. This may be helped or hindered by overpressure gradients or hydrodynamics. The only major difference that can be used to separate tertiary migration from secondary migration is the rate of petroleum supply. Trap failure, through capillary leakage, hydraulic fracture, or tectonism, supplies petroleum into a new carrier system much more rapidly than does a maturing source rock.

Definitions

Geochemists define petroleum as any subsurface material which, when produced, yields crude oil and/or gas. Most petroleum forms from the thermal degradation of kerogen during burial, although, strictly speaking, biogenic or bacterially formed gases should also be included. Hydrocarbons are molecules consisting only of carbon and hydrogen atoms. Although they are one of the principal constituents of petroleum, they are not the only components present, and so the two terms are not, strictly speaking, equivalent. Oil is the fraction of petroleum which is liquid at standard temperature and pressure, whilst the remainder is gas. Gas typically consists of compounds with up to five carbon atoms (C_1–C_5), whereas oil has six or more (C_{6+}), although some smaller molecules are sometimes present in oil and some C_{6+} compounds may be present in gas. Condensate is petroleum that is liquid at surface conditions, but exists in the reservoir in the gas phase as a gas condensate. There is no genetic connotation to this definition, although, in general, condensates tend to be of high thermal maturity.

Oils

Chemical Composition

Oil is a complex mixture, dominated by hydrocarbons, but with varying amounts of compounds containing sulphur, nitrogen, oxygen, and metals, principally nickel and vanadium. The chemistry of an oil is determined both by the nature and quality of the source rock and the depositional environment of the kerogen from which the oil formed, and by the thermal maturity of the source rock (i.e., the maximum temperature encountered in the source rock). For example, oil sourced from a marine carbonate is typically very heavy and sulphur rich, but becomes lighter and progressively sulphur depleted with increasing maturity. Clastic marine source rocks tend to produce lower sulphur, lighter oils. In addition, the composition of the petroleum may subsequently become altered in the reservoir by biological processes (biodegradation), thermal cracking, or physical separation (e.g., precipitation of high molecular weight components to form a tar mat).

At the most basic level, oil components can be divided into four main compound groups: saturated compounds, aromatic compounds, an NSO, Nitrogen-, Sulphur-, and Oxygen-bearing compounds, (sometimes called a residue or resin) fraction, and asphaltenes (Figure 1). In practice, the last two groups form a continuum, as their separation is based on solubility in the laboratory, rather than on a unique chemical composition. They are often referred to together as the polar fraction, as their molecules often have a significant surface charge, unlike saturated and aromatic compounds.

Saturated compounds These are generally the most abundant components of oil, comprising up to 90% of some light crudes. A large number of compounds are present within the saturated fraction, but these can be broadly divided into three groups: normal alkanes, branched alkanes, and cyclic compounds (Figure 2). All of these are said to be saturated as they contain no double chemical bonds.

Normal, or straight-chain, alkanes, denoted by the prefix '*n*', range in carbon number from five up to several hundred, but are dominantly in the range *n*-C_5 to *n*-C_{40}. Alkanes greater than about *n*-C_{20} are often referred to as the wax fraction, although here again the definition is based on laboratory solubility rather than on strict chemistry. In practice, industrial 'paraffin wax' also contains branched and cyclic alkanes. Within these higher molecular weight *n*-alkanes, oils derived from higher land plants usually show a dominance of odd carbon numbers over even, reflecting their origin from cuticular waxes of continental higher plants. With increasing maturity, the distribution of *n*-alkanes becomes progressively skewed towards shorter chain lengths and any generic information is lost. Normal alkanes are also particularly vulnerable to bacterial attack and are usually absent in biodegraded oils.

Branched alkanes contain one or more side-chains attached to the straight-chain backbone. These are quantitatively the most abundant fraction within the saturates. A special subgroup of the branched alkanes, called the isoprenoids, is worthy of note. These range from C_9 to C_{25} and are believed to be derived from the phytol side-chain of chlorophyll. The C_{19} and C_{20} compounds, pristane (Pr) and phytane (Ph), are of particular diagnostic value in determining the source of the oil. Coal-sourced oils

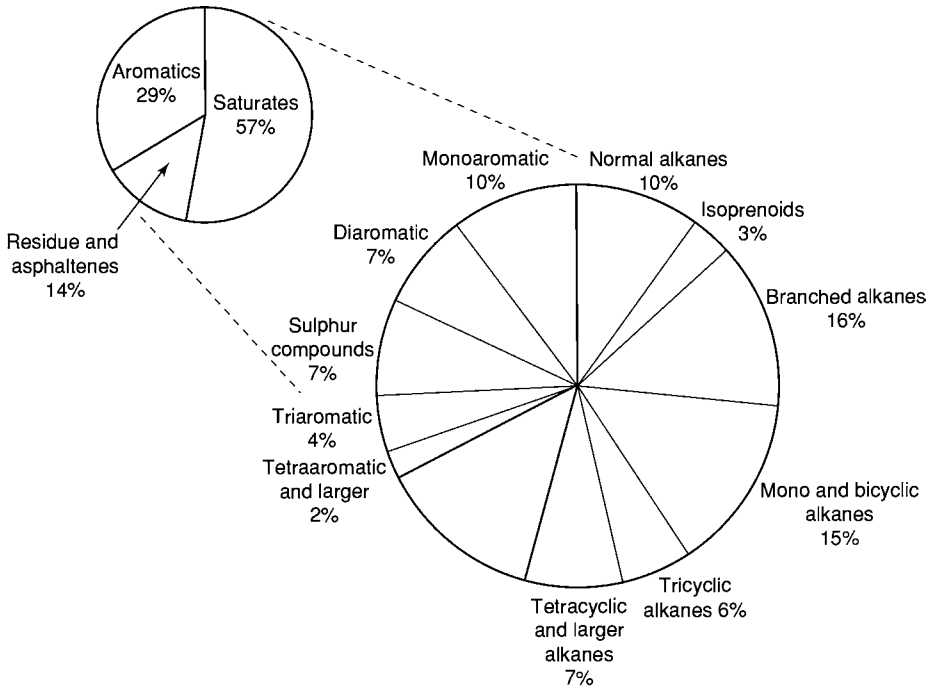

Figure 1 Average composition of oils based on between 100 and 500 samples depending on fraction.

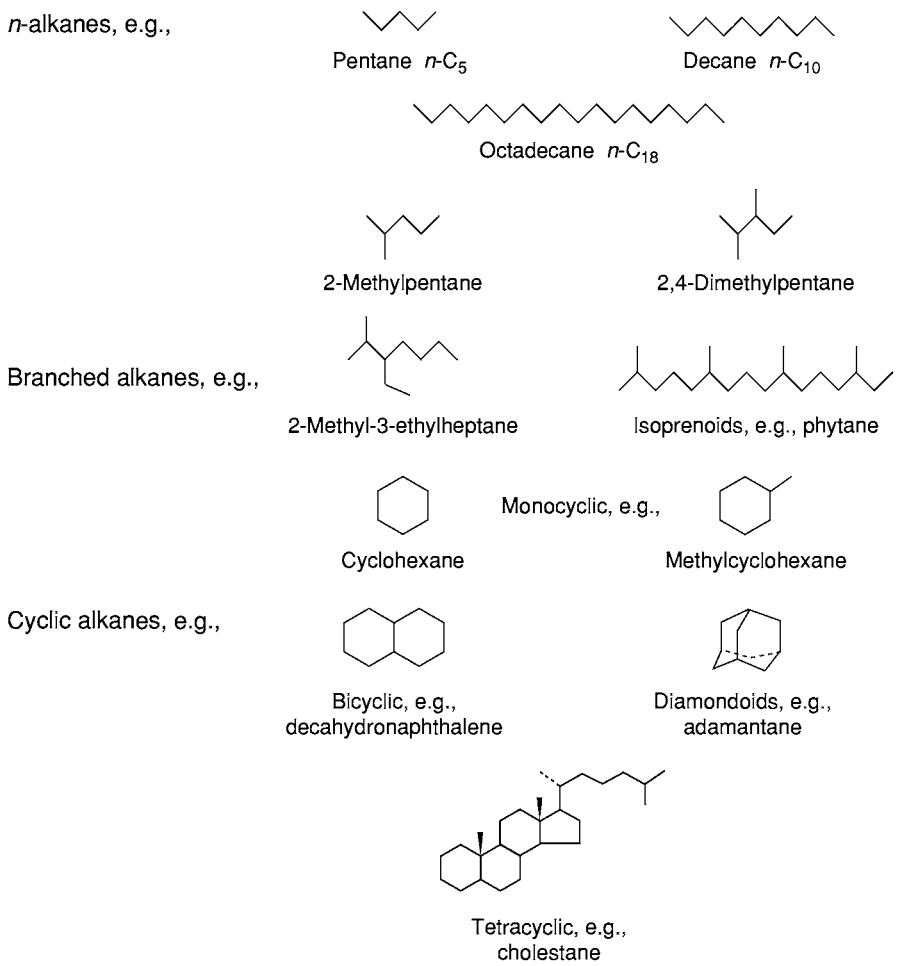

Figure 2 Typical saturated compounds in oil.

generally have a Pr/Ph ratio above three, whereas almost all aquatic kerogens produce oils with a Pr/Ph ratio less than this.

Cyclic alkanes contain carbon rings, usually with five or six carbon atoms in each ring. These are sometimes referred to as the naphthenes, in contrast with the straight and branched alkanes which are paraffins. These compounds may be monocyclic (one ring), or contain up to five or, in rare cases, more rings.

Amongst the saturated compounds (and, to a lesser extent, the aromatic and polar compounds too), some of the more complex molecules can have their origin traced back to specific biomolecules deposited in the source kerogen. They are therefore useful to determine the source of the oil. These so-called biomarkers (or geochemical fossils) are derived ultimately from bacterial or algal cell membranes, or from specific metabolites in algae, bacteria, or higher land plants, and a very large number are known. Some typical examples are shown in Figure 3. Particularly important amongst the polycyclic biomarkers are the pentacyclic steranes and tetracyclic triterpanes (hopanes), as, although present in only very low abundance, many of them are highly characteristic of the source input to the kerogen from which the oil was derived. In addition, subtle variations in the chemical structure of many of the biomarkers (such as their stereochemistry and degree of aromatization) are temperature sensitive, and hence can be used as molecular maturity indicators (see Figure 4).

Aromatic fraction Aromatic compounds contain one or more benzene rings within their structure (Figure 5). These generally consist of roughly equal amounts of one-ring, two-ring, and organosulphur compounds (mainly benzothiothenes and dibenzothiothenes; Figure 6), although lesser amounts of larger aromatic compounds are also present. Some of the more complex compounds, such as the so-called aromatic steranes, are formed by thermal alteration of the saturated equivalent, and hence their relative abundance is indicative of maturity (Figure 4).

Polar fractions The NSO and asphaltene fractions are made up of more complex compounds, usually containing nitrogen, oxygen, or sulphur (Figure 6). The larger molecules can be thought of as small fragments of kerogen. Asphaltenes are the highest molecular weight components present and are defined as the fraction that is not soluble in hydrocarbon solvents (usually hexane). In some heavy oils (such as those formed at low maturity or by bacterial alteration of an originally lighter oil), asphaltenes may comprise up to 50% of the total oil, but they are generally present as only a few per cent. It is the abundance of these polar fractions that determines in most part the viscosity of the oil.

The detailed chemistry of the polar fractions is less well understood than that of the other compound groups because of the complexity of many of the species present. However, recent research suggests that a number of the nitrogen- and oxygen-bearing molecules may be of value as indicators of migration distance, as their ratios potentially reflect the extent to which the oil has interacted with water since expulsion from the source rock.

Analytical Methods

Chemical analyses of oils are most frequently presented in graphical form rather than as tables of results, and so it is relevant to consider the most important analytical methods used to produce these plots. Although a very wide range of analytical tools are now used, by far the most important methods are based on chromatography.

Asphaltene separation and liquid chromatography The largest and most polar components are separated chemically as, by definition, asphaltenes are insoluble in hydrocarbon solvents (e.g., hexane or heptane). No further measurements are carried out on the asphaltene fraction other than perhaps carbon isotope measurements (see below) or occasionally pyrolysis to release smaller, more easily identifiable, components. After asphaltene separation, the remaining mixture is usually separated into compound groups using high-performance liquid chromatography (HPLC). This separates the saturated compounds, aromatic compounds, and residue fraction (the NSO fraction or resins).

Gas chromatography The saturated fraction (and sometimes the aromatic fraction) is then further analysed by gas chromatography (GC) (*see* **Analytical Methods:** Geochemical Analysis (Including X-Ray)). In this method, gas is used to force a sample through a long narrow tube. Small molecules elute first, whilst larger molecules are held up. It is therefore possible to resolve and quantify individual compounds of interest in the oil. The resulting gas chromatograms (Figure 7) show the concentration of each (resolved) compound plotted against the retention time in the chromatographic column. These show a number of features of interest, such as the distribution of the *n*-alkanes, the Pr/Ph ratio, the amount of wax (high molecular weight alkanes), and sometimes characteristic individual compounds of value in correlation studies. Gas chromatography is the method also used to determine natural gas composition.

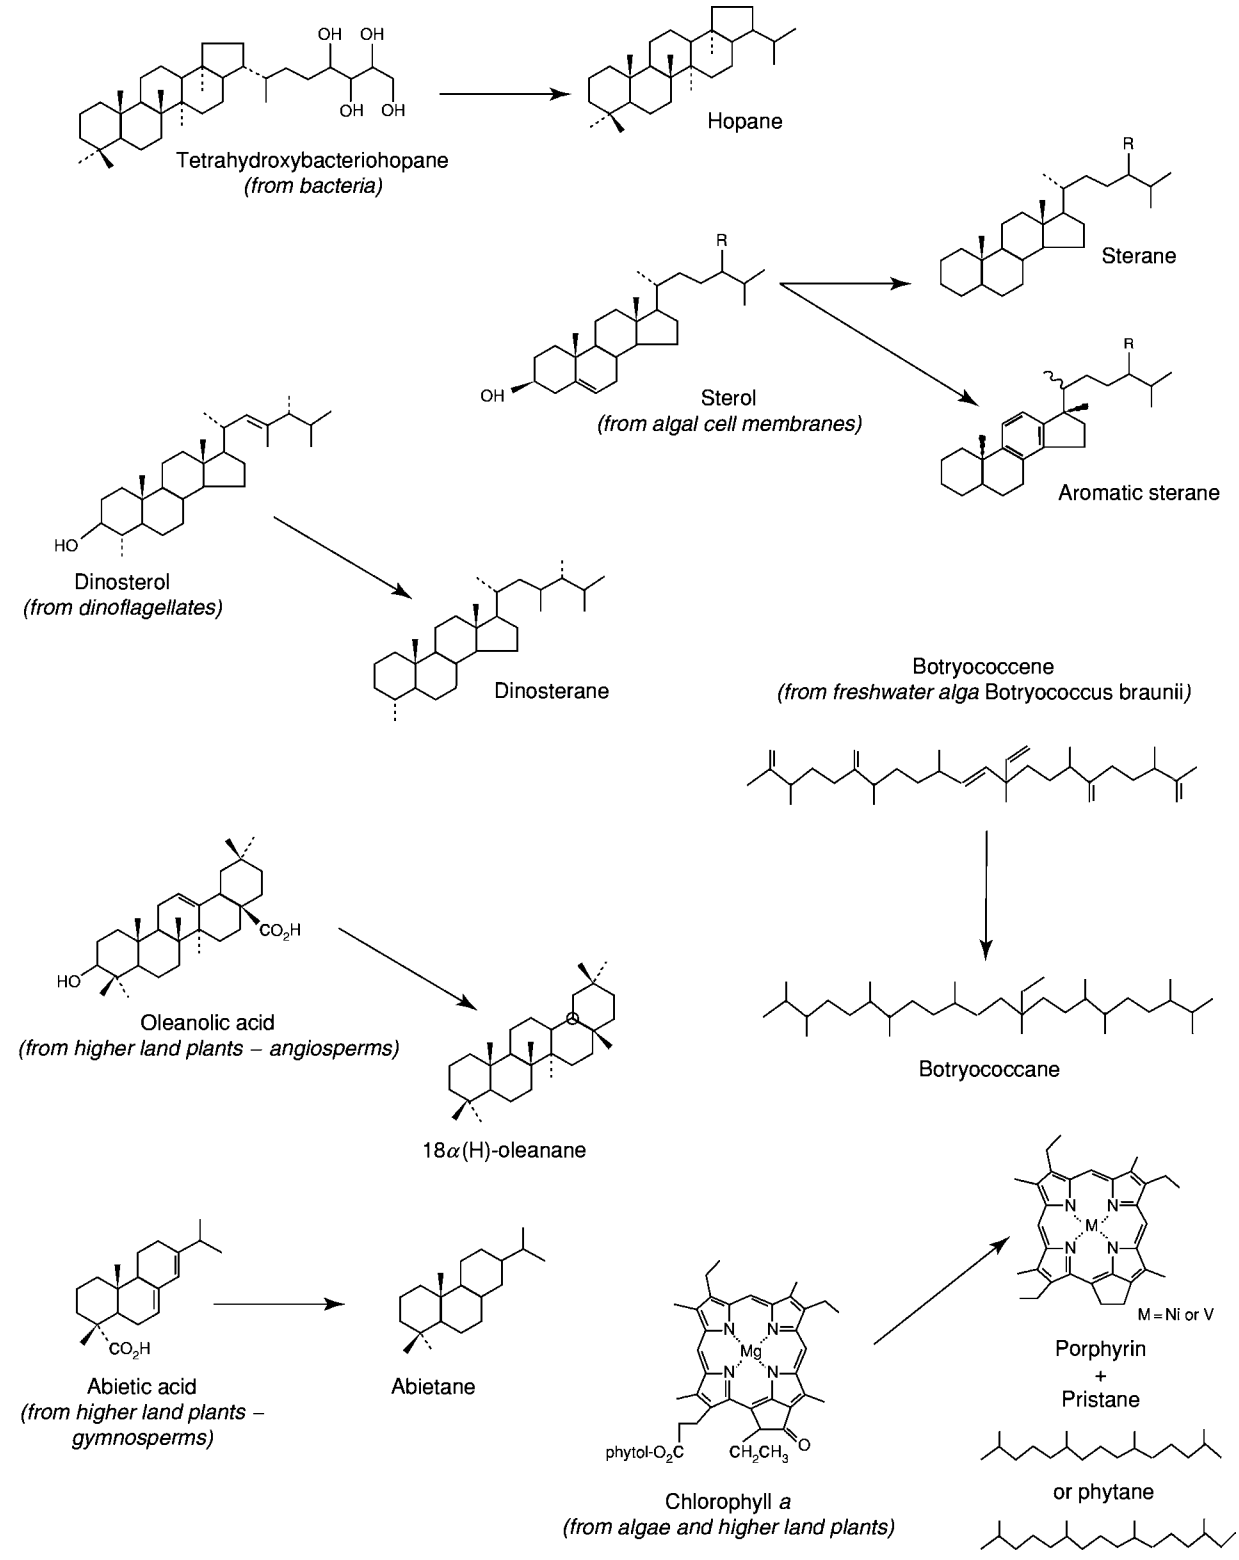

Figure 3 Origin of some common biomarkers.

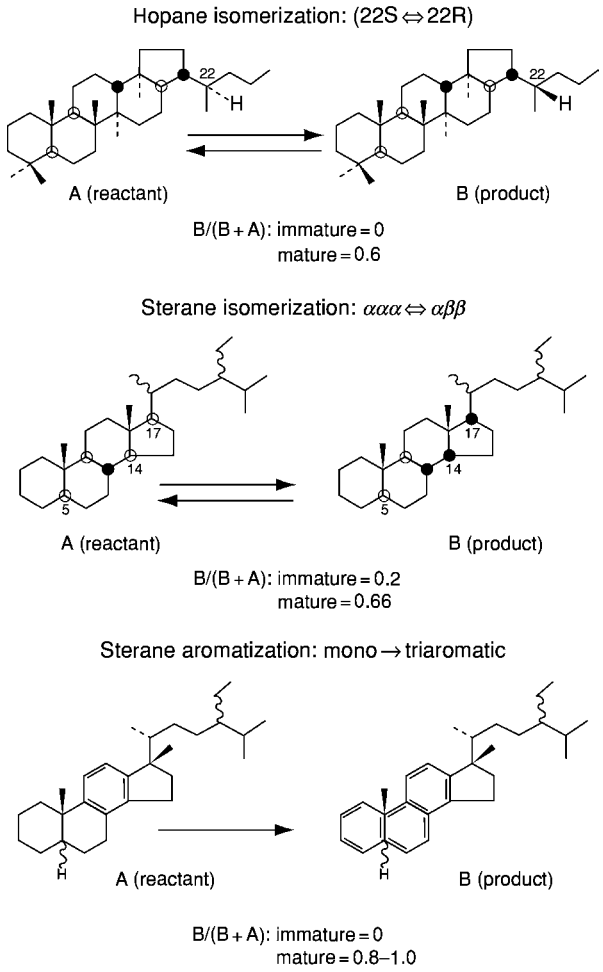

Figure 4 Examples of molecular maturity parameters.

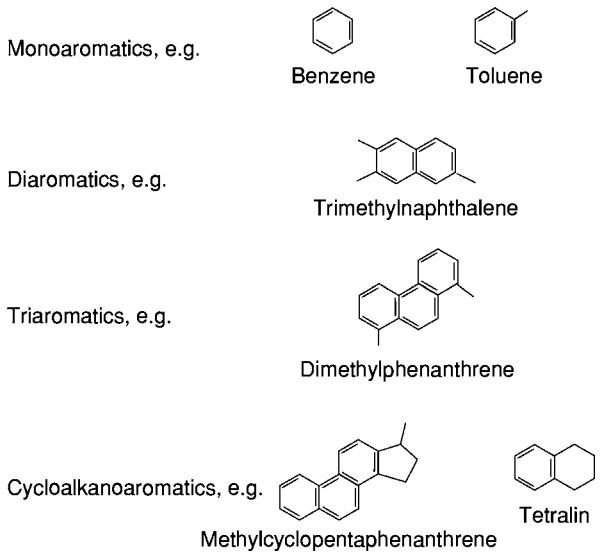

Figure 5 Typical aromatic compounds in oil.

Gas chromatography-mass spectrometry Most of the biomarkers of interest are present in only trace quantities, and so special methods are needed to measure their concentration. Central amongst these is gas chromatography-mass spectrometry (GCMS). This is similar to conventional GC, but a mass spectrometer is used as a detector. When a sterane, for example, enters the mass spectrometer, it fragments into many parts. However, all steranes produce a fragment with a characteristic mass (mass/charge ratio, *m*/*z*; *m*/*z* 217 in this case). Thus, by monitoring all fragments of *m*/*z* 217 as they come off the GC into the mass spectrometer, we are essentially resolving all of the steranes into individual compounds. The result is a plot similar to a GC trace but specific to the steranes. Similarly, the triterpanes (dominantly the hopanes) produce a characteristic fragment at *m*/*z* 191, and so on for all the other compound groups of interest. Figure 8 shows an example of mass 191 and 217 mass fragmentograms for a typical North Sea oil with some of the important peaks labelled.

Classification of Crude Oils

There are numerous schemes for classifying crude oils, but two main approaches dominate. The first is based on the relative concentrations of the main chemical classes and the most widely used of these was developed by the Institut Francais du Pétrole (Figure 9). Alternatively, and more useful for exploration purposes, oils can be classified according to the depositional environment in which their source kerogen was formed. A typical example of this is shown in Table 1, which includes some of the most relevant chemical characteristics for each environment. It should be noted, however, that, with increasing maturity, the chemical signatures are progressively lost as the characteristic compounds become progressively broken down to smaller, less diagnostic compounds.

Bulk Properties

The economic value of an oil is usually dictated by its bulk properties rather than its detailed chemistry, although the two are obviously inextricably linked. A number of standard measurements are used to define the bulk properties.

API gravity API gravity (from American Petroleum Institute) is a measure of the specific gravity of the oil at 60°F or 16°C. It is somewhat arbitrarily defined by the equation

$$\text{API}^\circ = (141.5/\text{specific gravity}) - 131.5$$

Table 1 Oil classification according to source type

	Typical characteristics at moderate maturity[a]					
	API°	*Wax*	*Sulphur*	*Nitrogen*	*Ni + V*	*Ni/V*
Marine carbonate or siliceous	25 30	Low	High	High	50 300	<2
Marine siliciclastic	35 40	Low	Moderate low	Moderate	0 50	<2
Lacustrine	30 35 and 45 50[b]	High	Low	Moderate	0 50	>2
Coal	30 45	High	Low	Low	~0	

API, American Petroleum Institute.
[a]With increasing maturity, API increases, and wax, sulphur, nitrogen, and metal contents decrease.
[b]Bimodal distribution observed.

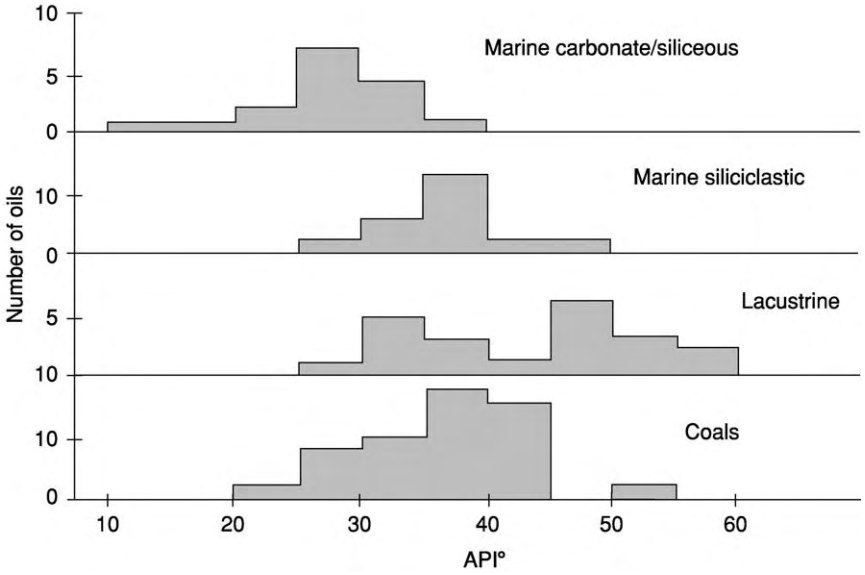

Figure 10 API (American Petroleum Institute) gravity variation of oils according to the depositional environment of the source kerogen.

This system is used as it gives an integer value that is easier to display than a four decimal place number (e.g., pure hexane with a specific gravity of 0.6594 is equivalent to an API of 83°). A heavy crude will generally have an API <25°, whilst a light crude will generally have an API between 35° and 45°. Most condensates have an API >45°. Pure water, by definition, has an API of 10°, and thus crudes with API <10° will not float on water.

The API gravity varies somewhat depending on the source of the oil (Figure 10), and also increases significantly with maturity regardless of source. Oils derived from carbonate or siliceous source facies are usually of lower API than those from other lithologies. In addition, bacterial alteration of oil in the reservoir can result in oils with especially low API values, and gravity segregation in thick homogeneous reservoir formations or highly compartmentalized reservoirs can lead to significant vertical and lateral heterogeneity, respectively.

Gas/oil ratio The gas/oil ratio (GOR) is the ratio of components that exist in the gas phase at surface conditions (dominantly compounds containing less than five carbon atoms) to the rest of the petroleum. It is traditionally expressed as standard cubic feet of gas per barrel of oil (sft^3/bbl), and 1 sft^3/bbl is equal to 0.178 m^3 m^{-3}. When dealing with gas condensates, it is often more convenient to express this ratio as the condensate/gas ratio (CGR) in terms of barrels of condensate per million standard cubic feet of gas (bbl/MMscf).

GOR varies depending on the source of the oil, but is influenced mainly by maturity. GOR increases enormously with increasing maturity.

Wax content The wax content is a reflection of the amount of high molecular weight saturated compounds (*n*-alkanes $>C_{20}$). Most oils range from 0% up to about 40% wax. There are two distinct sources of wax in oil. It may be derived ultimately

from cuticular waxes on the leaves of higher land plants or from long-chain unsaturated molecules synthesized by some freshwater algae. Consequently, many lacustrine or coal-sourced oils have a high wax content (Figure 11), although this decreases with increasing maturity. Wax deposits in pipelines and other equipment can cause mechanical problems.

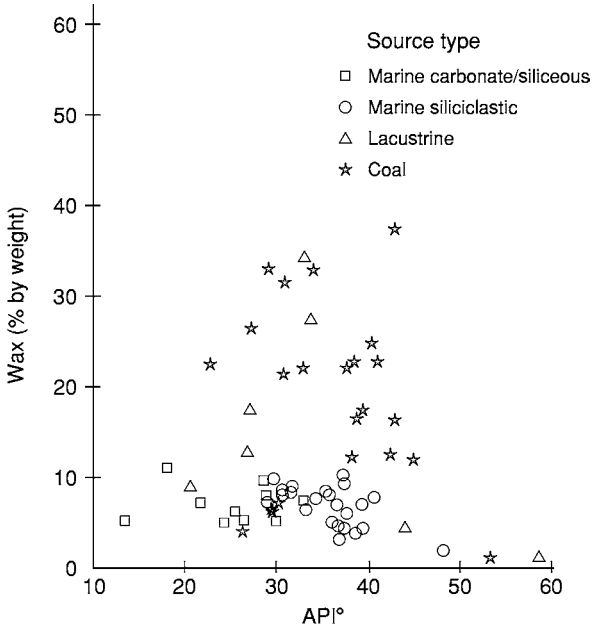

Figure 11 Wax content of oil types vs. API (American Petroleum Institute) gravity as a proxy for maturity.

Sulphur content The sulphur content of an oil has an important impact on its economic value as it causes problems during refining. The main control on the sulphur content is the kerogen type. Oils derived from carbonate or siliceous source rocks are higher in sulphur than those from other lithologies (Figure 12). This itself is a consequence of bacterial sulphate reduction: there is little free iron available in carbonate or siliceous sediments, and so the hydrogen sulphide formed reacts with the organic matter to give a sulphur-rich kerogen. All oils show a marked decrease in sulphur content with maturity.

Nitrogen content The nitrogen content of an oil is a reflection of the abundance of the NSO fraction and hence usually correlates with API gravity and viscosity. The nitrogen content is generally very low in oils sourced from coal, and highest in those derived from marine carbonate and siliceous sediments, but decreases markedly with increasing maturity (Figure 13).

Viscosity The viscosity of oils ranges from around 0.2 cP (2×10^{-4} Pa s) for a very light oil up to around 100 P (10 Pa s) for some very heavy oils. The viscosity is controlled dominantly by the abundance of the high molecular weight polar components (NSOs and asphaltenes), and hence shows a correlation with API gravity and sulphur content.

Distillation fractions Of interest to the refining process are the distillation fractions of an oil (i.e., the distribution of different boiling point fractions). The

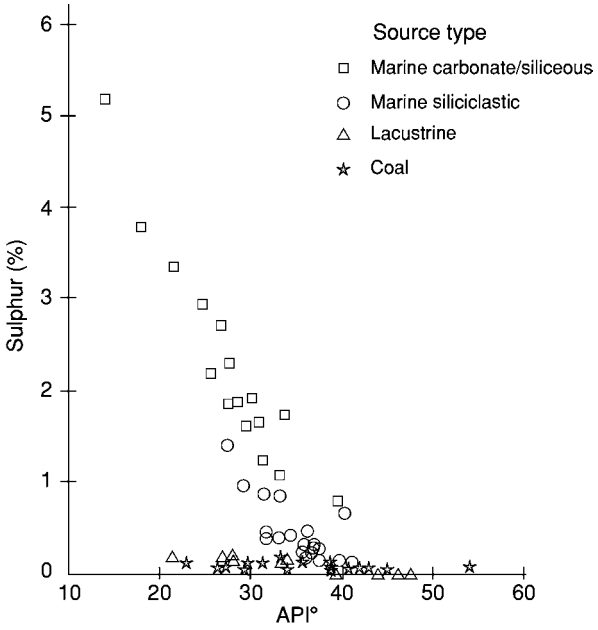

Figure 12 Sulphur content of oil types vs. API (American Petroleum Institute) gravity as a proxy for maturity.

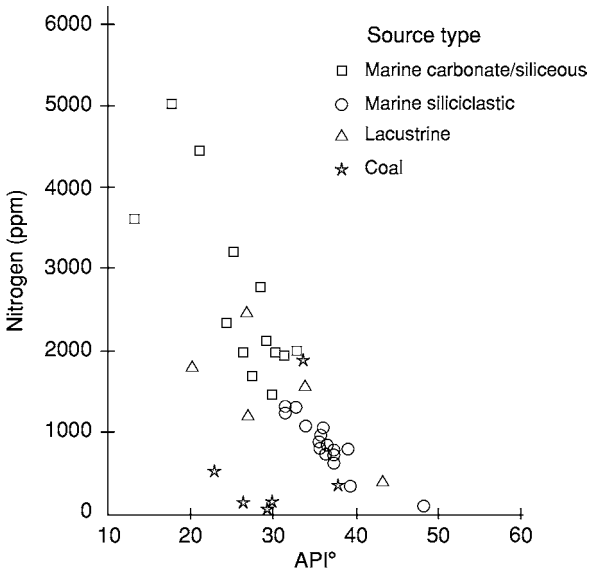

Figure 13 Nitrogen content of oil types vs. API (American Petroleum Institute) gravity as a proxy for maturity.

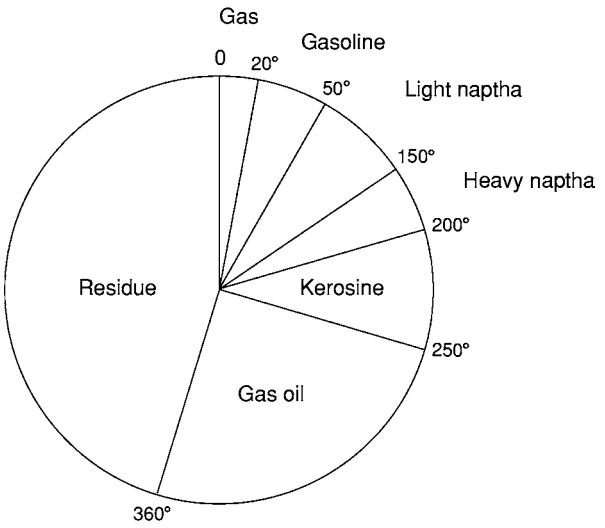

Figure 14 Distribution of boiling point cuts for a typical crude oil.

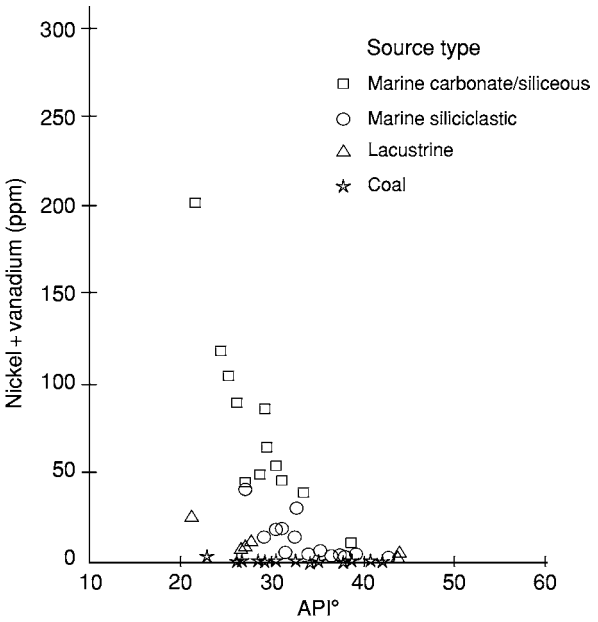

Figure 15 Metal content of oil types vs. API (American Petroleum Institute) gravity as a proxy for maturity.

higher the API gravity of an oil, the larger the yields of the lower boiling point cuts. Various names are applied to the different fractions, an example of which is summarized in Figure 14.

Metal content The metal content of oils is dominated by nickel and vanadium, although other metals, such as iron, zinc, copper, lead, molybdenum, chromium, manganese, cobalt, and arsenic, are also sometimes present in trace quantities. These metals are present dominantly in a specific group of cage-like compounds, called porphyrins (Figure 3), which are ultimately derived from chlorophyll. High nickel and vanadium contents significantly reduce the value of an oil, as they adversely affect the catalysts used in the cracking of oil at the refinery. Metal contents vary enormously, from less than 1 ppm in some Palaeozoic crudes up to 1200 ppm vanadium and 150 ppm nickel in the Boscan crude from Venezuela, and are again controlled by both the source type and maturity (Figure 15). In addition, the ratio of nickel to vanadium is of some diagnostic value in determining the source of the oil (Figure 16).

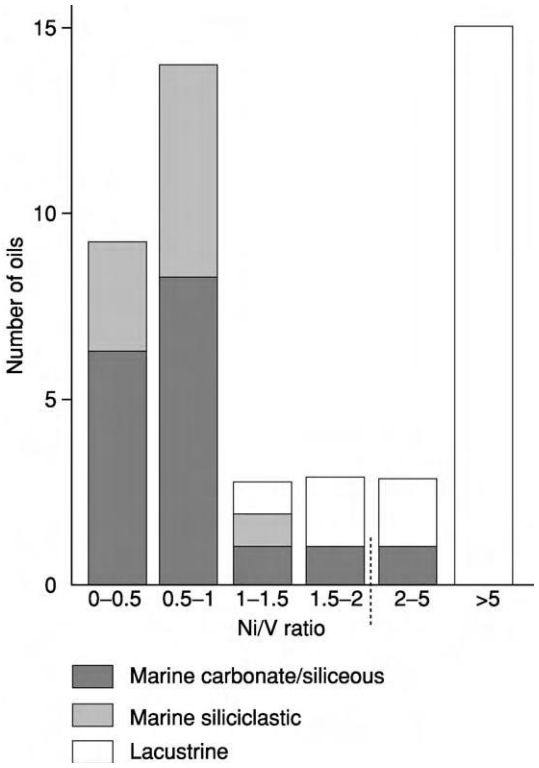

Figure 16 Nickel/vanadium ratios of different oil types.

Gases

Natural gases consist dominantly of hydrocarbons up to C_5 (pentane), together with varying amounts of inorganic components, principally nitrogen (N_2), carbon dioxide (CO_2), and hydrogen sulphide (H_2S).

Hydrocarbon Gases

Natural hydrocarbon gases can be either 'biogenic' (arising from bacterial processes, usually during early diagenesis) or 'thermogenic' (resulting from the effects of heat on oil or kerogen) in origin.

Biogenic (or bacterial) gases are formed in organic-rich sediments during diagenesis by a specialized

group of bacteria, the 'methanogens'. Methanogenic bacteria require anoxic, sulphate-free environments at temperatures below approximately 75°C. These are met, for example, in paddy fields, the intestinal tracts of higher organisms, and in marine sediments below the zone of sulphate reduction. Chemically, biogenic gases are almost pure methane.

Under the right conditions, biogenic gases can form substantial economic accumulations. They account for 15–20% of the world's gas resources, including the Cenomanian pay zones of the giant Urengoy field in western Siberia with ~180 trillion cubic feet recoverable reserves. They occur at depths down to 4600 m (Antonella, Po Valley) and in sediments from Holocene to Cretaceous age.

The thermogenic gases can be subdivided depending on their origin. 'Oil-associated gases' form from kerogen at the same time as oil is generated. They can be thought of as the short-chain component of the oil and are believed to be derived from the lipids (essential oils, fats, and waxes) of organisms. 'Non-associated gases' are derived from lignin, a component of higher land plants. They are the dominant component of gases derived from coals, although they are not strictly synonymous with coal-gas which may also contain cracked oil-derived gas, particularly where oil-prone coals are involved. 'Cracked oil gases' are formed from the thermal destruction of oil, either in the reservoir or by cracking of residual unexpelled oil in the source rock.

The chemistry of natural gases is basically simple. Hydrocarbon components are based on methane (CH_4) and the higher homologues ethane (C_2H_6), propane (C_3H_8), iso- and normal butane (C_4H_{10}), and iso- and normal pentane (C_5H_{12}). Hydrocarbon components containing more than five carbon atoms are generally referred to as the gasoline fraction and considered to be part of oil rather than gas. Unsaturated compounds, containing a double bond, such as ethene (ethylene), are rarely found in natural gases, although can form as a product of laboratory pyrolysis.

Because of the simplicity of gas composition, very little can be deduced from the composition alone, although two ratios are in common usage: the gas 'wetness' (strictly speaking the gas dryness!), $C_1/\Sigma C_{1-5}$, and the iso- to *n*-butane ratio, iso-C_4/*n*-C_4. Some authors also use simpler ratios, such as the methane/ethane ratio (C_1/C_2), or methane relative to ethane and propane ($C_1/C_2 + C_3$). In general, these are not as useful as the gas wetness index as they are open-ended scales (i.e., they extend to infinity). All of these ratios are affected by the gas origin, maturity, and sampling methodology, and generally also by secondary alteration processes, such as biodegradation. Dry gases are generally considered to contain less than 10% heavy hydrocarbons (i.e., $C_1/\Sigma C_n > 0.9$), although different authors use different cut-off points. It is therefore necessary to exercise caution when describing gases as 'wet' or 'dry'.

The best evidence of the source of a natural gas is from the stable carbon isotope ratios of the individual hydrocarbons (methane to butanes and sometimes pentanes). The bulk fractions of oils, and increasingly a number of individual compounds, are often also analysed for their stable carbon isotopic composition. The carbon isotope ratio is based on the ratio of the stable carbon isotopes ^{13}C and ^{12}C and is universally expressed in a standard 'del' (or delta) notation

$$\delta^{13}C = [(R_{sample} - R_{standard})/R_{standard}] \times 1000‰$$

in which R is the ratio $^{13}C/^{12}C$ and the units are parts per thousand or 'per mil'. The standard used for carbon is PDB, calcite from a fossil belemnite from the Cretaceous Peedee Formation of South Carolina, although secondary standards are now used in the laboratory. Positive values contain more ^{13}C than the standard, and are said to be isotopically heavier or enriched. Negative values are isotopically lighter or depleted.

When combined with basic chemical data for the gases, these allow the differentiation of the different sources of natural gas, estimates of their thermal maturity, and, under favourable conditions, the identification of the specific source rock involved (see examples in Figures 17 and 18).

Non-Hydrocarbon Gases

In many reservoirs, non-hydrocarbon gases (notably CO_2, N_2, and H_2S) are encountered in varying proportions. A number of sources for these may be proposed, although it is often difficult to be confident about their origin, even though isotope ratios of carbon, nitrogen, and sulphur can provide useful information. Table 2 shows composition data for a number of natural gases. The non-associated gases in particular contain large amounts of non-hydrocarbons. These reduce the economic value of an accumulation, partly by diluting the hydrocarbons and partly by causing problems in production (e.g., H_2S is both corrosive and highly toxic).

Nitrogen In some cases, nitrogen can be derived from basement rock, particularly from igneous sources. It can also be concentrated in biogenic

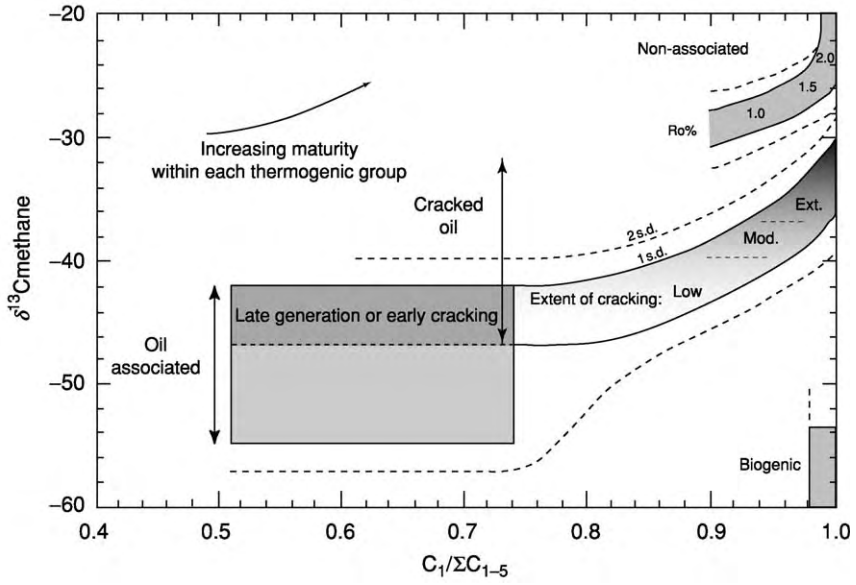

Figure 17 Differentiation of gas origins using gas wetness and carbon isotope ratios of methane.

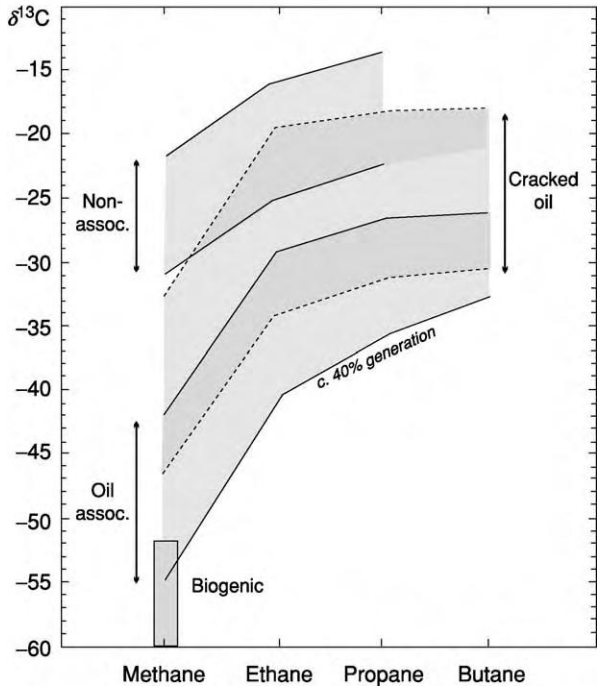

Figure 18 Isotope distributions in gases of different types.

gases by exsolution from flowing groundwater. However, by far the most important source is believed to be from kerogen breakdown (kerogen typically contains about 2% nitrogen by weight).

Table 2 Typical inorganic compositions of oil and gas fields (mol.%)

Area/field	CH_4	C_2 C_5	CO_2	N_2	H_2S
Oil associated					
Abu Dhabi/Zakum	76.0	20.3	2.3	1.1	0.3
Iran/Agha Jari	66.0	31.5	1.5	1.0	
N. Sea/Forties	44.5	53.6	0.6	1.3	
N. Sea/Brent	82.0	16.4	0.7	0.9	
Non associated					
Algeria/Hassi R'Mel	83.5	10.2	0.2	6.1	
France/Lacq	69.3	5.5	9.6	0.4	15.2
Holland/Groningen	81.3	3.5	0.9	14.3	Trace
New Zealand/Kapuni	46.2	7.9	44.9	1.0	
N. Sea/West Sole	94.4	4.0	0.5	1.1	

Nitrogen is generated from organic matter, particularly during the advanced stages of maturation. It has also been proposed that different types of kerogen yield different amounts of nitrogen. Experimental cracking of coals under laboratory conditions indicates that coals can generate up to 6% of nitrogen in total. Kinetic studies, based on laboratory experiments, suggest that gases containing more than 40–50% nitrogen are generated in excess of 300°C, after the main phase of hydrocarbon generation. These experiments imply that, in nature, gas with 50% nitrogen must have been formed by preferential trapping of late-stage generation products, whereby

the gas from the initial stages of generation has not been trapped.

Carbon dioxide Carbon dioxide (CO_2) has a number of possible sources, although most of these usually only contribute small quantities of gas. Although bacterial action produces some CO_2 under specific conditions, the most important sources are kerogen breakdown, inorganic reactions in the reservoir, and deep-seated CO_2.

CO_2 sourced from kerogen occurs as a result of thermal decarboxylation of kerogen. This occurs typically between about 50 and 100°C, before the main phase of oil and hydrocarbon gas generation. This reaction generally contributes only 1 or 2% CO_2 to the total gas. Inorganic reactions are limited to relatively hot reservoirs and are the result of chemical buffering between carbonates and silicates. These can either increase or decrease the CO_2 concentration, depending on the specific mineralogy involved and on the reservoir temperature and pressure. Nevertheless, many tens of per cent of CO_2 may result. Deep-seated CO_2 is often associated with igneous activity, but is also commonly the result of carbonate decomposition in the basement. This is probably the most important source of CO_2 in very high CO_2 (>30%) regions.

Hydrogen sulphide Hydrogen sulphide (H_2S) is an unpleasant, toxic gas occasionally found in large quantities in reservoirs. There are three main sources: bacterial sulphate reduction (of only limited occurrence), thermal cracking of kerogen or oil, and gas souring (thermochemical sulphate reduction). In addition, in an oil reservoir, H_2S preferentially resides in the water phase. This means that, even if there is little H_2S produced when the field is initially brought on stream, the field may subsequently sour as it goes into decline and the water cut increases.

A major source of H_2S is via the thermal cracking of kerogen or oil. Many compounds in oil contain sulphur, and the thermal degradation of these at very high temperatures leads to the formation of H_2S. Such a process becomes more important with increasing temperature. It is frequently associated with carbonate-sourced oils or kerogens as these are richer in sulphur.

The production of H_2S in deep, hot carbonate/evaporite reservoirs is probably the most important source of sour gas. Above approximately 140°C, the ratio of H_2S to methane often increases dramatically in proportion to temperature due to reaction between methane and gypsum or anhydrite, represented in its simplest form by

$$CaSO_4 + CH_4 \rightarrow CaCO_3 + H_2S + H_2O$$

However, in practice, numerous other parallel and intermediate reactions also occur.

Gas Hydrates

M Hovland, Statoil, Stavanger, Norway

Introduction

Oceanic gas hydrates have attracted massive scientific and, not least, political attention over the past years. This is because of their dual role as a potential energy resource and as a geohazard/potential climate mediator. Interest in these compounds is reflected not only in the number of recent scientific projects aimed at studying and sampling oceanic hydrates, but also in the virtual flood of books, articles, and websites dedicated to these 'mysterious' substances.

Gas hydrates are crystalline, ice-like compounds composed of water and gas; the gas molecules are trapped within a cage-like framework of hydrogen-bonded water molecules. These structures are formed under very specific temperature and pressure conditions in an environment with adequate water and gas. The right conditions can be found on land (in polar regions, where surface temperatures are very cold) and within water or seabed sediments at depths exceeding 300–500 m and where the temperature is adequately low (generally <10°C). Mathews, in *The Log Analyst*, described hydrates as follows:

> Hydrates form when one species (known as the host) forms a crystal lattice containing voids or cavities that physically entrap other guest molecules. In natural gas hydrates, the host is water and the guest can be any common constituent of natural gas such as CH_4, C_2H_6, C_3H_8, C_4H_{10}, CO_2 or H_2S. Natural gas hydrates can have two possible structures, depending on the size of the guest molecules. Both structures consist of a network of water molecules hydrogen bonded to each other in a manner similar to water ice. (Mathews (1986))

Figure 1 shows a diagram of gas hydrates; the water molecules form a lattice containing 'guest' (gas) molecules – this is also called a clathrate substance in chemistry. The conditions under which gas hydrates are stable (Figure 2) are tightly controlled by temperature and pressure, but are also affected by the chemistry (i.e., including the salinity) of the pore water and the composition of the 'guest' gases. Chemicals (such as salts and methanol) that reduce the pressure/temperature envelope of hydrate stability are called hydrate inhibitors.

Because they tend to block pipes and flowlines in oil and gas fields, gas hydrates have been the focus of well-controlled laboratory studies for many years. Laboratory observations illustrate clearly how dynamic gas hydrates can be: at times these compounds are permeable and at times they present a complete barrier to flow. In a laboratory hydrate reactor at a Statoil facility in Norway, an initial attempt at forming hydrate plugs was carried out with a gas mixture of methane and isobutane, and tap water in the absence of hydrocarbon liquids. Hydrates were initially formed by injecting water droplets into the gas atmosphere at a pressure of 60 bar. A total of 13.5 litres of water was injected during 1.5 h at a subcooling temperature of 13°C. Gas was periodically circulated through the hydrate plug from the bottom of the reactor and the plug was periodically allowed to mature undisturbed for several days. After a static maturation period, an additional 4 litres of water was injected at the top of the plug. Most of the water was drawn into the plug, which acted as a sponge, and remained in the plug for the rest of the experiment. The plug remained porous throughout the entire 20-day-long experiment and grew to a length of 40 cm. When a pressure difference was introduced over the plug, the video recordings demonstrated that gas bubbles easily moved through the internal channels of the plug. Hence, the nature of the channels determined the permeability of the plug. Gas bubbled through the channels until more hydrates were formed and blocked further migration.

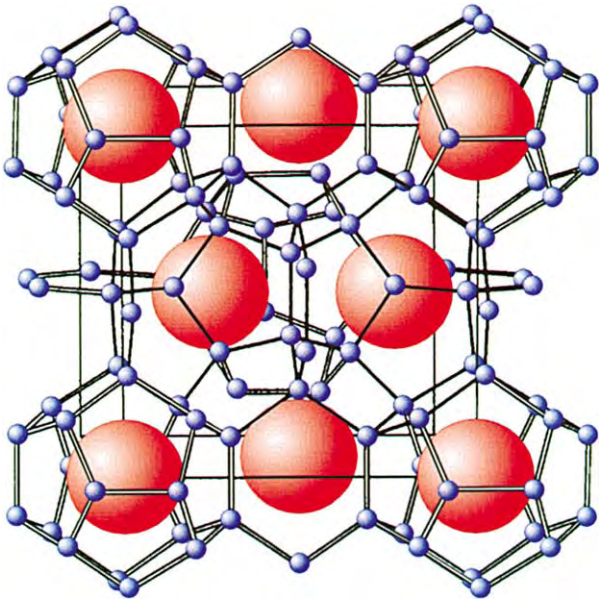

Figure 1 Diagram of a gas hydrate, showing how water molecules form a lattice around 'guest' gas molecules. The chemical name for this cage like solid structure is 'clathrate'. Diagram courtesy of Bjørn Kvamme.

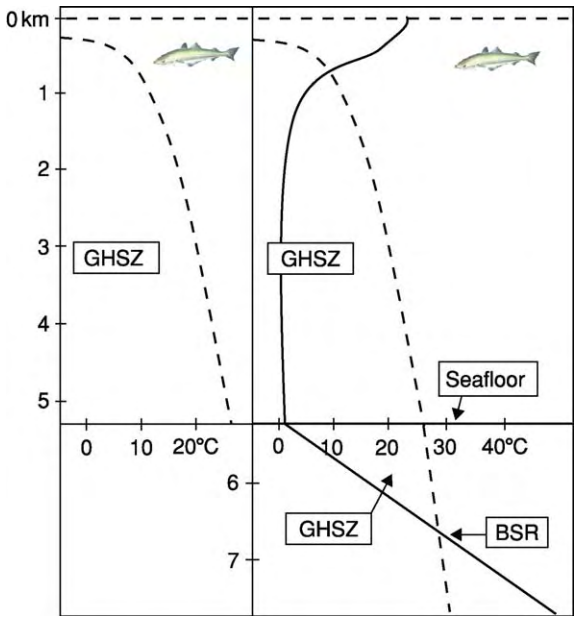

Figure 2 Methane hydrate stability field. The gas hydrate stability zone (GHSZ) in ocean water is determined by pressure and temperature. The stability envelope of gas hydrates in seawater is shown schematically on the left. Gas hydrates usually will not form at water depths of less than about 300 m and will not form in open seawater systems because of seawater circulation and the relatively high solubility of methane in seawater. However, in the confines of sedimentary pores in ocean bottom sediments (right hand diagram), gas hydrates will be stable and may form more or less permanently. Because of the increase in temperature with water depth (the geothermal gradient), hydrates will not be able to form beyond certain depths, indicated by the bottom simulating reflection (BSR), where the temperature gradient curve intersects the hydrate stability curve.

Figure 3 Core sample number 1249F 8h 2, from the Ocean Drilling Program Leg 204, drilling on Hydrate Ridge, the Cascadia Accretionary Prism, off the coast of Oregon, USA. The sample shows how gas hydrates (white) may occur in shallow, porous sediments. Photograph courtesy of Anne M Tréhu and the Shipboard Scientific Party, Ocean Drilling Program Leg 204, 2003.

The gas then found new channels until these were blocked as well. Thus, the plug gradually became less permeable. By measuring the gas released during melting and the water volume after complete dissociation, the plug content was calculated. The volume percentages of hydrates, free water, and free gas in the plug were 12, 38, and 50%, respectively. Hence, the actual hydrate content in the plug was low and the porosity of the plug was concluded to be as high as 88%.

In early work on gas hydrates, it was suspected that they were impervious to fluid flow, and that the entire sediment column within the gas hydrate stability zone (GHSZ) was cemented by gas hydrates. The active migration of free gas through a GHSZ and the porous nature of gas hydrates have since been amply demonstrated experimentally and are known to occur in nature. Gas hydrates may form rapidly when small-molecule gases leak into the sediments, and they may dissociate ('melt') rapidly when disturbed by heating or depressurization. When sediment-hosted hydrates dissociate, they return free gas and water to the environment, which may result in a total change of the physical sediment conditions and even of the seabed topography. Consequently, at water depths and sediment depths within the GHSZ, any planned interaction with the seabed has to take into consideration the possible existence and potential formation of gas hydrates.

When high-porosity sediments such as buried sands and gravels are present in regions with hydrocarbon flux, within the GHSZ, these sediment layers are likely to have developed into massive gas hydrate reservoirs. This has been demonstrated by the Mallik gas hydrate research well in the Mackenzie Delta, Canada. Also, with increasing hydrocarbon flux and increasing tectonic activity, the amount of gas hydrates within the near-surface sediments will increase, as has been demonstrated by, among others, the Geochemical Exploration and Research Group (GERG), in the Gulf of Mexico. In addition, the seafloor topography will be increasingly affected, and the presence of gas hydrates may even lead to very large slope failures and seafloor collapse events.

In regions with a very high fluid (hydrocarbon) flux through the seabed, masses of gas hydrates may form within the sediments, as found at Hydrate Ridge, off the coast of Oregon, USA (Figure 3). Here, seabed sampling showed that pure gas hydrates occurred in layers or in joints several millimetres to decimetres thick, generally oriented parallel to bedding, but sometimes cutting the bedding planes obliquely.

There was not one instance observed where the hydrates occupied the original sediment pore spaces and cemented the sediment framework on a microscale level. Rather, they filled large secondary pore spaces, either as fractures or joints, or seemed to create their own spaces during growth, by fracturing the sediment framework, most commonly along bedding planes. The internal fabric of the pure hydrates also showed a peculiar structure, with large, filled pores, resembling bubble-pack material.

Another important aspect of gas hydrates is that they chemically desalinate the ambient pore water. This characteristic is used by some geochemists to determine how much gas hydrate has been formed in low-permeability sediments, by studying the chlorinity of the pore waters. During Ocean Drilling Program (ODP) Leg 204 on Hydrate Ridge, this phenomenon was studied in detail. Among the most surprising findings of this leg was the rate at which hydrates form near the ridge summit. Salts are excluded when hydrates form, and the excess salt in the pore water diffuses away from the gas hydrates with time. However, if the hydrates form very rapidly, the salts do not have time to diffuse and the water in the sediment pore spaces will become saltier than seawater. Because of the hydrate inhibitor effect, gas hydrates will not be able to form within such brine-filled sediment pockets in the future, another factor that causes sedimentary inhomogeneities.

Detection and Distribution of Gas Hydrates

It is relatively easy to map the 'potential gas hydrate' distribution (i.e., the distribution of locations in which suitable physical conditions occur in the ocean sediments). However, the expected distribution frequency may be overestimated because, even within the GHSZ, gas hydrates will form only if there is adequate water within the sediments to form the 'host' molecules, and an adequate supply of gas 'guest molecules' (for example, methane). The origin of the gas is immaterial, so methane, being the most common gas, may be of either thermogenic or bacterial origin.

Indirect evidence for gas hydrates in ocean-floor sediments first came from anomalous reflections observed on seismic profiles recorded during the Deep Sea Drilling Program (DSDP), Leg 11, on the Blake Outer Ridge, off the eastern coast of the USA (*see* **North America:** Atlantic Margin). The special reflection event (Figure 2), called a bottom-simulating reflection (BSR), is an acoustic interface generated by a (diagenetic) phase boundary. It is anomalous owing to its highly reflective appearance, representing an abrupt change in acoustic impedance. It is also anomalous in that it cross-cuts bedding planes and is of reverse acoustic polarity. Sedimentary strata below the BSR are usually more strongly defined (i.e., enhanced) compared to those above it, where lithological layers tend to generate only weak reflections. This upper zone is therefore referred to as 'seismically transparent' or as 'blanking' and is suspected to be caused by hydrate 'cementation' and relatively high acoustic velocity.

Although the mapping of BSRs can aid in determining the presence of gas hydrates below the seafloor, some areas with gas hydrates do not have BSRs. It was long thought that a BSR was a necessary and adequate indicator of *in situ* gas hydrates, but one important result of the dedicated ODP BSR investigations is that this assumption was found to be partly false. In some places, drilling through BSRs has failed to find gas hydrates; in other cases, gas hydrates have been found where there is no BSR.

A prominent BSR occurring adjacent to the Storegga Slide scarp, off the coast of Norway, was investigated by drilling in 1997, as part of the geotechnical investigations for field development of the Ormen Lange field. However, no gas hydrates or temperature anomalies were found in the sampled sediments. Furthermore, only very little methane occurred in the pore waters below the BSR. These 'negative' results indicate that the existence of a BSR is no guarantee that there are detectable amounts of gas hydrates or free gases in the sediments. The question about what actually produces the seismically detectable BSR is therefore valid. Off the coast of Norway, it was concluded that the feature perhaps represents a palaeo-BSR, and that although the gases and gas hydrates may once have been present, they are no longer there in quantities that are of any practical consequence.

The true nature of BSRs and how they develop are therefore not yet fully understood. There is some consensus that they develop mainly as a consequence of the acoustic contrast between relatively high-velocity, gas-hydrate-charged sediments above low-velocity sediments. The low-velocity characteristic is attributed to free gas beneath a hydrate layer. A BSR may therefore be indicative of gas hydrates above the BSR, free gas beneath the BSR, and the diffusive migration of gas through the whole sediment package, i.e., from below the GHSZ to the seabed.

One of the most surprising results from ODP Leg 164, at Blake Ridge, was the finding of bacterial activity near the BSR. This finding is thought to demonstrate that the sediments near and below the BSR form a biogeochemically dynamic zone, with carbon cycling occurring through methane, acetate, and carbon dioxide. At Site 995, pore water acetate was present in very high concentrations, reaching

~15 mmol l^{-1} at 691 mbsf (metres below seafloor), ~1000 times higher than 'typical' near-surface concentrations (2–20 μmol l^{-1}). Potential rates of acetate metabolism were extremely high and could not be sustained without influx of organic carbon into the sediment; hence, *in situ* rates are likely to be lower than these potential rate measurements indicate. However, there is evidence for upward migration of high concentrations of dissolved organic carbon into the sediments at these sites. Based on these observations, it can be concluded that the BSR represents a physicochemical and perhaps even a biogeochemical 'reaction zone' brought about by the advection of light hydrocarbons; the hydrocarbons accumulate as free gas below the local GHSZ and form hydrates above – thereby rendering an acoustic reflector that can be imaged by seismic methods.

In 2001, Kvenvolden and Lorenson provided an updated overview of worldwide gas hydrate occurrences:

> An inventory of global occurrences shows 77 places in which the presence of gas hydrate is inferred by geophysical, geochemical, and geological methods. This inventory includes 19 places where samples of the substance have actually been recovered. Most natural gas hydrate contains methane that was generated by microbial processes. Methane with a thermal origin occurs in gas hydrate only where deeper deposits of thermogenic natural gas provide a source of the methane. The potential amount of methane in global gas hydrate occurrences is very large, with current estimates converging at about 10 teratonnes of methane carbon.

Gas Hydrates as an Energy Source

It has long been speculated that methane hydrates in ocean sediments may represent the greatest reservoir of methane on the planet, offering a clean and abundant energy source for the future. Historically, there has been a great disparity between various estimates of methane locked up as hydrates in ocean sediments. This can be explained by the fact that previous estimates had assumed that the gas hydrate-bearing sediments contained massive hydrates, whereas sampling has shown that hydrates normally occur as small, finely dispersed crystals and aggregates within the sediments; average concentrations may be as little as 3% by volume – more like the ore of a metallic mineral than a traditional hydrocarbon reservoir. But integrated over the world's oceans and Arctic tundras, the total methane stored in gas hydrates is about 10^{19} g, i.e., about 10 Mt, which represents an order of magnitude more carbon than exists in the biosphere, according to Nisbet.

In the Outer Niger Delta, potential BSR-associated gas hydrates have been considered for production

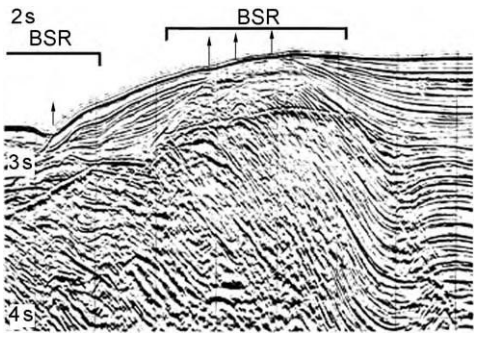

Figure 4 The bottom simulating reflection (BSR): Four of the main BSR characteristics are evident on this 2D seismic record from off Nigeria: (1) depth below the seafloor is more or less constant, (2) the BSR is anomalously strong, (3) the BSR cross cuts bedding planes, and (4) the BSR is of reverse polarity with respect to the seafloor reflection. These four aspects, respectively, mean that the BSR (1) is temperature dependent rather than pressure dependent, (2) is caused by a relatively large impedance contrast (i.e., jump in density and/or sound velocity with depth), and (3) is fluid/gas related (i.e., diagenetic rather than lithologically related), and that (4) the P waves reflect from a boundary with an inverse impedance contrast (i.e., where the density is reduced and/or the material's sound velocity is reduced with depth).

(Figures 4 and 5). However, their suspected dispersed nature suggests that they could be extracted only by open-pit mining, a method not currently viable, because the water depth is between 1000 and 2000 m! But attempts to find commercial oceanic gas hydrates have not yet been abandoned. There is hope of finding thick deposits of sandy turbidites containing massive methane hydrates at a 900-m water depth in the Nankai Trough off the coast of Japan. Japanese scientists and the Ministry of Economy, Trade, and Industry (METI) will be going ahead with a three-dimensional seismic acquisition and a full-scale exploration drilling campaign in the Nankai Trough over the next few years.

Oceanic methane hydrate deposits may be of strategic interest. Even if the growth of fossil-fuel consumption continues to slow in Europe, North America, and Japan as conservation and alternative energy sources come to play larger roles, the rest of the world inevitably will require much more energy than it now uses. Creating the means to exploit gas hydrates could be a matter of national security. This is why Japan has long devoted a substantial effort to studying natural-gas hydrates, including the drilling and analysis of a number of test wells. Strategic planning also accounts for the rising interest in hydrates within the US Department of Energy.

Several years ago, Japanese researchers teamed up with Canadian and US scientists to explore commercial exploitation of gas hydrates by drilling through

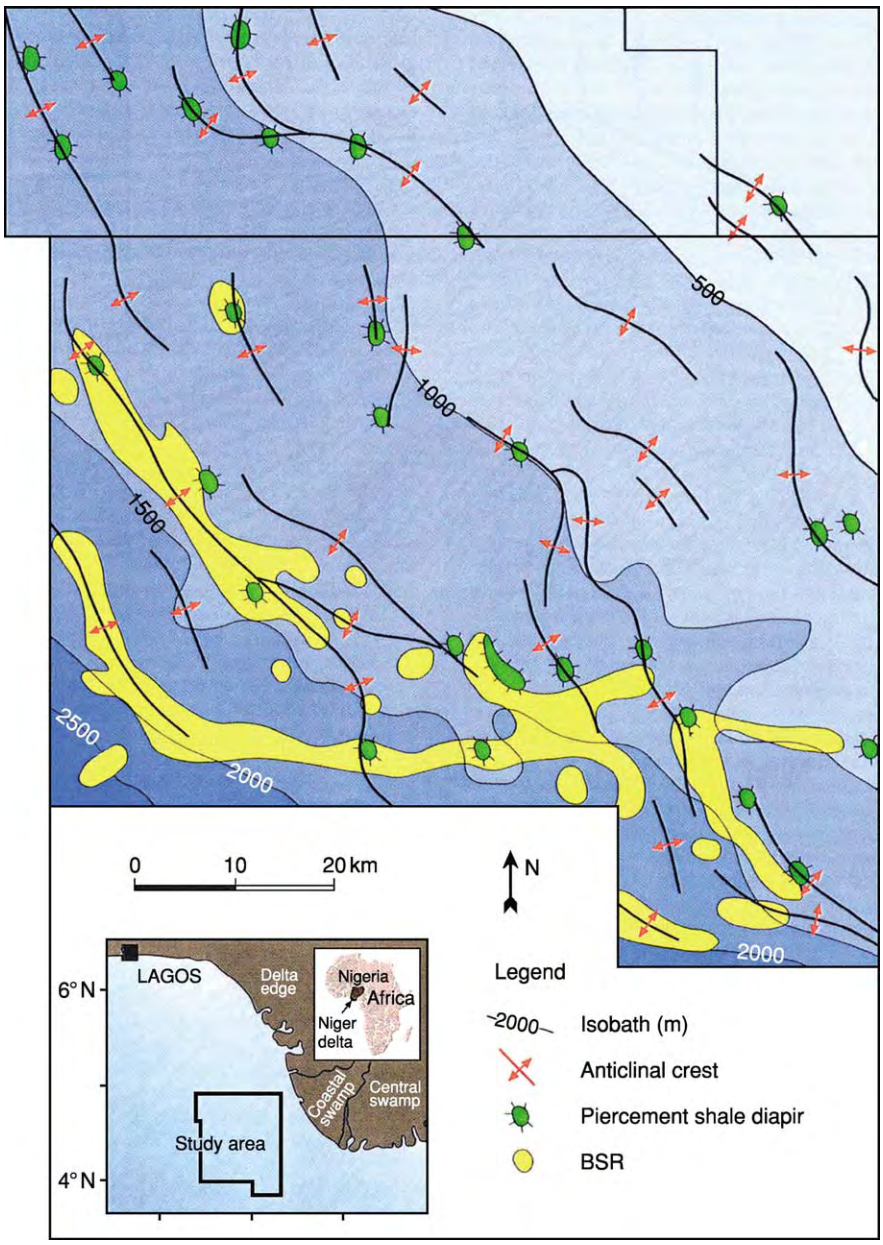

Figure 5 Map showing an area in the Outer Niger Delta Front where resource estimates of gas hydrates have been made. The yellow regions define areas with bottom simulating reflections (BSRs), i.e., strong gas hydrate indicators. The green circular features represent mud volcanoes, where fluids and mud erupt on the seafloor and build low lying sediments cones. Depth contours are in metres. Note that the BSRs occur only in water depths greater than about 900 m.

known, thick hydrate occurrences in Arctic Canada, the so-called Mallik well. In 2001, this project was expanded into a multinational campaign, including personnel from India and Germany. They have investigated both warm water circulation and pressure release as production means of freeing up the subsurface hydrate-locked gas. In 2002, Adam wrote that

> Those involved said that they were encouraged by the amount of methane produced enough to ignite a flare similar to those seen burning over oil rigs. But whether the yellow flame is merely symbolic or a genuine step forwards remains to be seen. The researchers are confi dent that they will get more energy out than they put in, but not [enough] to pipe it to a power station.

The most promising areas to look for available gas hydrate-associated energy are probably at active deep-water mud volcanoes. Large volumes ($\sim$25 Mt year ^{1}) of gas escape from deep-water mud volcanoes, suggesting that global gas flux from the

seafloor may be underestimated. The European Community is currently investing money into research on gas hydrates in order to assess the potential benefits of or hazards posed by these resources. As part of a European research programme (HYDRATECH), a specially designed laboratory apparatus (a resonant column) is to be constructed to simulate the conditions that allow gas hydrates to be grown artificially. The resonant column will also be used in experiments conducted to characterize the seismic signature of sediments containing gas hydrates. The results of the experiments will allow scientists to better identify and estimate the uses of or threats posed by gas hydrates. However, because even one of the world's best mapped and documented seabed areas still keeps its geological secrets well hidden, the race for exploitable hydrates may take a long time. As expressed by Lorenson and co-workers in 2002:

> Despite years of geophysical prospecting for hydrocar bons, the spatial and vertical distribution of deep gas hydrate in the Gulf of Mexico is not well known. This uncertainty hinders both the determination of the economic potential of gas hydrate resources in the region . . . and their potential as a geohazard.

Gas Hydrates as a Geohazard and Climate Mediator

Extensive data collection efforts on the Louisiana continental slope in the Gulf of Mexico have demonstrated that ambient gas hydrates in sediments are sensitive to small temperature and pressure changes. A temperature increase in the water column as small as 1.0–1.5°C caused distinct dissociation of the gas hydrate, leading to outgassing. Smaller fluctuations in fluid flow were also recorded at the tidal frequency, implying that very small perturbations in the ambient pressure conditions may lead to dissociation. The assessment of a potential drilling site or deep-water construction site, including potential pipeline routes, therefore, has to include an evaluation of the possible presence and formation of gas hydrates. It is therefore necessary to use and interpret all of the available signs of gas hydrate presence, including indirect means, such as interpretation of seismic, sonar, and topographic features, and direct ground-truthing means, such as visual observation and seabed sampling. Ground truth is required to calibrate wide-area surveys and derived results. Within a large dataset, small areas must be examined at the highest resolution and geotechnical standards. The interpretation of the wide-area dataset can then be constrained and the data made relevant within the whole of the wide-area survey. In addition, small areas that have been selected for exploration drilling, or because they constitute a representative seafloor, require optical inspection using video cameras; inspection should be made over relatively wide areas and for every sampling point.

An assessment of potential gas hydrates should also go hand in hand with a theoretical consideration and analysis. Because the regional and local diffusive and focused flux of light hydrocarbons through the sediments is of such importance, it may also be important to quantify the hydrocarbon flux from the seafloor into the ocean, and because of the dynamic nature of the hydrates, long-term monitoring of subcropping or outcropping hydrates could be useful at certain deep-water construction sites. Experiments for performing such studies in the Gulf of Mexico are being planned.

Recent interpretation of high-resolution seismic records of seafloor sediments on the Cascadia margin, off the coast of Vancouver Island, Canada, suggests a periodic disintegration of oceanic gas hydrates. Thus, vertically oriented acoustically anomalous 'chimneys', also called 'wipeouts', which are perturbations penetrating through the GHSZ, indicate fine-scale fluid flux through the upper seafloor. It has been suggested that these vertical intrusions are associated with upward flow of warmer fluids. Therefore, where seafloor fluid expulsion and methane hydrate deposits coincide, the base of the hydrate stability zone might exhibit significant roughness and increased surface area. Increased area implies that significantly more methane hydrate is close to being unstable and hence is closer to dissociation in the event of a lowering of pressure due to sea-level fall. On the Norwegian continental slope, north-east of the Storegga slide scarp, similar features are common on multichannel and high-resolution seismic records. In this region, many of the columnar 'chimneys' penetrate up to the seabed surface and are clearly associated with large pockmarks containing heaps of methane-derived limestone blocks.

'The clathrate gun' hypothesis, developed by Kennett and co-workers, is based on sediment sampling in the Santa Barbara Basin during ODP Leg 146B. Abrupt changes in the $\delta^{13}C$ values for marine organisms were observed in the samples, and it was speculated that the reason was abruptly changing methane contents in the atmosphere and oceanic water due to the dissociation of gas hydrates in ocean sediments. In association with the publication of the hypothesis, James Kennett made the following conclusions on this matter:

> Although no single, unequivocal proof exists for the hypothesis we present, a broad range of evidence suggests it. We expect reluctance by scientists to support such an

idea at this stage without further testing, but if the hypothesis holds, it will require a major shift in thinking about what drives Quaternary climate change.

However, it seems Kennett does not need to worry about reluctant scientists, because recent geological and palaeoclimatic results support the notion that methane released from oceanic gas hydrates is the main culprit in rapid warming events in the past. Smith and co-workers, for example, in 2003, reported suspected massive methane release during deglaciation, only about 14 000 years ago. Their conclusions are based on high-resolution stable isotope records from marine cores on the East Greenland shelf; these records exhibit three rapid light $\delta^{13}C$ events (-3 to -7%) in benthic and planktic foraminifera that are spatially and temporally transgressive. Smith and colleagues invoke that a combination of pressure release (due to ice melting) and temperature increase (associated with ice shelf retreat) has caused large masses of oceanic methane hydrates to dissociate suddenly. A similar but much more severe episode occurred about 55 million years ago, during the Paleocene/Eocene thermal maximum (PETM) global warming event. Based on seabed coring near Antarctica, researchers concluded that there must have been a massive release of carbon-12 into the ocean and atmosphere – an injection that must have occurred because of methane hydrate destabilization.

The main challenge now is to find out what triggers such destabilization. There are several possibilities, including ocean warming ('melting' of oceanic hydrates), lowering of mean sea-level and submarine landslides (depressurizing oceanic hydrates), and large impact events, all of which are equally difficult to document. Perhaps the triggering mechanism is quite feeble, such as a very slight warming or a very slight lowering of sea-level, but at some point, the balance is tipped, leading to a cascade of events. It is known, for example, that there are thousands of submarine mud volcanoes located on the ocean floor. These are known to represent 'pressure release valves' that may suddenly erupt violently, if disturbed by earthquakes, etc. The most dramatic and freak observation of an underwater mud volcano blowout (violent eruption) occurred in the Caspian Sea, on 18 November 1958. By chance, the event was photographed from the city of Baku, 20 km away from the eruption site, the Bachar Bank mud volcano, located at a water depth of 150 m. The flaming jet of gases at first shot several km into the sky. Later, it was estimated to stabilize at a height of 500 m and was topped by a large, 120-m-long horizontal flame. Judging from these dimensions, the jet must have been issuing at supersonic velocity from the sea surface, and the pressure must have been released directly from a depth several thousand metres below the seabed. It is known that the sea-level of the Caspian Sea is about 28 m lower than mean sea-level (MSL). Furthermore, the Caspian Sea drains the Volga River system and is known to adjust its level over long time-spans of 20 to 40 years, in response to suspected long-period, gradual, and cyclic climate changes. The Caspian Sea experienced a high-stand in the late 1930s, followed by a low-stand in 1974, which was followed by a new high-stand in 1996. Therefore, the triggering of the Bachar Bank natural blowout event could possibly have been the gradual (feeble) lowering of the Caspian sea-level. Although mud volcanoes are associated with gas hydrates, their formation mechanism is generally poorly understood.

All-in-all, it may be concluded that sediment-hosted gas hydrates and free gas located below capping layers of hydrates are dynamic, interesting, natural substances that may promise future wealth, but also wrath – if not treated with respect.

The Petroleum System

C Cornford, Integrated Geochemical Interpretation Ltd, Bideford, UK

Introduction and Definitions

The term 'petroleum system' implies an understanding of the generation of oil and gas within a source rock, followed by their expulsion, migration, entrapment, and survival to the present day. The petroleum system approach focuses on the 'genesis' of petroleum and hence the 'source rock', rather than merely the current location of oil and gas and hence the 'trap'. This differentiates the petroleum system approach of the 1990s from the 'play' concept of the 1970s and 1980s (Figure 1).

A simple definition of a petroleum system might be 'all commercial oil and gas deriving from a single pod of mature source rock'. With a better understanding of efficiencies and losses in the processes, this definition has developed to 'a petroleum system accounts, in terms of *volumes*, *composition*, and *process efficiencies*, for all commercial oil and gas expelled from a single pod of mature source rock'. What constitutes a 'commercial accumulation' varies with circumstances, such as oil composition, drilling costs, oil prices, political stability, and proximity to market.

Use of the petroleum system concept accepts that commercial oil and gas is generated from organic matter (kerogen) in sedimentary rocks. These rocks are at or have been buried to temperatures in the range 80–165°C (oil) or 145–220°C (gas), and the petroleum is expelled from the source rock, migrates, and then accumulates in traps. The term is inapplicable if an inorganic origin of petroleum is adopted and when exploring for biogenic methane, and unhelpful when exploring for coal-bed methane and shale-gas (gas trapped intimately within seam coal and shales, respectively).

A discussion of petroleum systems can be broken down into the contributing processes, viz:

- Source rock deposition and kerogen accumulation;
- Maturation of source rock upon burial;
- Generation of hydrocarbons in the source rock;
- Expulsion of oil and gas out of the source rock;
- Migration of oil and gas to the reservoir; and
- Alteration of reservoired hydrocarbons during survival to the present day.

These processes are illustrated gastronomically in Figure 2 and discussed in more detail in the subsequent sections.

In mapped terms (Figure 3), the prospect or trap is surrounded by a drainage area (polygon), from which oil generated within and expelled from mature source rock is focussed during migration towards the proposed accumulation. As illustrated, the actual amount of oil or gas generated will be determined by the richness of the source rock (type of organic matter, e.g., marine or terrigenous kerogen) and the maturity level reached (e.g., oil- or gas-mature). To undertake a full volumetric calculation, the source rock yield and thickness is also required.

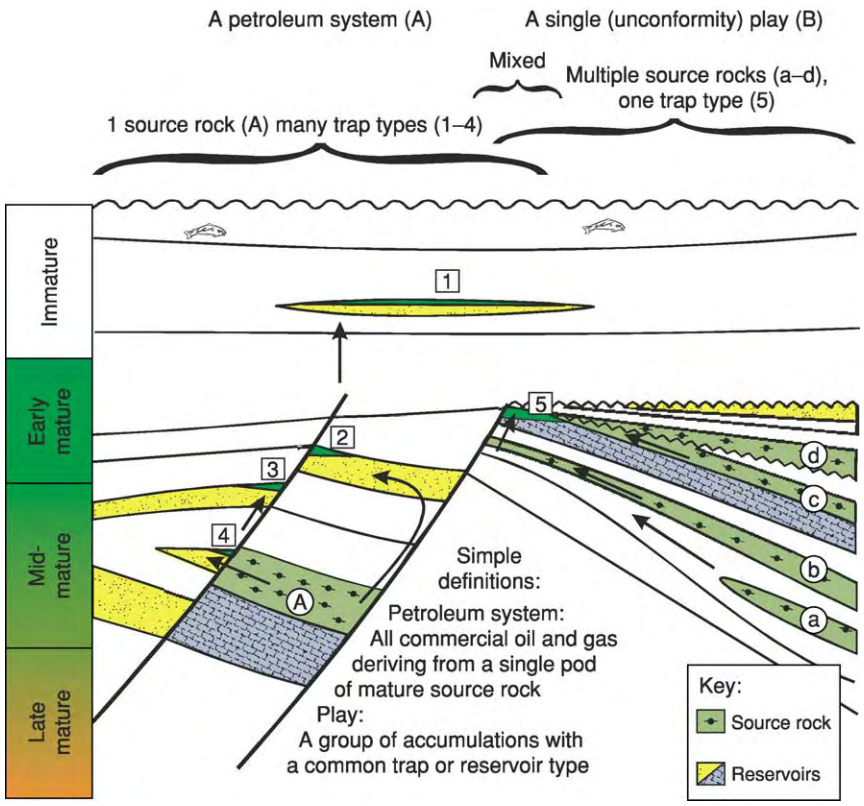

Figure 1 Contrasting the petroleum system with the play concept used for hydrocarbon exploration.

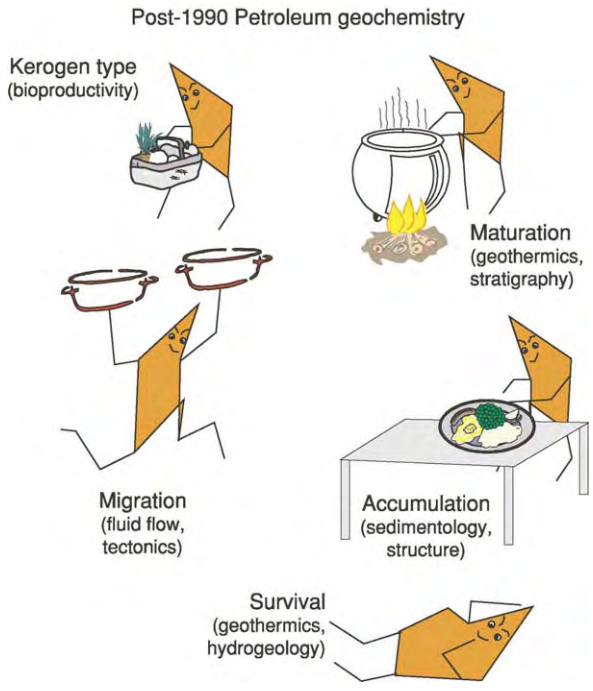

Figure 2 The petroleum system seen as a series of processes starting with (sedimentary) organic matter and resulting in a satisfyingly long lasting accumulation! Note the proceedings can be seen in terms of geological processes (text labels) or molecular activities (cartoon figures).

Source Rocks

Oil and gas are generated in organic-rich sediments, the source rock. As sediments accumulate, the soft body parts of organisms settle out with the mineral grains and carbonate or siliceous skeletal debris. The soft body parts are dominantly protein, carbohydrate, and fats, and in the case of the higher land plants, lignin. On bacterial attack and initial burial, these tissues condense to form kerogen. Most aquatic or littoral sedimentary environments have an abundant supply of organic matter, but petroleum source rocks require, in addition, a depositional environment promoting the preservation of that organic matter.

Source Rock Deposition

Depositional environments favouring the accumulation of petroleum source rocks are illustrated in Figure 4 in the context of a section through a tectonic plate. The amount of kerogen present in sediments is a balance between bioproductivity, survival, and dilution by inorganic grains. To take some extremes:

Low productivity—Aeolian (wind-blown) desert sandstones where land plant growth is restricted due to the extremely arid environment.

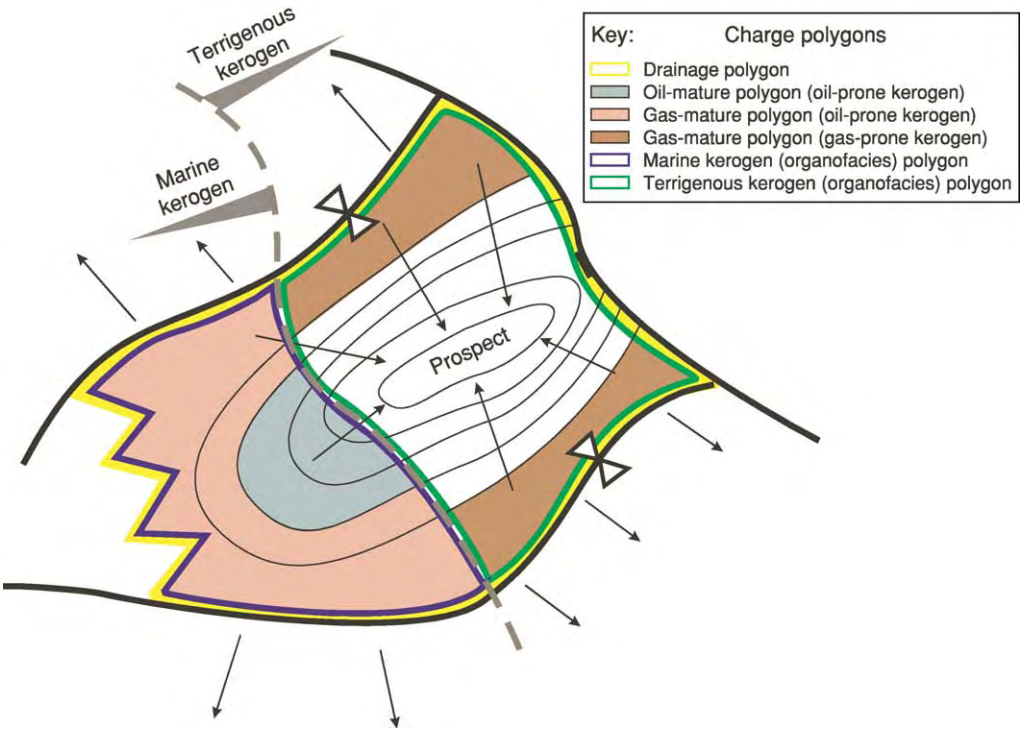

Figure 3 Mapping a trapping structure and the surrounding source rock drainage polygon supplying the oil and gas. The overall drainage area is bounded by faults and synclinal and distal boundaries and contains maturity kitchen and kerogen type polygons.

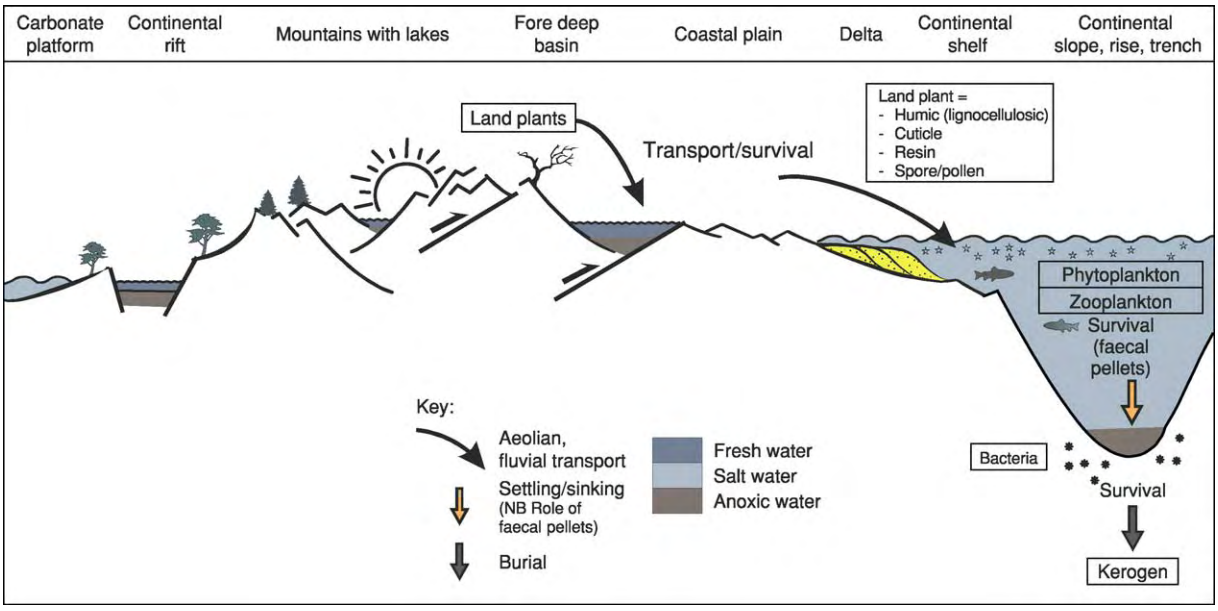

Figure 4 Environments where bioproductivity and depositional environment favour the accumulation of organic rich sediments.

High productivity—Areas of ocean upwelling where the enhanced supply of nutrients fuels explosive growth of phyto- and zooplankton.

Poor survival—Chalk composed almost exclusively of coccolith skeletal debris (high bioproductivity) but where all the coccolith body tissues are destroyed by bacterial activity under strongly oxic open marine conditions.

Excellent survival—Early rifting phases of oceans where both optimum sedimentation rates and anoxic conditions of the lakes and enclosed seaways promote high rates of organic matter preservation.

Strong dilution—The prolific sediment supply of major deltas produces organic lean delta-front and pro-delta sediments despite high bioproductivity.

Minimal dilution—Coals where the lignocellulosic and other tissues of high-productivity land plants are well preserved in a delta-top environment starved of (or bypassed by) mineral grains.

As illustrated above, the aspects of the depositional environment favouring organic preservation are anoxia and elevated sedimentation rates, though excessive sedimentation rates will eventually lead to dilution.

As implied in Figure 4, organic matter falling to the ocean or lake floor has to pass through various zones of bacterial degradation (Figure 5). The normal open-water oxic bacterial community is highly effective at destroying oil-prone organic matter, so time spent in this zone has disastrous effects on potential oil source rocks. These conditions are found in the water column and surface sediments in the open ocean, but in strongly stratified basins (e.g., the present-day Black Sea) only the top of the water column may be oxic.

Thus to summarize (Figure 6), the optimum oil-prone source rocks are deposited where anoxia develops in an aqueous environment enjoying high rates of sedimentation. The combination of high sedimentation rates and oxic environments favours the accumulation of gas-prone source rocks such as coals. The combination of depositional conditions and kerogen amount and type is termed 'organofacies', as discussed in the next section.

Source Rock Characterization

For a sediment to be considered a potential petroleum source rock it has to contain or have contained an appropriate amount and type of organic matter

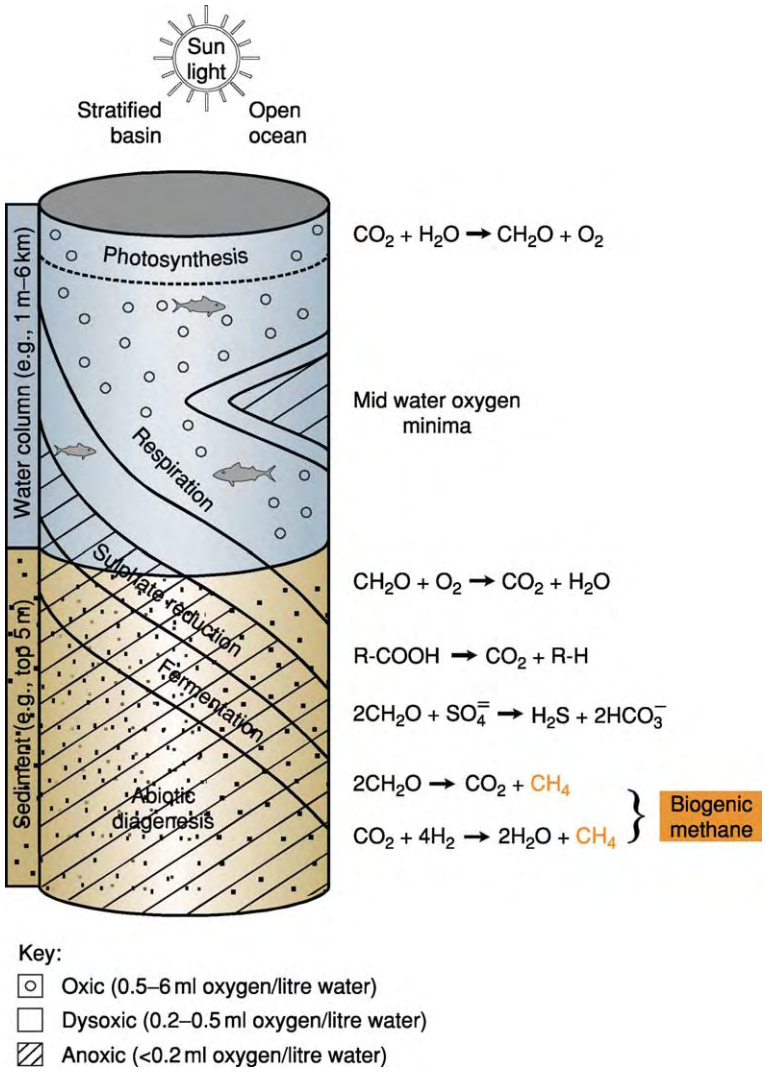

Figure 5 Processes affecting organic matter deposition and preservation.

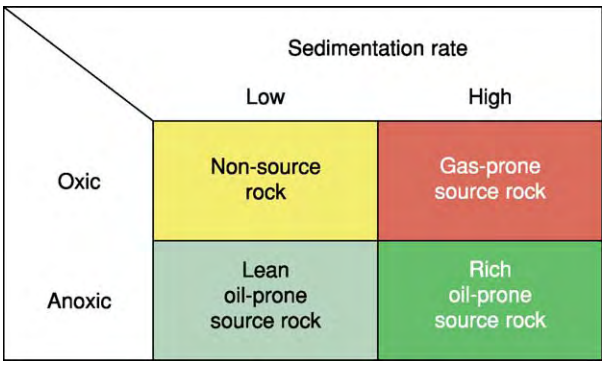

Figure 6 Summary of major processes controlling petroleum source rock accumulation (red gas prone; green oil prone).

(kerogen). In the same way that the mineral grains of a sediment can be linked to the conditions of deposition via the 'lithofacies', kerogens can be linked to depositional conditions via the 'organofacies'. An organofacies is characterized by a specific combination of organic matter abundance and type.

Abundance of organic matter The amount of kerogen is determined as the total organic carbon (TOC), measured as the weight percentage of the rock (Figure 7). The amount of organic matter can then be described as fair, good, or very good, as suggested in Figure 8. Experience has indicated that carbonate source rocks require lower TOC values to reach a certain level of source potential, probably due to more efficient expulsion of any generated hydrocarbon.

Type of kerogen—optical methods The most graphic way to determine the types of organic matter comprising kerogen is to view kerogen using optical microscopy. This technique is termed 'organic petrography' and is a combination of coal petrographic and palynological techniques and nomenclature. For a full organic petrographic characterization, three types of microscopy are needed:

- Reflected light (also used for vitrinite reflectance);
- Transmitted white light (also used for palynology); and
- Ultraviolet (UV) excitation fluorescence.

The reflected light technique is also the basis for the common maturity parameter, vitrinite reflectance, whereas kerogen colour in transmitted light and fluorescence colour can also contribute to maturity estimations (see next section).

A view of the same area of a bituminous coal thin section using all three methods is shown in Figure 9 with the logic for classification shown in Figure 10.

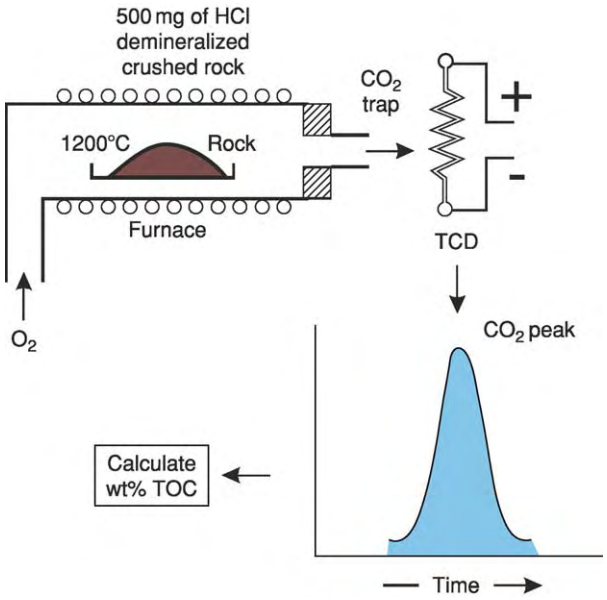

Figure 7 Schematic of a carbon analyser used to determine total organic carbon (TOC wt%) by burning acid demineralized rock powder in oxygen in a furnace at 1200°C, and determining the amount of carbon dioxide (CO_2) liberated.

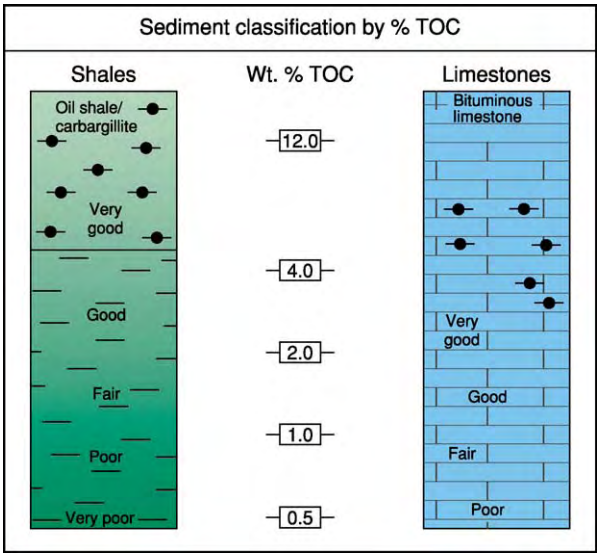

Figure 8 Quality of petroleum source rocks based on amount (but not type) of organic matter.

Discrimination using fluorescence can only be made for relatively shallowly buried sediments (e.g., <4 km burial) where the kerogen is in the immature to mid oil-mature levels of maturation. From Figure 9 it can be seen that this coal contains oil-prone spores and cuticle, gas-prone lignocellulosic vitrinite, together with inertinite (fungal sclerotinite and semifusinite)

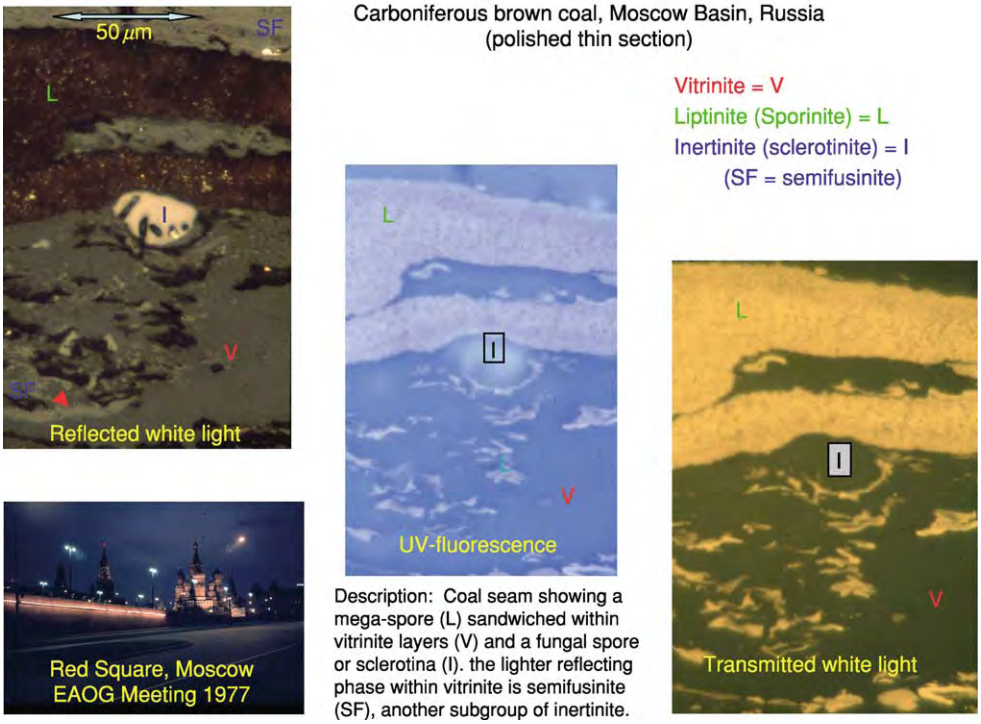

Figure 9 Reflected, transmitted, and fluorescent light views of a polished thin section of Russian carboniferous coal showing oil prone lipinite, gas prone vitrinite, together with inert kerogen macerals (inertinites).

with little or no hydrocarbon potential. The inert material is the result of oxidizing land plant material, this mainly being fossil charcoal resulting from natural forest fires and spontaneous combustion of humus.

The combination of these microscopy techniques allows the visible particulate organic matter to be classified into three groups:

- Oil-prone liptinites (fluorescent at low maturity and low reflectance);
- Gas-prone vitrinites (nonfluorescent and medium reflectance); and
- Inert or dead carbon (nonfluorescent and high reflectance at all levels of maturity).

The decision tree used by the organic petrographer is illustrated in Figure 10, where the initial distinction between fluorescent oil-prone liptinites and the nonfluorescent components is followed by high and low reflectance to split the latter into gas-prone and inert particles. Occasionally some vitrinites can exhibit low levels of flourescence. Some further breakdown of the three primary groups is also shown.

Visual descriptions (or a photograph) of a kerogen provides an excellent overview of the large variety of plant and animal tissues preserved in the sediment. However, this diversity of kerogen types also gives rise to a bewildering range of descriptive terms (Figure 11). Some of the commonest general terms are equivalences with respect to provenance (see comments in right column) and oil and gas potential (left column).

The coal micrographs shown in Figure 9 are unusual in that a polished thin section has been made to allow viewing in reflected and transmitted light together with fluorescence. As illustrated in Figure 12, visual characterization of the kerogen in sedimentary rocks may be undertaken on polished rock surfaces (reflected light and fluorescence) or on kerogen concentrates. The kerogen concentrate is made by removing carbonate with hydrochloric acid (HCl) and quartz and silicates (mica, etc.) with hydrofluoric acid (HF). The kerogen concentrate may still contain heavy minerals and pyrite, which can be removed by centrifuging in a high-density liquid. Some organic matter can be lost, so if a representative kerogen is required this step may be omitted.

Whole rock and kerogen concentrates are contrasted in Figure 13. The advantage of the 'whole rock' method is that the sedimentary context of the kerogen is preserved and the tedious acid digestion process—with associated health and safety issues—is omitted. The disadvantage is the dispersed nature of the kerogen makes some identifications difficult and quantification impossible. In contrast, viewing a representative kerogen concentrate allows for semiquantitative compositional estimates (%liptinite,

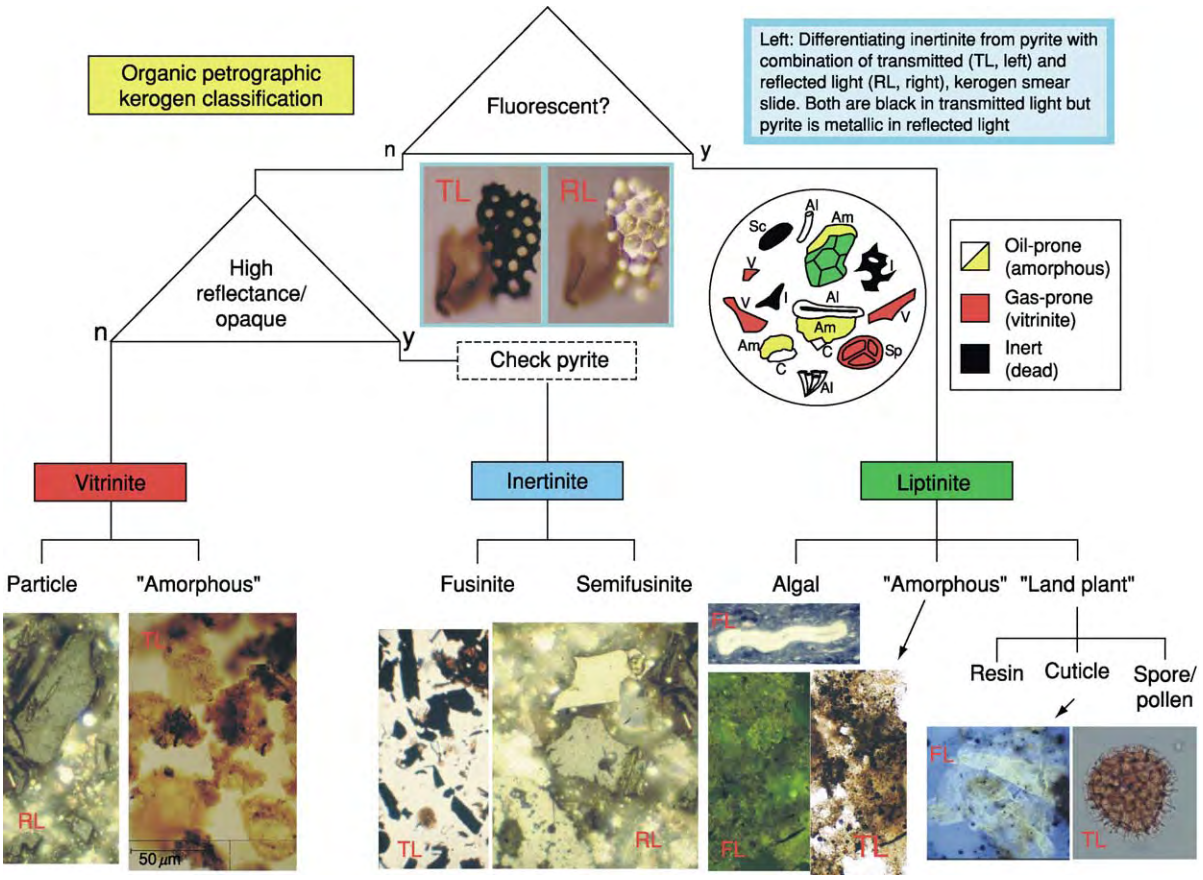

Figure 10 Classification of immature and mature kerogens using reflected (RL), transmitted (TL), and fluorescent light (FL) microscopy (y = yes, n = no).

Equivalent kerogen nomenclatures					
Hydrocarbon potential	Coal petrography	Palynology	Chemistry	Rock eval	Comments
Oil-prone (cracking to condensate andgas)	Liptinite	Algal/ Amorphous	Sapropel	Type I (Type IS)	Pure algal Includes bacterial biomass
Light oil, condensate-prone	Exinite	Herbaceous		Type II (Type IIS)	Cuticle gives waxyoil, Type II can be a mix of Types I, II land IV
Gas-prone	Vitrinite	"Woody"	Humic	Type III	Amorphous vitrinite and oil-impregnated fluorescent vitrinite exist
Dead carbon	Inertinite	"Coaly"	(not recognised)	Type IV (or IIIB)	Minor gas potential from semi-fusinite

%vitrinite, %inertinite) as the particles are closely packed and may be viewed in all three microscopy modes (Figure 14).

Type of kerogen—pyrolysis methods Pyrolysis, particularly the widespread commercial Rock-Eval family of analysers, rapidly yields 'cheap and cheerful' information concerning kerogen type, maturity, potential yield of hydrocarbon, and the presence of migrated hydrocarbons. Developed by the Belgians and popularized by the French, Rock-Eval pyrolysis has become the most widespread apparatus for geochemical screening of drill samples. Its popularity derives from its modest sample requirements together with its relative cheapness and simplicity (though not necessarily reliability) of interpretation. For most applications, TOC data are required for the interpretation of Rock-Eval data. The recent versions of the Rock-Eval machine do, however, produce an 'organic carbon equivalent' value, arguably dispensing with the need for separate TOC data (*see* **Analytical Methods:** Geochemical Analysis (Including X-Ray)).

The conventional Rock-Eval machine progressively heats (pyrolyses) powdered rock in an inert atmosphere to produce the following sequence of events (Figure 15):

- Release of the 'free' hydrocarbons to give an S_1 peak (to about 300°C).
- Simulation of maturation and generation of new hydrocarbons from the kerogen (300–550°C) to yield a second peak, S_2, with maximum at temperature T_{max} (°C).
- Release of organically bound CO_2 over the temperature range 300–550°C to give an S_3 peak.

The interpretation of pyrolysis results in general and Rock-Eval in particular covers many aspects of petroleum geochemistry. Interpretation is normally undertaken using industry-standard cross-plots. The simplest, termed the pseudo-van Krevelen diagram, plots the oxygen index against the hydrogen index.

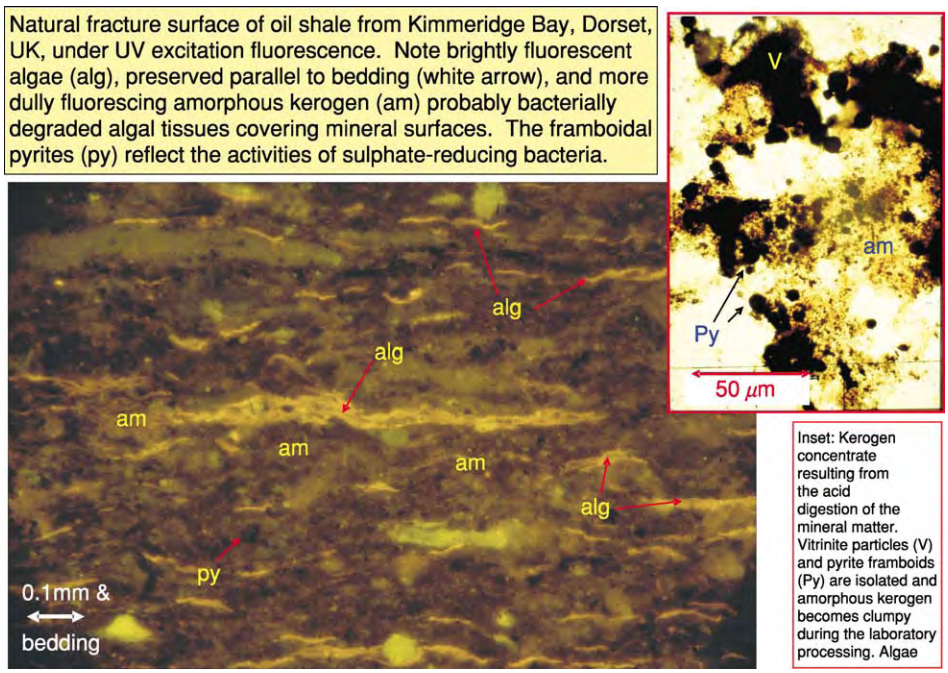

Figure 13 Visual kerogen descriptions can derive from whole rock surfaces viewed in reflected light or fluorescence (main picture) or as a kerogen concentrate in transmitted white light (inset).

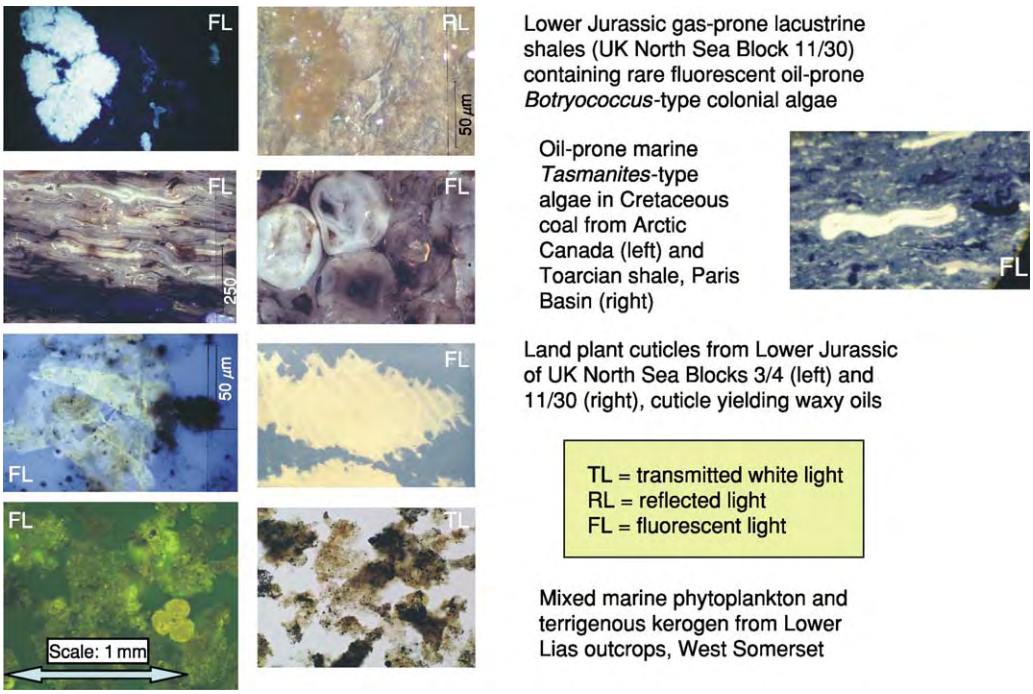

Figure 14 Some typical oil and gas prone kerogen associations illustrated as organic petrographic micrographs.

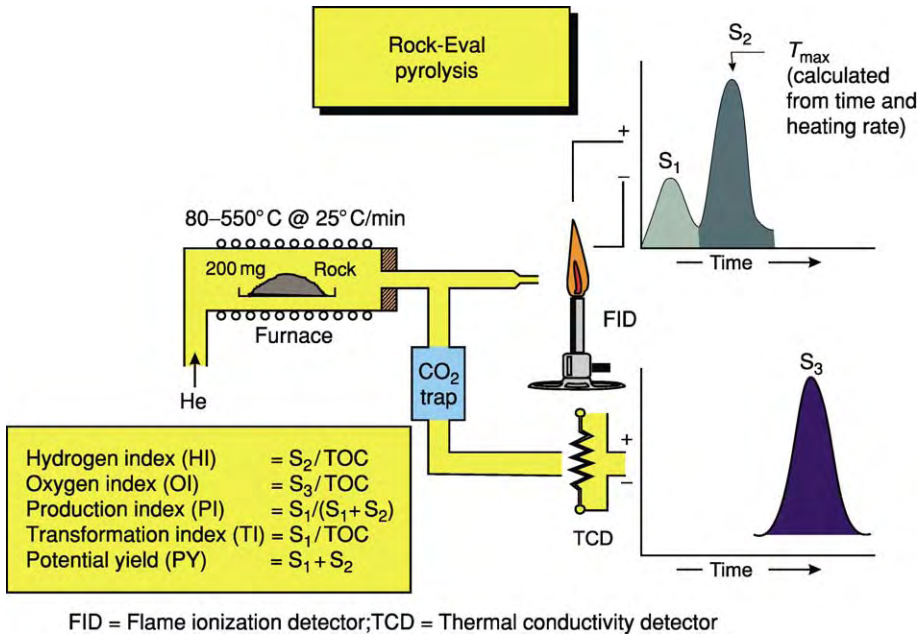

Figure 15 Schematic of the Rock Eval pyrolysis apparatus, output, and (with TOC) derived parameters.

This is shown in Figure 16, where four main kerogen types can be identified:

- Type I kerogen of algal origin, which is oil-prone;
- Type II kerogen deriving from a number of origins though all are oil-prone:
  - Land plant spores, exines, and resins;
  - Bacterially degraded algal (originally Type I) kerogen; and
  - A mixture of Type I (algal) and Type III (humic) particles.
- Type III kerogen of lignocellulosic or humic origin which is gas-prone;
- Type IIIb or IV kerogen defined as altered (oxidized) humic material or fossil charcoal: it has no oil or gas potential.

The reliability of oxygen indices has been questioned since some carbonates (e.g., iron carbonates) decompose at the temperatures where the 'organic CO_2' is being collected (see Figure 15). High oxygen indices are suspect if deriving from rocks with high carbonate contents.

A more detailed approach to kerogen identification is shown in Figure 17, where a plot of the Rock-Eval S_2 yield versus TOC is used to identify the average percentage of dead carbon (%DC) as the intercept of the best-fit data trend on the TOC axis. An incremental part of this intercept has also been interpreted as resulting from the adsorption of S_2 organics on active mineral surfaces.

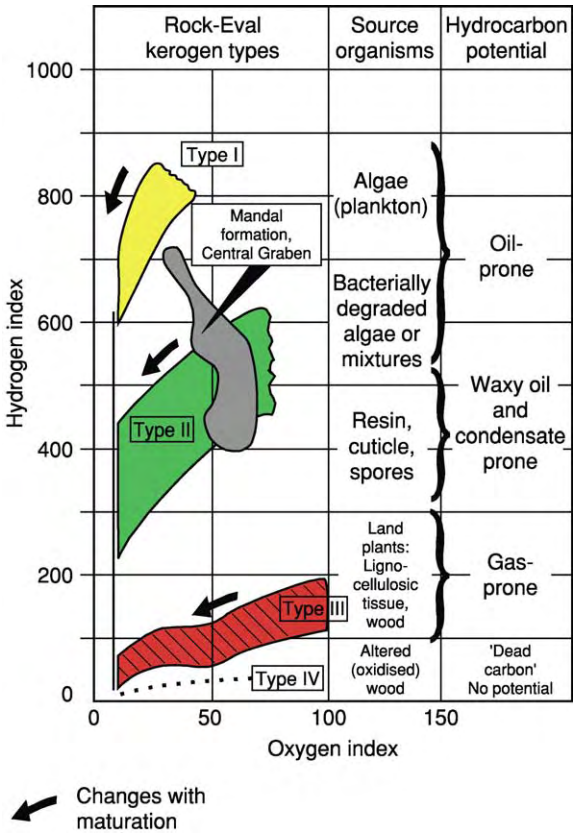

Figure 16 Kerogen type from Rock Eval hydrogen indices (mg Pyrolate/g TOC) and oxygen indices (mg CO_2/g TOC), with maturity trends indicated by the heavy black arrows.

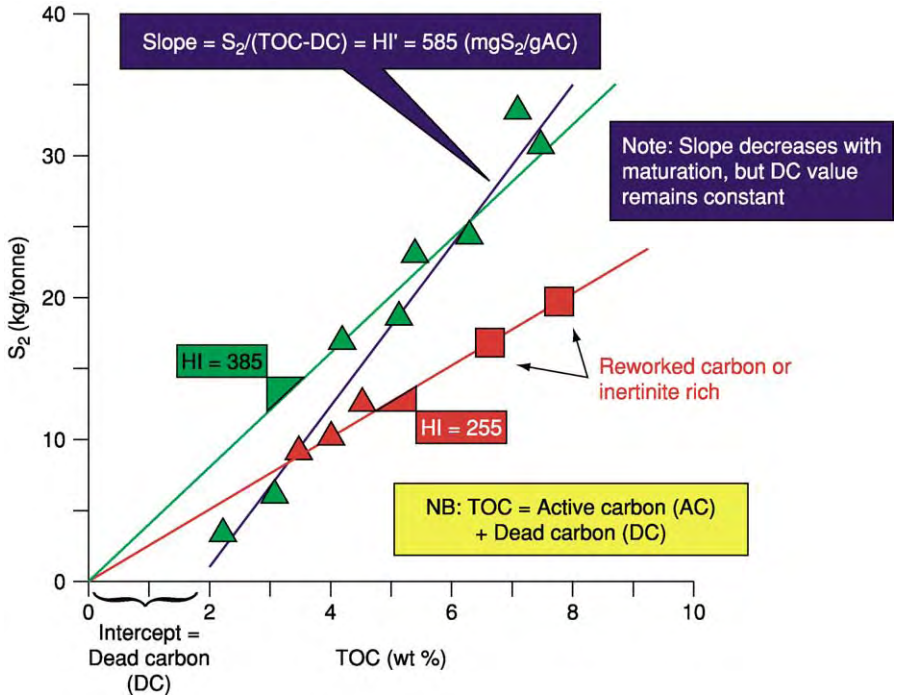

Figure 17 A more detailed determination of kerogen type in immature and early mature kerogens using Rock Eval S_2 and TOC data where the gradient is hydrogen index (S_2/TOC in units of mg Pyrolysate/g TOC).

Green and red trends (data plus lines) pass through the origin of the graph and define two types of kerogen with HI of 385 and 255 mg g TOC ^{1}, respectively. Ignoring two points, a single blue trend better fits all the values. The TOC can then be considered as the sum of dead carbon (DC) and active carbon (AC):

$$\%\text{TOC} = \%\text{DC} + \%\text{AC}$$

Note %TOC represents a percentage while TOC refers to a ratio.

It follows that the slope of the blue trend in Figure 17 is a modified hydrogen index (HI′), calculated on a dead-carbon-free basis (HI′ = 585 mg S_2/g AC ^{1}):

$$\text{HI}' = 100 \times S_2/(\%\text{TOC} - \%\text{DC}) = 100 \times S_2/\%\text{AC}$$

The above analysis is really only applicable to immature and early oil-mature kerogens (see next section). The determination of kerogen type for mid-, late-, and post-mature kerogens can be addressed with Figure 18, where Rock-Eval T_{max} is the maturity parameter. The typical bacterial-algal Type II kerogen shows a small increase in hydrogen index in the immature stage (up to $T_{max} = 430°C$), followed by a linear decrease, which reflects oil generation up to about $T_{max} = 465°C$. The gas-prone Type III kerogen with a lower initial hydrogen index falls slowly over a larger T_{max} maturity range.

For the highly oil-prone Type I algal kerogen the immature/early mature boundary can be as high as $T_{max} = 440°C$, but once reached the rapid generation of oil produces a swift decrease in hydrogen index. A singular kerogen type is likely to require its own T_{max} calibration: for example, generation from a sulphur-rich Type IIS kerogen produces a reduction in hydrogen index at an anomalously low maturity level. Thus, using the Rock-Eval pyrolysis approach to kerogen typing requires knowledge of source rock maturity.

The pyrolysis S_2 peak can be trapped and passed to a gas chromatograph (GC) to produce a characteristic fingerprint (Figure 19). This pyrolysis-GC fingerprint differentiates oil-prone kerogen dominated by the alkane–alkene doublets, from gas-prone kerogens where the aromatic compounds such as toluene, xylenes, and low-molecular-weight alkanes dominate.

Kerogen type can also be determined somewhat more indirectly from a number of other kerogen properties, such as elemental analysis, stable carbon, and hydrogen isotopes, and the molecular fingerprints from biomarkers, such as steranes and terpanes.

Using these more sophisticated properties a source rock kerogen can be attributed to an organofacies based on water chemistry (fresh, saline, hypersaline),

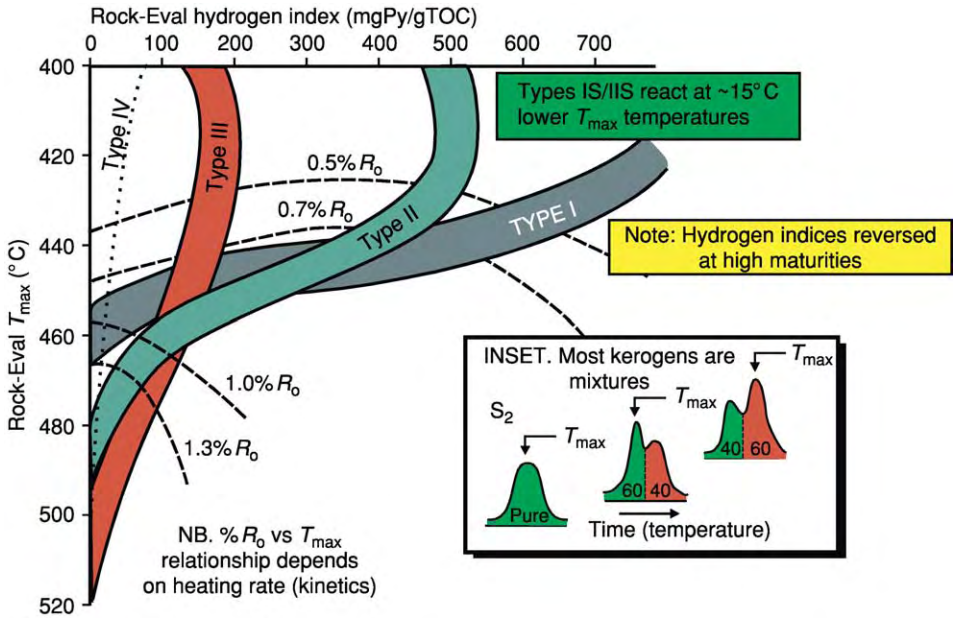

Figure 18 The effect of maturity changes on hydrogen index values for the three major kerogen types.

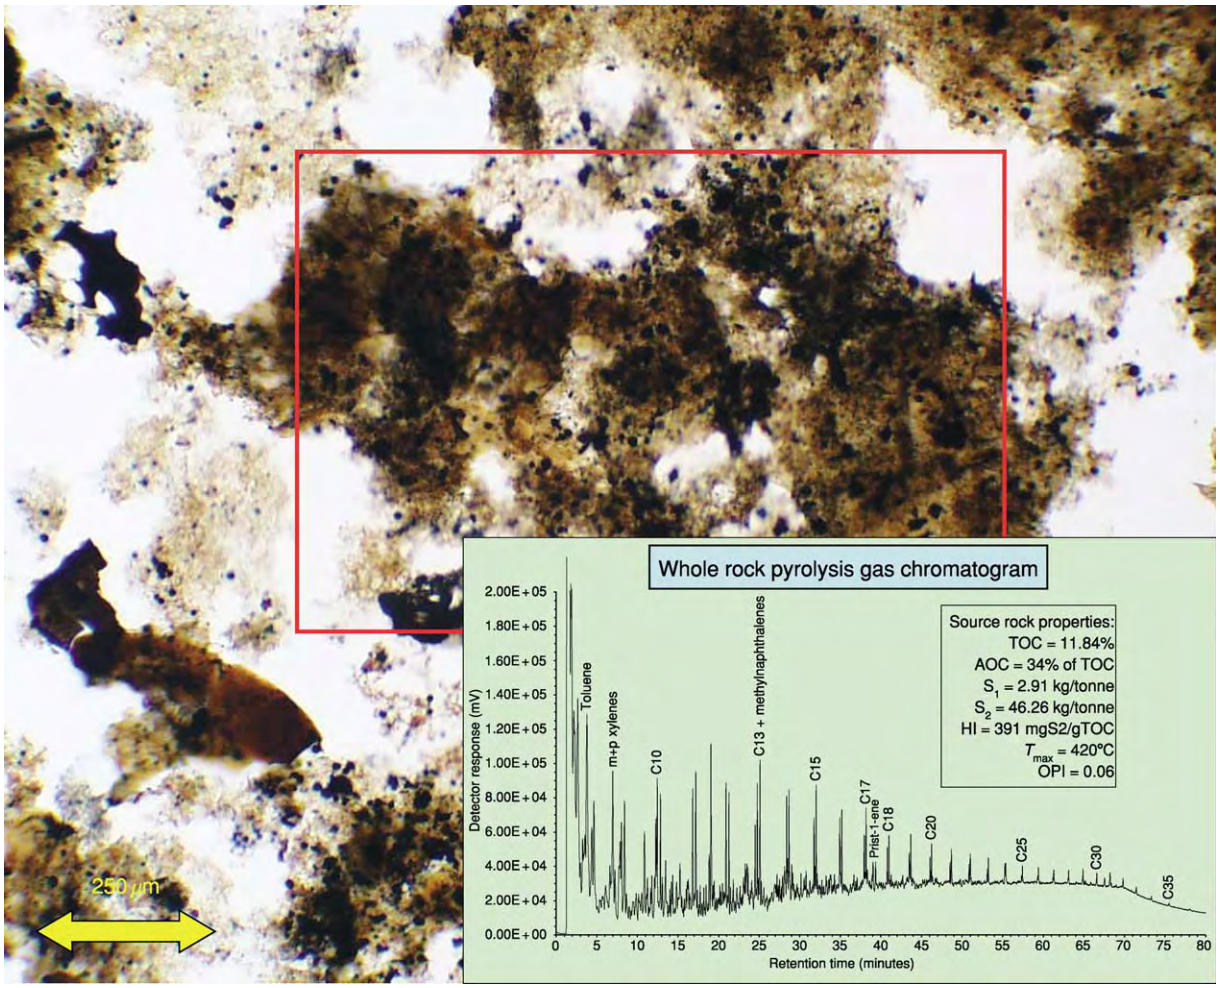

Figure 19 Kerogen typing using pyrolysis GC fingerprints to confirm the presence of oil prone kerogen (Lias shale from a well in the UK Western Approaches).

mineralogy (clastics, carbonates), and dissolved oxygen levels (anoxic, dysoxic, oxic) at deposition. In addition the molecular and isotopic signature can place limits on the stratigraphic age and types of organism contributing to the kerogen. The importance of these molecular and isotopic properties is that they are carried with the oil to the trap or surface seep. This allows the organofacies of the source to be estimated from migrated oil and hence address the question of oil–source rock correlation.

Maturation

As any sediment is buried the contained organic matter is matured as a function primarily of increasing temperature, with ancillary effects of time and possibly pressure. Maturity can be related to the stages of hydrocarbon generation and can be used to constrain geological models. In this section maturity is defined in terms of temperature and time, using measured indicators such as Rock-Eval T_{max}, vitrinite reflectance, and spore colour indices. Some common maturity parameters are related to oil generation levels in Table 1 and to gas generation levels in Table 2.

These equivalencies shown in Table 1 and Table 2 are subject to a number of caveats:

- Different responses to temperature and time for different kerogens (kinetics);
- Differences between sampling and laboratory analytical procedures; and
- Different concepts of what constitutes early, mid-, and late maturity.

The recommended procedure is to validate these equivalencies using locally generated data from within the project area.

The most common technique for measuring source rock maturation is vitrinite reflectance, developed for studies of coals in the 1960s and 1970s. It has subsequently been increasingly applied to sediments and derived kerogen concentrates. The reflectance of a material ($\%R$) is a function of its refractive and absorptive indices together with the refractive index of the observational medium (air, water, oil, etc.), as expressed by Beer's equation:

$$\%R = [(n - N)^2 + n^2k^2]/[(n + N)^2 + n^2k^2]$$

where n = the refractive index of the material, N = the refractive index of the measuring medium, and k = the absorptive index of the material.

The basic vitrinite reflectance technique is shown in Figure 20, where the upper left panel illustrates the reflected light polarizing microscope fitted with a photomultiplier detector. The reflectance is measured relative to a glass or crystal standard:

$$\text{vitrinite reflectance} = (\text{PMR of vitrinite}/\text{PMR of standard}) \times \text{reflectance of standard}$$

where PMR = photomultiplier response.

Reflectance, determined orthogonal to a polished surface, is expressed as a percentage of the incident light. It may be measured in air ($\%R_a$, typical of Russian data) or using oil-immersion objectives ($\%R_o$, typical in the West).

The first step for determining vitrinite reflectance is to identify vitrinite in general and the 'right type' of vitrinite (termed telocollinite) in particular (Figure 20A, inset). If all organic particles are measured, the low reflecting liptinite (L) may be differentiated from vitrinites (V) and the high-reflecting inertinites (I) (Figure 20B, upper histogram). This is rarely undertaken. In practice only particles believed

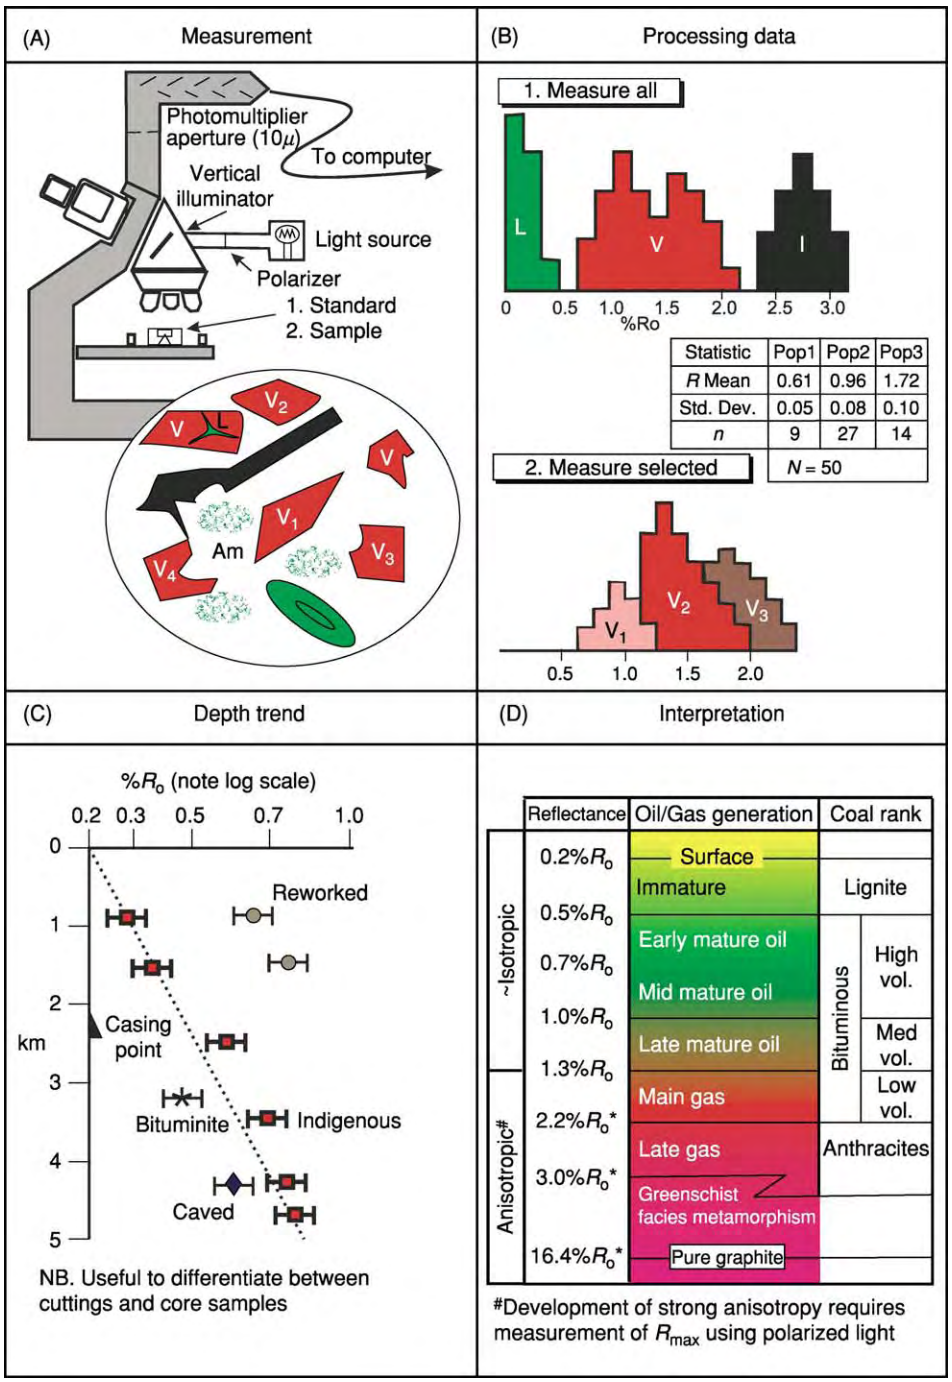

Figure 20 The measurement and interpretation of vitrinite reflectance for determining the maturity of sedimentary rocks in general and oil and gas source rocks in particular.

by the petrographer to be vitrinite are measured (Figure 20B, lower histogram): typically between 20 and 50 particles of vitrinite are measured, and an arithmetic mean value calculated. If multiple populations of vitrinite are recognized, then individual mean values are calculated for each population (Figure 20B, inset table).

If linearly polarized light is used (Figure 20A, see 'polarizer'), rotating the microscope stage and hence the sample with produce a maximum ($\%R_{o,\,max}$) and a minimum ($\%R_{o,min}$) if the material is optically anisotropic. As a result of maturing under overburden pressure, vitrinite develops bedding-parallel anisotropy at the late oil and early gas

generation levels ($\sim 1.0\%R_o$). If the vitrinite is anisotropic and maximum and minimum reflectances are determined, then the mean of the maximum values may be reported ($\%R_{o,\ \text{mean-max}}$). Theoretically the maximum $\%R_{o,\ \text{max}}$ is the most significant indicator of maturity.

The interpretation of the mean vitrinite reflectance values is normally undertaken by plotting $\%R_o$ on a log-scale against sample depth (Figure 20C), where anomalies may be recognized as plotting away from the linear trend. The interpretation then uses the industry-standard relationship with both oil and gas generation windows and coal rank (Figure 20D). Discontinuities in the maturity trend may be seen at unconformities (where the amount of uplift may be estimated from the offset), and excursions may relate to intrusions or hydrothermal flow. As well as defining the maturity of the sampled section, the reflectance trend can be projected to predict—in the absence of major unconformities—maturity levels ahead of the drilling bit.

In addition to vitrinite reflectance two other maturity parameters are commonly reported, Rock-Eval T_{max} (Figure 15), and kerogen or spore colour estimated on TAI (1–5) and SCI (1–10) scales, respectively. Acronyms are defined and equivalences detailed for oil and gas generation in Table 1 and Table 2, respectively. Although the T_{max} values are often available in large numbers, in a single well they often show substantial scatter with respect to depth. In contrast, fewer visual estimates of kerogen colour are determined, but they often produce a better maturity trend with depth. Spore colour estimates are particularly reliable since reworked or caved spores and spores introduced with drilling mud or other contamination can be readily identified as being out of stratigraphic sequence.

Finally the maturity involved in a petroleum system will normally be interpreted in the context of basin modelling and a burial history plot (Figure 21). The burial history plot (time and hence stratigraphy versus depth) traces the burial depth (and temperature) for each modelled strata (black lines) from deposition to the present day, including periods of uplift reflecting erosion at the palaeosurface. Compaction is modelled by various methods as the sediments are progressively buried, and the temperature grid (red lines) calculated from geothermal gradients or mantle heat flow. The heat flow calculation requires the knowledge of the thermal conductivity of each sediment unit—a function of mineralogy and porosity (compaction):

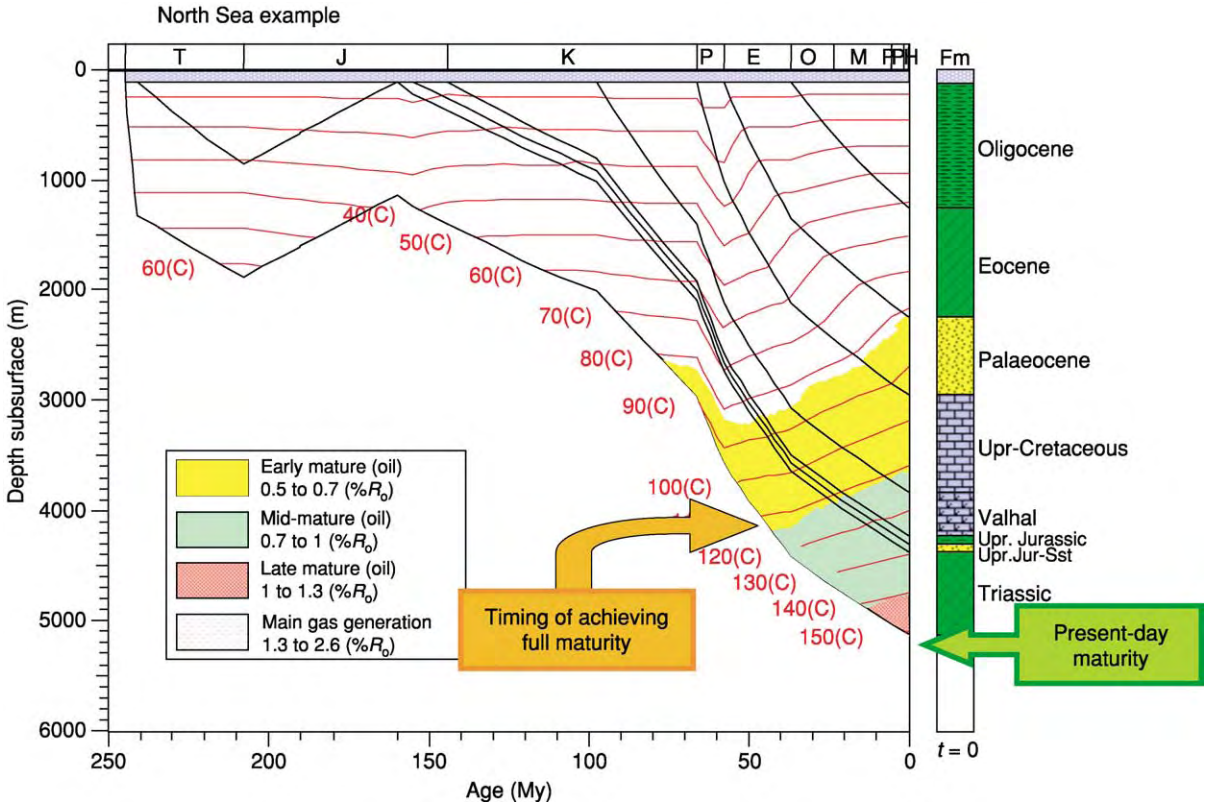

Figure 21 Burial history model showing present day and palaeotemperature and early , mid , and late mature oil windows defined by vitrinite reflectance.

$$\text{Heat flow}(\text{mW m}^{-2}) = \text{Geothermal gradient}\ (^{\circ}\text{C km}^{-1}) \times \text{Thermal conductivity}\ (\text{W m}^{-1}\,^{\circ}\text{C}^{-1})$$

The calibration step then minimizes the difference between measured and modelled temperature (by adjusting heat flow) and maturity parameters as given in Table 1 (by adjusting uplift, etc.). From knowledge of the temperature history for each stratum, the kinetics of decomposition of the kerogens (i.e., the generation of oil and gas) are modelled using the Arrhenius equation. Once calibrated, the model is used to predict the amount, composition, and timing of hydrocarbon generated as discussed below.

Generation and Expulsion

The process of generation describes the conversion of kerogen to petroleum (oil and gas):

$$\text{Kerogen} \xrightarrow{TR} \text{oil} + \text{gas} + \text{residue}$$

Generation, as opposed to maturation, is measured in terms of the extent of kerogen conversion (transformation ratio, TR) and is used to define the oil and gas windows (shown as yellow, green, and red areas in Figure 21).

The generation process can be monitored by laboratory measurement of the volumes (or masses) of generated oil or gas extracted from source rocks (Figure 22), or liberated during pyrolysis (Figure 23). Although the former is constructed from solvent extraction of the materials within source rocks as a fraction of the TOC (units of milligrams of extract per gram of TOC), the latter is reported as the Rock-Eval pyrolysis production index [$\text{PI} = S_1/(S_1 + S_2)$]. The PI is the ratio of the free hydrocarbon (S_1, kg t^{-1}) as a function of the remaining pyrolysate (S_2, kg t^{-1}). In both cases, the onset of generation (early generation) is indicated by an increase in yield. While the early generation phase starts the build-up of petroleum in the source rock, the continuation of the process saturates the source rock, leading to expulsion and eventually the cracking of oil to gas.

Assuming a typical geological heating rate (e.g., 1°C My^{-1}), the following maturity zones can be defined with respect to oil generation, expulsion, and cracking from Type II oil-prone kerogens:

Immature, <80°C (<175°F): No significant oil generation in the source rock: biogenic methane can be generated in recent and shallowly buried sediments.

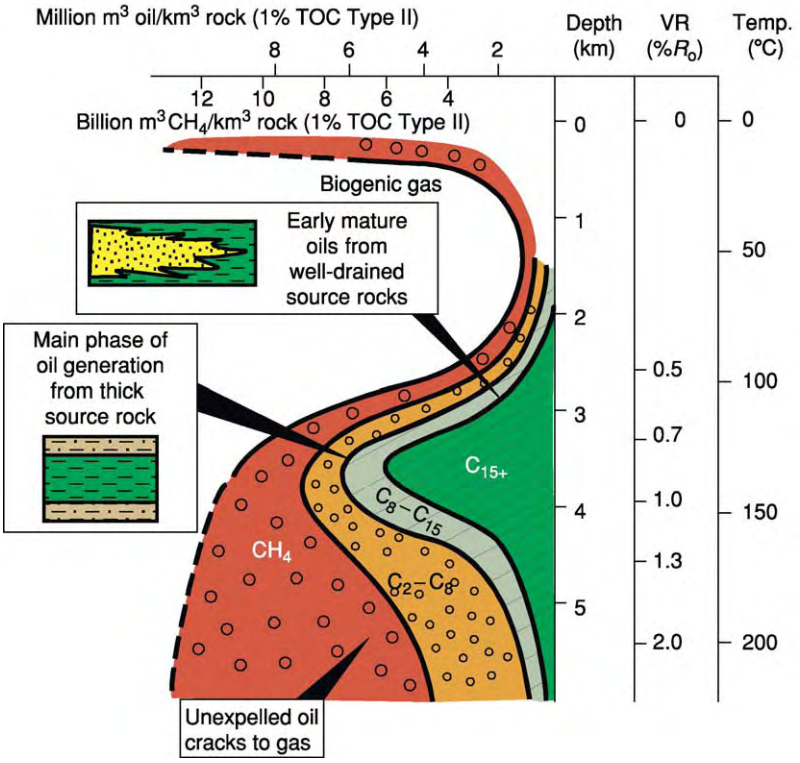

Figure 22 Illustration of generation based on a summation of methane, gas gasoline (C_2 C_8), light oil (C_8 C_{15}), and $C_{15}+$ fractions measured in marine source rocks containing 1% TOC of Type II kerogen at different levels of maturity.

Early mature, 80–115°C (175–240°F): Oil starts to generate in and saturate the source rock, hydrocarbons only being expelled in situations promoting highly efficient primary migration (e.g., where fault scarp fan sands, turbidites, or deltaic sands interdigitate with a source rock claystone or coals, or with fractured cherts and carbonates).

Mid-mature, 115–145°C (240–295°F): This is the main phase of oil generation and expulsion. Oil is expelled from 'massive' source rock units with efficiencies eventually in the range 60–80%.

Late mature, 145–160°C (295–330°F): Waning generation associated with cracking of unexpelled oil to give progressively lighter oils and condensate. Continued generation/expulsion phase particularly in poorly drained source rocks.

Post-mature, >165°C (>330°F): No remaining oil generative capacity exists in the source rock kerogen, and unexpelled or reservoired oil is cracking down to condensate and wet gas.

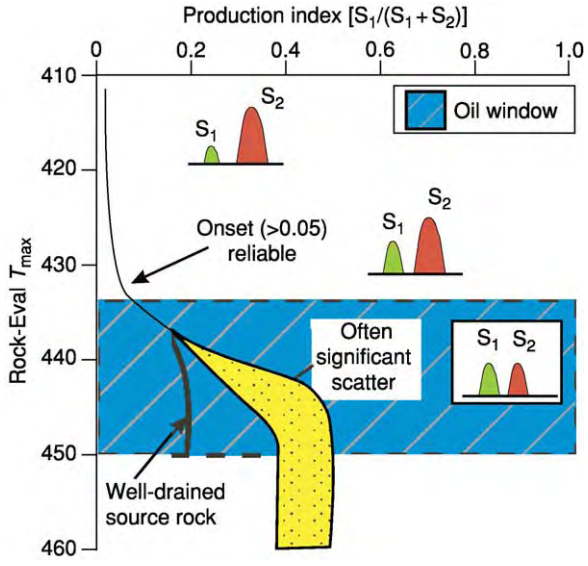

Figure 23 Oil generation as indicated by the Rock Eval production index (PI) where the maturity trend depends on both generation and expulsion (retention).

The temperatures given above relate to corrected wire-line log temperatures and Tertiary effective burial, as in the North Sea. Studies related to DST temperatures quote higher temperatures (up to 12°C higher) for these boundaries, while absence of temperature correction can produce substantially lower temperature boundaries. Lower temperature (e.g., 10°C lower overall) may be expected where a Mesozoic burial event is the controlling factor, while higher temperatures (up to 25°C higher) are reported where rapid Neogene–Quaternary burial controls generation.

Both extract yields and production index discussed above are measured parameters. The theoretical and hence modellable measure of kerogen degradation is the transformation ratio on a scale of $0 \rightarrow 1$:

$$\text{TR} = \text{Generated petroleum} / \text{Original petroleum potential}$$

where:

$$\text{Generated petroleum} = \text{Original petroleum potential} - \text{Residual petroleum potential}$$

The original petroleum potential is determined from immature source rocks of the same organofacies, whereas the residual petroleum potential is determined from the source rocks as it is buried through the oil and gas window. The equivalence of the transformation ratio as a measure of generation to the maturity parameters discussed in the previous section (Tables 1 and 2) is given in Table 3 for oil generation from Type II kerogen and Table 4 for gas generation from Type III kerogen.

Generation is a kinetically controlled process, being a function of the effects of both temperature and time on the breakage of chemical bonds in the kerogen present in the source rock. It can be modelled using simple reactions or networks of competing or sequential reactions, expressed in terms of the Arrhenius equation. The Arrhenius equation effectively expresses the ease of degradation of the kerogen to petroleum as a distribution of chemical bond strengths reflecting the C–C, C–H, C–O–C, C–S–C, and C–N–S bonds holding the kerogen network

Table 3 The generation defined oil window approximately related to some common maturity parameters

Parameters (oil & gas)	*Temperature (°C)*	*Transformation ratio[a] (0 1)*	*Vitrinite reflectance (%)*	*Spore colour index (1 10)*	*Rock Eval T_{max}(°C)*

Mid mature	115 145	0.15 0.65	0.7 1.0	5.0 7.0	442 455
Late mature	145 165	0.65 0.95	1.0 1.3	7.0 9.0	455 465
Post mature	>165	>0.95	>1.3	>9.0	>465

[a]Transformation ratio of Type II kerogen (LLNL).

together. Each of these chemical bonds has a unique strength (activation energy), depending on the adjacent atoms and functional groups, together with stereochemistry. Using the information shown in a burial history plot (Figure 21) to solve the Arrhenius equation, the extent of kerogen degradation can be modelled.

The understanding of generation in both space and time is at the centre of the use of the petroleum system concept to explore for oil and gas, and this requires the use of computer calculation and modelling. The calculation of a theoretical transformation ratio using the Arrhenius equation can be undertaken using industry standard kinetics and basin modelling software, and can be used to calculate generation as a function of depth (Figure 24) and geological time (Figure 25).

The generation versus depth plot (Figure 24) is a simplification in that it assumes that all units within the modelled section contain the same kerogen type

Table 4 The generation defined gas window approximately related to some common maturity parameters

[a]Transformation ratio of Type III kerogen (LLNL).

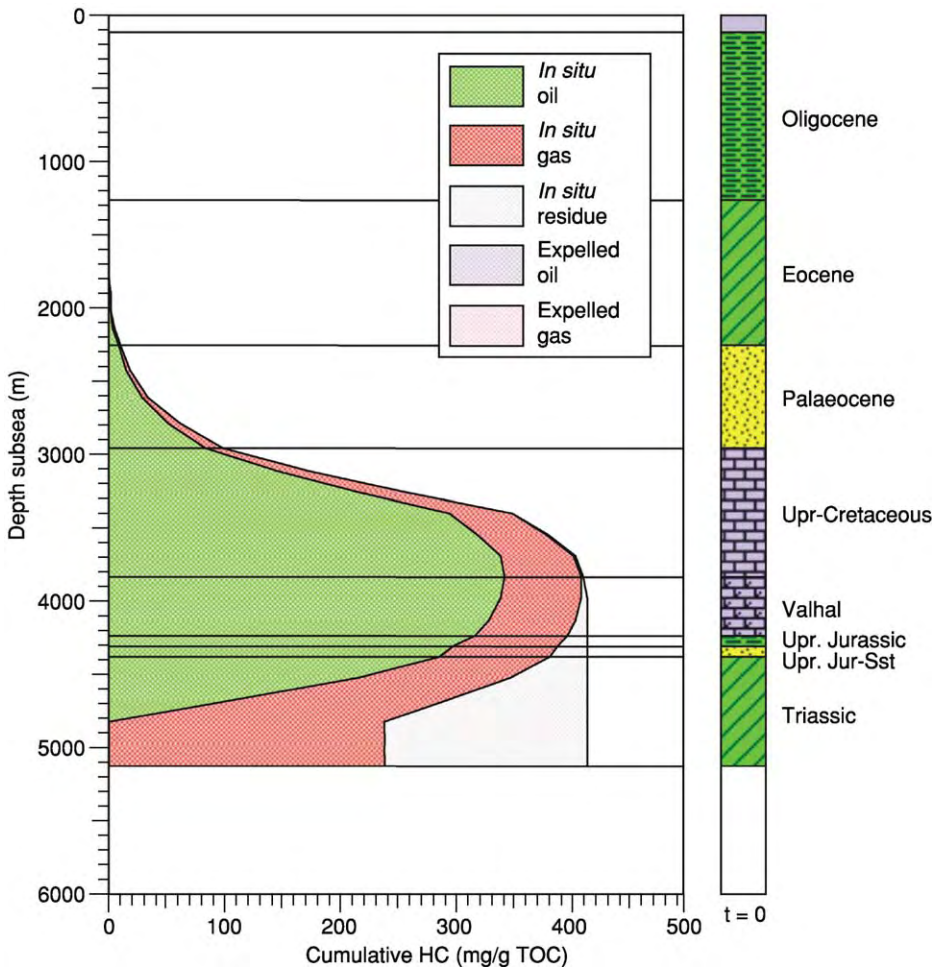

Figure 24 Computer modelled depth trend for the potential generation of oil and gas, assuming all rock units contain a common kerogen type (compare with Figure 22 based on measured data).

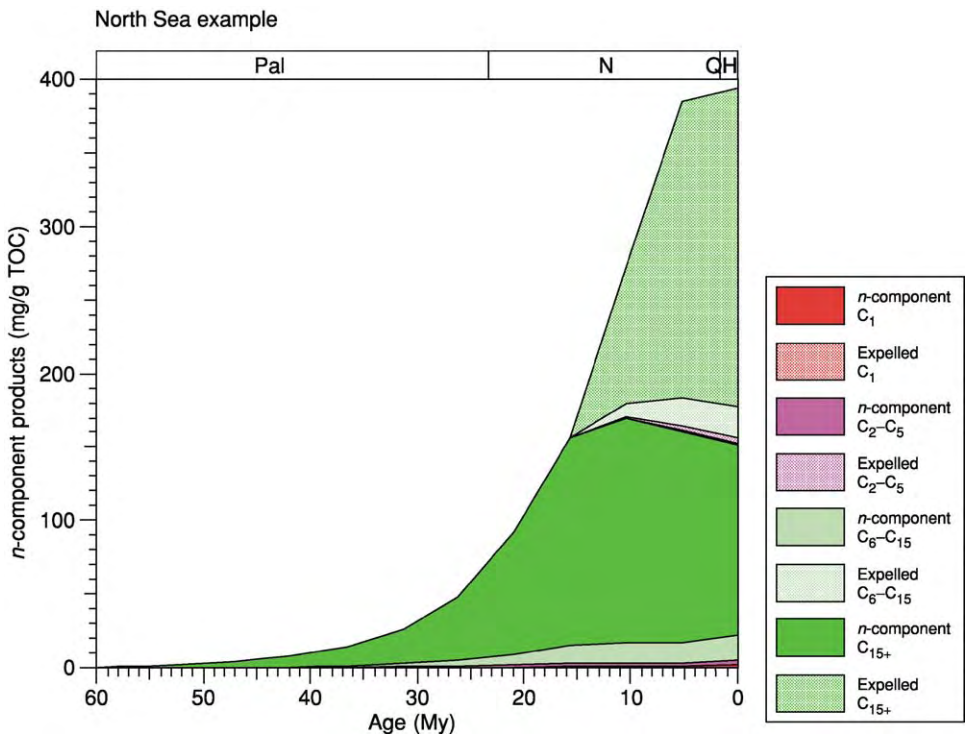

Figure 25 Computer modelled generation and expulsion of oil and gas through time from a single source rock unit containing kerogen.

(unlikely). In this case the kerogen is modelled to be broken down to oil and then oil potentially cracked to gas in a two-step procedure:

$$\text{Kerogen} \rightarrow \text{Oil} + \text{Primary gas}$$

$$\text{Oil} \rightarrow \text{Secondary gas}$$

Considering generation in terms of geological time, a single source rock unit will progressively generate a range of products, grouped somewhat arbitrarily as methane plus wet gas, light oil, and main oil ranges of molecules in Figure 25. The subdivision of oil into these molecular ranges, though subjective, is useful for estimating compositional risk in oil exploration.

In the source rock, these molecules form a single petroleum phase (monophasic mix), which can be modelled as being expelled from the source rock once the pore space in the source rock is saturated. Expulsion is poorly understood in terms of process, but well understood in terms of efficiency. Possible mechanisms for petroleum expulsion include movement:

1. From high to low pressure potential—with pressure also causing rock fracturing;
2. From high to low concentrations (diffusion);
3. Under capillary forces induced at mineral pore throats;
4. Under capillary forces through a continuous kerogen 'wick'; and
5. In aqueous solution during decompaction and clay dehydration.

A combination of these mechanisms possibly contributes to expulsion from the source rock, the relative contributions being the basis for the current debate. The favoured view envisages the dominant process as being based on pressure, where compaction coupled with the generation of hydrocarbon fluids from solid kerogen and temperature-induced expansion of pore fluids produces overpressure in the source rock. The overpressure eventually fractures the source rock, sporadically releasing the fluids into the migration pathway.

The expelled hydrocarbon yields shown in Figure 25 are calculated from the total generated less that required to saturate (a fraction of) the porosity of the source rock. The modelled porosity can be calculated using one of a number of possible compaction equations.

A quantitative understanding of expulsion efficiency is essential for successful prospect evaluation. Expulsion efficiency (EE) is defined in mass units as:

$$\text{EE} = \text{Petroleum expelled}/\text{Petroleum generated}$$

where

$$\text{Petroleum expelled} = \text{Petroleum generated} - \text{Petroleum retained}$$

and

$$\text{Petroleum generated} = \text{Initial potential} \times \text{Transformation ratio}$$

Within a basin such as the North Sea, which contains a uniform oil-prone source rock organofacies in the Upper Jurassic Kimmeridge Clay Formation, the initial potential is determined by analysis of immature source rock samples from the rim of the basin. The retained (i.e., generated but not expelled) petroleum can be determined by solvent extraction or pyrolysis (S_1 peak—see Figure 15). The transformation ratio can be determined from modelling, equated with vitrinite reflectance or pyrolysis T_{max} (e.g., Table 3) or from ratios of the initial to measured hydrogen index (e.g. initial HI = 600, present HI = 300, therefore TR = 0.5). Examples of the range of expulsion efficiencies calculated from North Sea source rock data are shown in Figure 26, where values rise from about 20% at 3.0–3.5 km to about 50% at 4.0 km with the deepest samples exhibiting values in the 75–95% range.

Considering dry gas (methane) generation in, and expulsion from seam coals requires an understanding of additional factors, in particular the very high

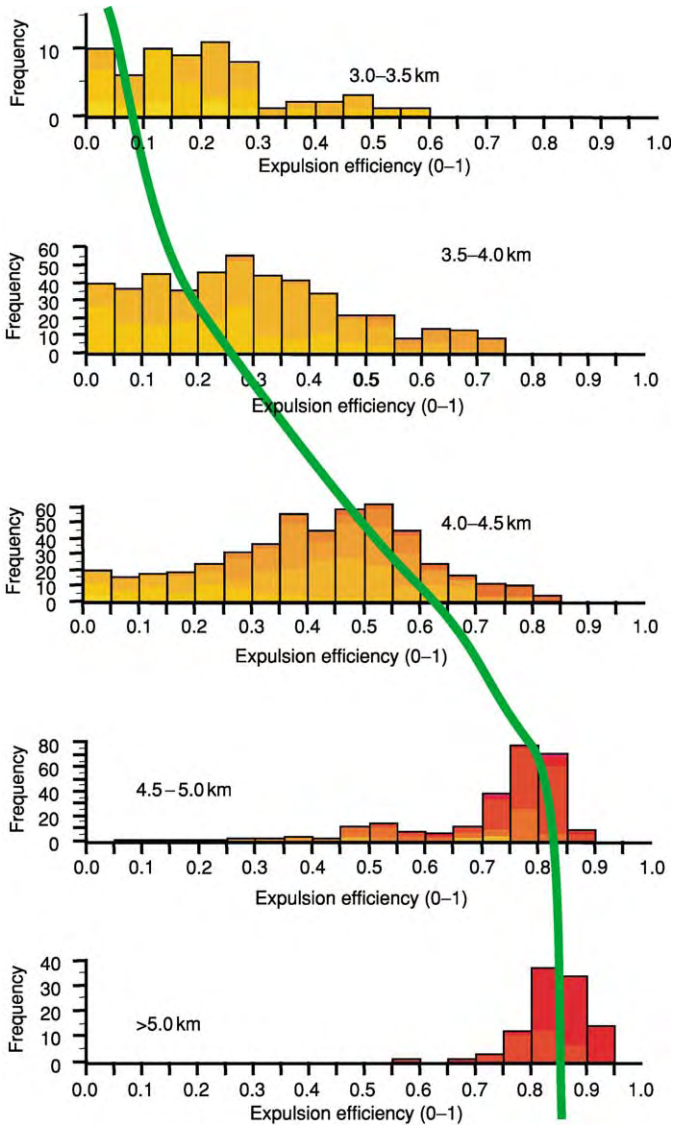

Figure 26 Expulsion efficiency as a function of depth in the North Sea based on solvent extraction (green trend line, from Larter (1988)) and Rock Eval pyrolysis data (histograms).

surface area (macro-, meso-, and microporosity) of coal in general and the vitrinite maceral in particular. The developing understanding seems to suggest a three-step process:

1. Generation of the methane from humic kerogen;
2. Adsorption of the methane on the abundant porosity of vitrinite; and
3. Expulsion of the methane at higher maturity as the porosity collapses.

In all cases the expelled monophasic petroleum leaves the source rock, but will only form commercial accumulations if migration provides a focus towards a trap. The processes controlling migration are discussed in the next section.

Migration

How petroleum travels long distances in the subsurface is a matter for speculation: facts are hard to come by.

Certainly oil being more buoyant than water, and gas being more buoyant than both, there is a natural tendency for the upward movement of separate gas and oil phases in a water-saturated permeable sediment. The fluids are essentially separating out within the porous media of sedimentary rocks. Attempting to understand the processes contributing to migration requires some knowledge over a large range of scales of the properties of the solid rock and the fluid phases flowing therein (Figure 27). The scales are not only

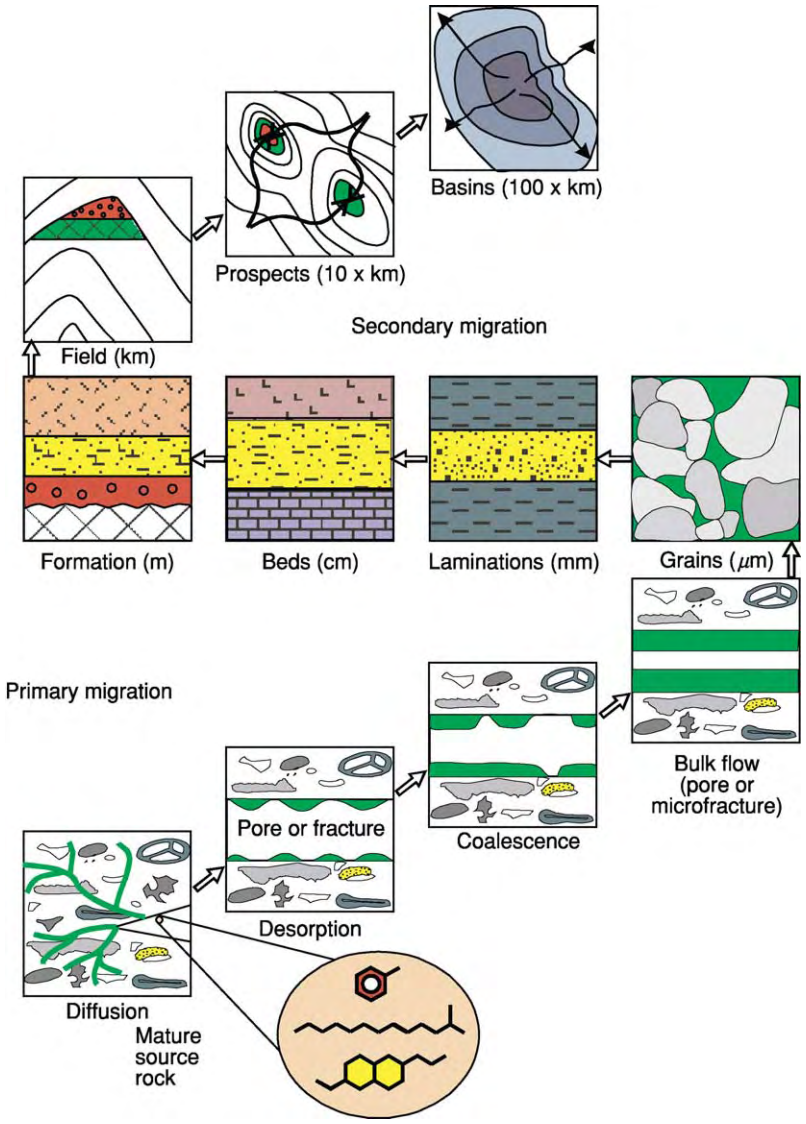

Figure 27 Our understanding of how oil and gas move through water saturated rock requires a study of flux over a large range of scales. Modified after Mann *et al.* (1991).

those from sedimentary grains to basins, but also from oil molecules to accumulations containing billions of barrels of oil.

At deposition, sedimentary rock is initially porous, but compaction and diagenesis rapidly reduces the porosity. Once sediments are indurated (compacted and cemented), fracture porosity may take over as the dominant conduit allowing fluid flow. Thus fluids can move through both intergranular or fracture porosity.

Once expelled into a more porous conduit such as a sandstone bed, a fault plane, or diagenetically altered carbonate, petroleum will start to move upwards under the force of buoyancy (Figure 28, inset). The buoyancy derives from the lower density of oil (typically 0.86 g cc $^{-1}$ or 36°API) relative to formation water (typically 1.03 g cc $^{-1}$), as in the kitchen where fat rises to the surface of milk. Once within the migration conduit the petroleum will rise to the roof of the rock layer and if the layers are tilted, the 'river of oil' will move up-dip and along zones of highest permeability from high point to high point. When seen at outcrop, this produces a braided network of oil-saturated rock, running under the top-seal of the migration conduit (Figure 28).

Migration can also be influenced by any water flux sharing the same migration route (hydrodynamic control) or by pore pressure gradients associated with the progressive increase in pore throat diameters (permeability control). The pore throat diameters together with wettability essentially control the permeability of the rock with respect to oil or gas.

Migration distances can vary widely. In situations where mature source rock is interbedded with reservoir sands the migration path may only be a number of metres. Large accumulations, however, demand the gathering of oil and gas over a wide area, and hence long-distance migration pathways. In the North Sea migration distances are mainly in the range 10–20 km with 65 km as a maximum. In large basins such as the West Canada Basin and West Siberian Basin migration pathways of many hundreds of kilometres have been proposed.

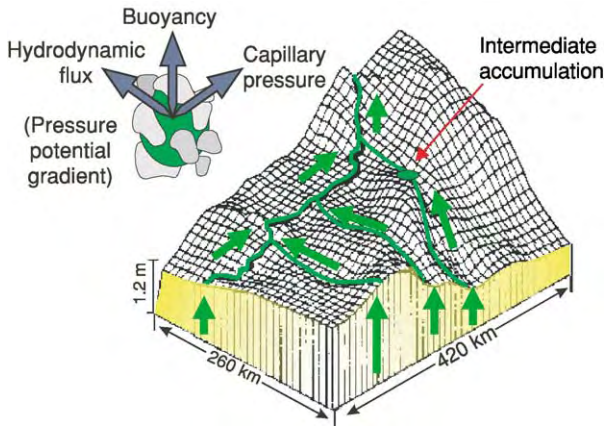

Figure 28 Migration occurs as 'rivers of oil' running up dip mainly under the influence of density driven buoyancy, though hydrodynamic flux and capillary pressure may exert ancillary controls. Modified after IES (1985).

As the expelled monophasic petroleum moves upwards under buoyancy, the pressure and temperature regime will change and the bubble-point or dew-point may be reached (Figure 29). Separation into a liquid (oil) phase and a gas phase will result, and these may migrate separately due to differential buoyancy and relative permeabilities.

Studying a petroleum system demands an understanding of the efficiency of the migration process. This is probably the least well-quantified element of a petroleum system, and is normally determined by difference:

$$\text{Accumulation} = \text{Generated} \times \text{Expulsion efficiency} \times \text{Migration efficiency}$$

Therefore

$$\text{Migration efficiency} = \text{Accumulated}/(\text{Generated} \times \text{Expulsion efficiency})$$

The above equation can be used to determine the migration efficiency if the size of an accumulation, the amount generated, and expulsion efficiency are all known. Calibrated against known accumulations, the migration efficiency can then be used to predict the petroleum charge to undrilled prospects. Migration efficiencies are not widely discussed or reported, but values seem to fall in the range of 50% (maximum) to 0 (i.e., no oil or gas reached the drilled prospect). It may be helpful to consider the inefficiency of migration as the residual oil left behind along the migration path. The recognition that oil migration is a focussed process affecting only a small percentage of the rock between kitchen and accumulation fits well with the calculated migration efficiencies.

Accumulation and Survival

Once charged to the trap, the survival of the petroleum depends on a good seal and avoiding the effects of various oil alteration processes. An approach to use bulk, molecular, and isotopic characterization of oil and gas to identify such reservoir processes is shown in Figure 30. As emphasized in the figure, the analytical approach to differentiating between oil alteration processes requires knowledge of the geometry and history of the trap.

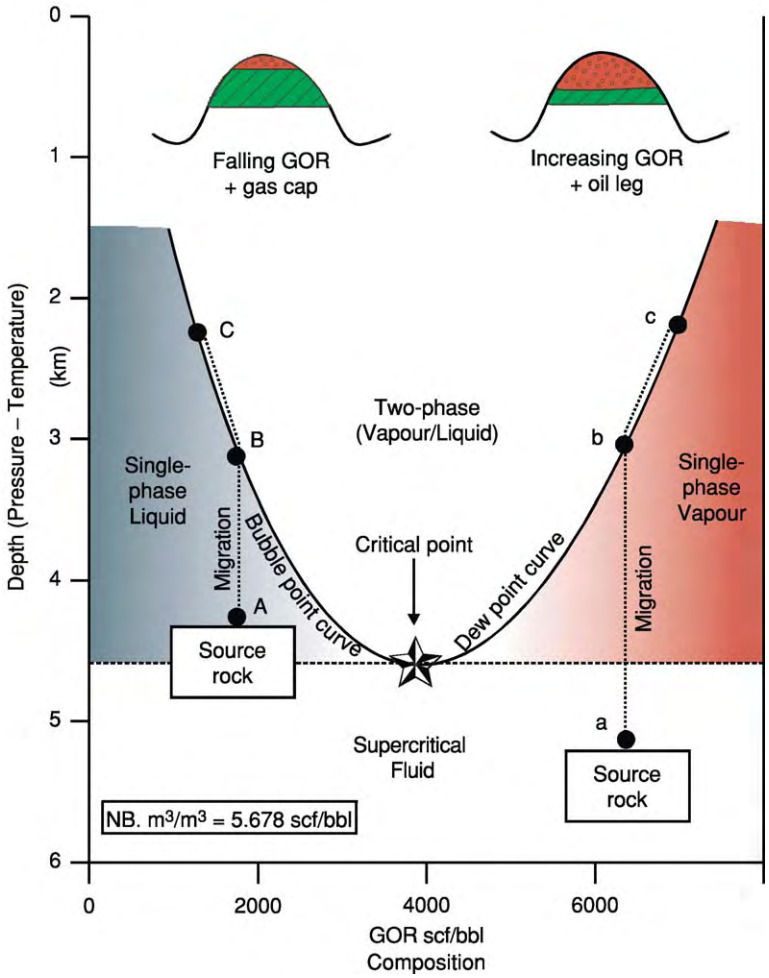

Figure 29 Phase separation of upward migrating petroleum depending on the initial gas/oil ratio (GOR) and reductions in temperature and pressure.

In terms of a seal, efficiencies range from near perfect in the case of intact salt (Halite) to 'highly leaky' in the case of thin and poorly compacted mudstone containing a significant portion silt and fine sand. Diagenetic cement can greatly enhance the sealing efficiency of more porous strata, even when relatively shallow. In essence the efficiency of a seal must be measured against the charge rate if generation continues, or the time since charge ceased if in the past. A more specific and dramatic way of breaching the seal of the trap is faulting.

For structural traps, the prediction of whether a fault is a seal or a migration conduit is complex, the controlling factors being only poorly understood at present. Some unusual seals comprise a hydrodynamic trap, where a counterflow of formation water opposes the buoyancy of the oil, and shallow seals in the Arctic involving the permafrost layer or gas hydrate (*see* **Petroleum Geology:** Gas Hydrates).

The concept of the 'half-life' of an oil or gas field has been proposed, this being defined as the time (millions of years) required for half of the charge volume to escape through the seal. Gas sealed by mudstone has a half-life in the range 30–60 My, and oil about an order of magnitude greater. A continuous and stable halite seal can be considered near perfect with an infinite half-life.

A number of intrareservoir processes are listed towards the base of Figure 30, and of these the most common are bacterial degradation and thermal cracking. These occur when the reservoir is unusually cool (<65°C) and unusually hot (>165°C), respectively.

Of the listed intrareservoir processes, bacterial degradation is arguably the most destructive. In essence it occurs when petroleum accumulates in a reservoir that is at a temperature allowing bacterial degradation of the oil or gas. As reported, the maximum

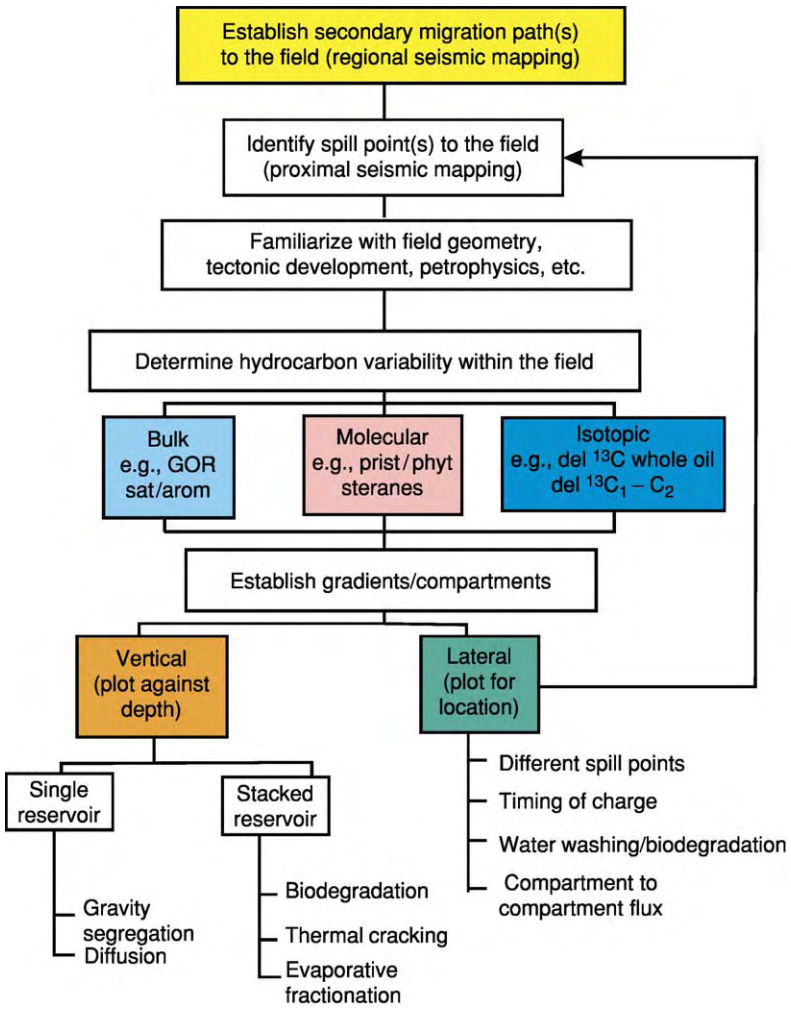

Figure 30 Steps required to identify and interpret vertical and lateral compositional gradients resulting from intrareservoir processes.

temperature boundary is in the range 65–75°C, the range reflecting different oil chemistries, formation waters, and hence active bacterial communities, together with different methods of measuring reservoir temperatures. In nature, viable bacteria will be preserved if the reservoir has never been buried to temperatures hotter than about 90°C. If hotter and then uplifted to a cooler regime, meteoric water influx into the reservoir is required to reintroduce bacteria.

The bacterial alteration of the oil progresses with the selective removal of various families of molecules (Table 5). The sequence of removal is broadly *n*-alkanes > branches alkanes > cyclic alkanes -> aromatics, this reflecting the 'digestibility' of hydrocarbon molecules by the bacteria.

Bacterial degradation of a gas accumulation removes the wet gas components (C_2–C_5) and in particular propane (C_3) with preferential removal of molecules with the ^{12}C isotope. Thus an initial wet gas is reduced to a dry gas accumulation of >95% methane with isotopically heavy residual propane. Bacterial activity is often confirmed by the thin rim of biodegraded heavy oil below the dry gas.

Most reservoirs are cooler than the source rocks from which they were filled. If the petroleum-filled reservoir is buried to higher temperatures, the oil will crack to condensate and gas (Table 6). This process of intrareservoir cracking starts at about 160°C and black oil is normally destroyed by 175°C. This has been termed the base of the oil preservation (as opposed to oil generation) window. An oil trap that has suffered intrareservoir cracking will be recognized as containing gas, with black flecks of pyrobitumen seen occupying some of the remaining porosity:

$$2 \times \text{oil}(CH_2) \rightarrow \text{pyrobitumen}(C) + \text{methane}(CH_4)$$

Table 5 The degree of bacterial degradation of oil on a 1 10 scale based on progressive loss of specific chemical groups

Degree of bacterial degradation	*Loss of named molecules indicates stage of biodegradation*

System Efficiencies

Based on the definition of a petroleum system given at the start of this article a gross system efficiency may be defined as:

$$\text{System efficiency} = \text{Discovered petroleum}/\text{Generated petroleum}$$

Expressed as a percentage, reported system efficiencies fall in the range 0.5 to 30%. This range includes both natural variations attributable to the geology and errors in our understanding thereof. Based on the previous discussion and as illustrated in Figure 3, the simple equation given above can be expanded to give a more complete description of the controls:

$$\text{Discovered petroleum} = (\text{area of field} \times \text{thickness of reservoir} \times \text{porosity}) - \text{losses}$$

$$\text{Generated petroleum} = \text{source rock yield} \times \text{thickness} \times \text{area} \times \text{transformation ratio}$$

In addition to technical uncertainty in the above measurements, the reported values for 'discovered petroleum' may also be influenced by commercial and political considerations.

Uncertainty in the 'generated petroleum' value will include variations in total organic carbon, kerogen type, and its variation with source rock thickness: the transformation ratios (Table 3) for discrete areas of mature source rock will be determined from measured and modelled maturity data. These areas will be measured by planimeter on basin-scale mapping derived from the interpretation of a regional seismic grid. If the generated and discovered petroleum values are precisely defined, then the efficiency of the petroleum system is essentially the expulsion efficiency multiplied by the migration efficiency.

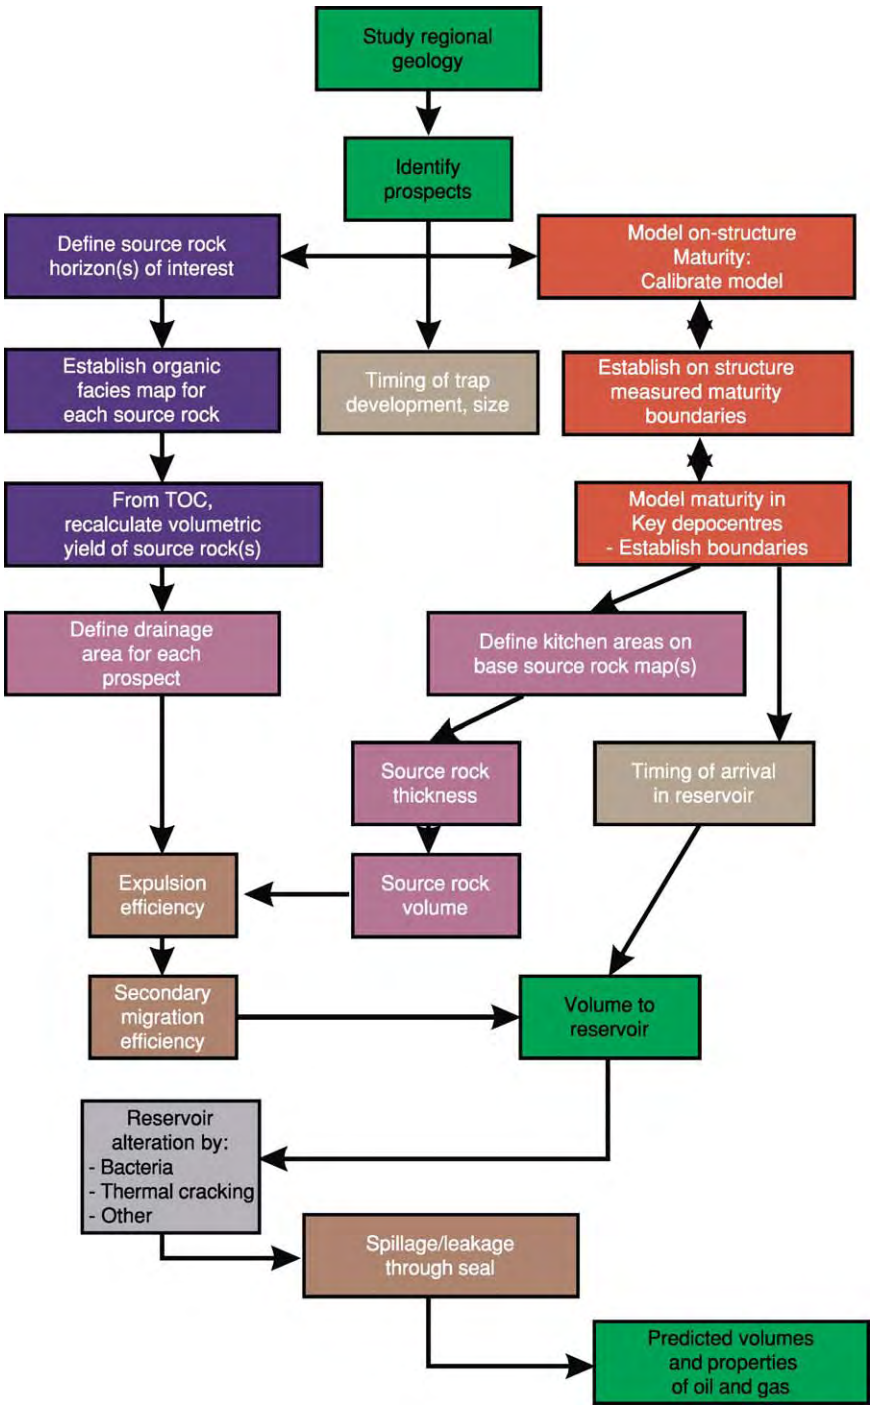

Figure 31 A summary of the steps leading to the determination of the efficiency of a petroleum system.

A possible workflow tying all these factors together is given in Figure 31 by way of a summary.

Exploration

J R Parker, Formerly Shell EP International, London, UK

Introduction

All commercial accumulations of hydrocarbons are found within, or in close proximity to, sedimentary basins, but not all sedimentary basins contain oil or gas. The presence of large quantities of hydrocarbons in a sedimentary basin requires (Figure 1)

- a source rock rich in organic carbon,
- sufficient heat over long periods of time to convert this organic carbon into hydrocarbons,
- migration pathways that enable the hydrocarbons to migrate away from the source rock,
- a suitable reservoir rock that is sufficiently porous for the hydrocarbons to accumulate and sufficiently permeable to allow the hydrocarbons to be produced at economic rates,
- an effective seal to prevent leakage from this reservoir, and
- a closed structure (a geometrical disposition of the reservoir and seal) to prevent further migration of the hydrocarbons.

Petroleum exploration depends primarily on the scientific understanding of these factors (*see* **Petroleum Geology:** Overview). However, exploration remains a risky business with an uncertain outcome, both in terms of the degree of confidence of realizing a successful outcome (probability of success) and in terms of the amount of hydrocarbons to be found in the case of success (success volume).

Thus, to justify an exploration programme, the expected benefits must exceed the expected costs. The principal benefit is the value of any oil or gas found, while the costs are those incurred in carrying out the programme. Hence, it is an important task of the petroleum geologist to develop quantitative estimates of the probability of success and of the likely recoverable volumes that may be present. In many countries the petroleum laws provide for governments and exploration companies to negotiate contracts that, typically, oblige a company to carry out an exploration programme of agreed scope and cost and entitle it to participate in the development and production of any oil and gas discovered in return for an agreed share of the rewards. Thus, even before exploration starts, a careful assessment of the risk and possible benefits is required.

The basis of this assessment is the so-called expected-monetary-value (EMV) calculation, in which the risk-weighted value of the potential reward should exceed (or at least equal) the risk-weighted cost of the potential loss, as risk without benefit is unacceptable:

$$\mathrm{NPV} \times \mathrm{POS} > \mathrm{AEC} \times (1 - \mathrm{POS})$$

where NPV is the net present value (monetary return in the case of a successful project), POS is the probability of success (chance that the project will be successful), AEC is the abortive exploration cost (the lost investment in the case of failure), and (1 – POS) is the probability of failure (complement of the probability of success).

An exploration programme is, therefore, a carefully planned series of activities aimed at discovering whether oil and gas fields are present in a particular area and, if present, whether they are sufficiently large and productive to be economical. Based on an analysis of the geological information, often involving sophisticated computer modelling of geological processes and an analysis of analogous information from petroleum provinces around the world, the probabilities of finding reserves of certain magnitudes can be assessed. In a well-defined area with fully appraised discoveries, for instance, there may be a high degree of certainty about the current reserves but little chance of finding major additions. In a speculative venture in a little-known area, on the other hand, the chances of finding any hydrocarbons may be low but there is an outside chance of making a very large discovery. However, even with the most sophisticated analysis, the discovery of any quantity of oil and gas cannot be anticipated with certainty, and petroleum exploration remains a classic example of 'decision-making under uncertainty'.

Exploration Methods

Exploration methods are the techniques employed in the search for oil and gas. Their primary purpose is not directly to find oil and gas but to provide evidence about the geology of the subsurface, the interpretation of which may eventually lead to drilling and the discovery of hydrocarbons.

Geological Analysis

The first stage in any exploration programme is to define a 'play' concept to explain how oil and gas may have accumulated in the basin. A play is defined

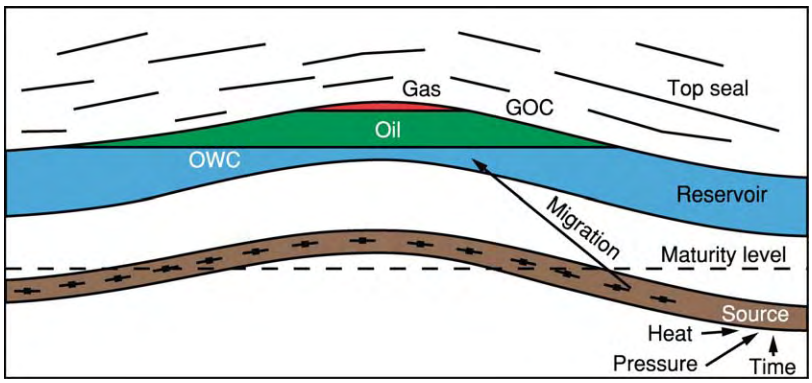

Figure 1 Geological conditions for hydrocarbon accumulation, showing the migration of oil and gas from mature source rock into an initially water filled reservoir. GOC, gas oil contact; OWC, oil water contact. Reproduced with permission of Nautilus Limited.

as a group of prospects (sites of potential hydrocarbon accumulation) and any related fields having common oil or gas sources, migration relationships, reservoir formations, seals, and trap types, thus sharing common elements of geological risk (Figure 2).

The analysis of hydrocarbon plays involves the synthesis and mapping of all the key geological parameters controlling the occurrence of oil and gas, which are principally source, maturation and migration, reservoir, trap, timing, seal, preservation, and recovery (Figure 3).

Geochemical techniques can help to establish the presence of a suitable source rock, while sedimentary geological models can predict the distribution of reservoir and seal rocks. Data are derived from previously drilled wells in the basin (although not necessarily testing an identical play), from traditional field geology (examining surface outcrops within or on the margins of the basin), and from remote sensing (Figure 4) (which may elucidate the geological structure of the area). For previously unexplored areas lacking in 'hard' data, concepts can be tested against analogous basins elsewhere in the world. Play analysis helps to estimate the risks and potential volumes of prospects, as the absence of any one of the factors listed above invariably means that there will be no hydrocarbons in the prospect; a poor development of source rock will mean a limited generation of hydrocarbons, and a poor development of reservoir rock will mean only limited opportunities for entrapment.

Geophysical Analysis

Several geophysical techniques are used to enhance the geological understanding of a basin. Gravimetric (*see* **Analytical Methods:** Gravity) and magnetic surveys (both surface and airborne) (Figure 5) can be used in a reconnaissance mode to delineate the deeper parts of the basin and the major highs before undertaking much more expensive seismic surveys (*see* **Seismic Surveys**). However, seismic surveys are the most important geophysical tool for obtaining a detailed understanding of the subsurface structure, including identifying likely migration paths, inferring the relative timing of trap formation and charge, delineating the geometry and size of potential traps, and even establishing the presence of hydrocarbons themselves.

Seismic surveys involve recording artificially generated shock waves that are reflected or refracted from the different rock strata, and they require a suitable sound source and an appropriate set of detectors. Dynamite has largely been replaced on land by special trucks called vibrators, which have metal plates on their undersides to shake the ground in a controlled manner (Figure 6). At sea, powerful air or water guns are the main energy sources. The reflections are picked up by receivers called geophones on land and hydrophones offshore (Figure 7), which are laid out in such a way as to form directional antennae, termed arrays. Geophones and hydrophones work in a similar way to seismographs, which register earthquakes, but all data are recorded in digital rather than analogue form.

When gathering data in new or little-explored areas, two-dimensional seismic surveys are generally acquired first; with lines spaced as much as 20 km apart, these can cover a great deal of ground at comparatively low cost. If these surveys show interesting structures, then more closely spaced two-dimensional lines can be shot to provide a more detailed picture. However, for an enhanced understanding of the structural and reservoir detail of a prospect, three-dimensional seismic surveys employing a dense grid of lines are commonly used, even in the exploration phase before any wells have been drilled or hydrocarbons discovered. This is

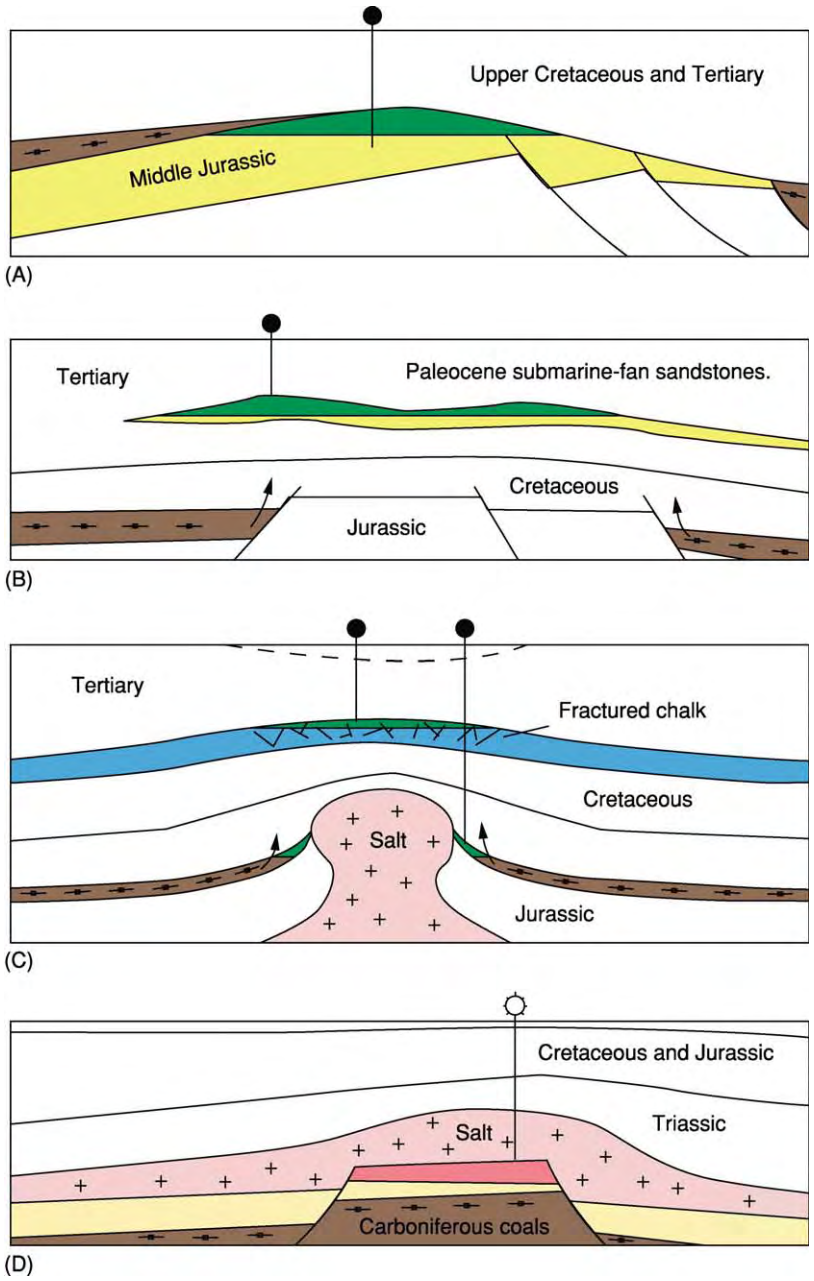

Figure 2 North Sea play types: (A) a truncated tilted fault block, typical of the northern North Sea; (B) a drape or pinchout trap, typical of the central graben; (C) a salt induced structure typical of the central graben; and (D) a horst block capped by salt, typical of the southern North Sea. particularly true in geologically complex areas, where the cost of a three-dimensional survey can be considerably less than the cost of a mislocated well.

A traditional two-dimensional seismic survey is shot along single lines to provide vertical slices through the Earth's crust; from a series of parallel and intersecting lines, the three-dimensional structure of the subsurface can be interpreted (Figure 8). However, the assumption is that the reflections seen on each line originate within the plane of the vertical slice, whereas in reality many of the reflections originate from inclined rock layers that may be hundreds of metres outside the plane of the seismic line; also, the gaps between the lines may hide faults and other geological complexities. These limitations have been overcome by the use of three-dimensional seismic surveys, which employ multiple sound sources and simultaneous recording by lines of detectors laid out in a dense grid to

acquire a true three-dimensional picture (Figure 9). This development has been made possible by an almost exponential increase in computer power over the years coupled with a concomitant decrease in cost, which has enabled the vast amount of data acquired by three-dimensional surveys to be quickly processed, separating true signals from interference and providing a clearer picture by accurately locating all reflections in their true subsurface positions.

Increasing sophistication in both seismic acquisition and seismic processing techniques allows the direct identification of hydrocarbons in the subsurface. Each interface between separate rock layers will reflect some of the sound waves back towards the surface, and the amplitude of this reflection depends on the nature of that interface. For a porous rock, such as a sandstone, the reflectivity will depend in part on the fluid present in the rock pores, and from this it may be possible to identify oil, gas, and water in the subsurface (Figure 10).

An extension of this concept that is being increasingly applied is the so-called four-dimensional or time-lapse seismic survey. A three-dimensional seismic survey is re-acquired at regular intervals (say, every 3–4 years) over a producing field. The changes in the positions of the reflections indicating the positions of the oil–water contact and the gas–oil contact are used

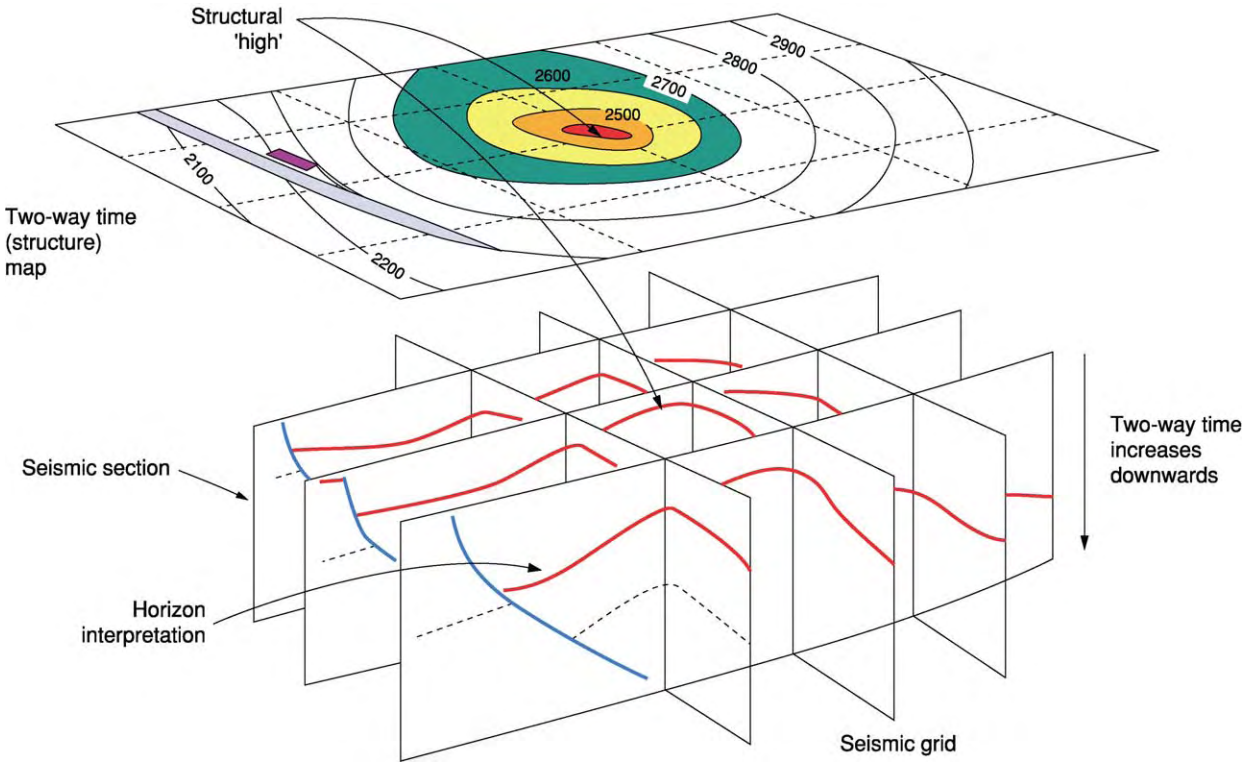

Figure 8 Interpretation of a two dimensional seismic survey. A geological horizon is traced around all the lines of the grid and then plotted in map view. Reproduced with permission of Nautilus Limited.

to monitor the efficiency with which oil and gas are being produced from the field and can identify areas that are not being drained for future infill drilling (Figure 11).

The increase in computer power that has allowed the acquisition and processing of the vast amounts of data resulting from three-dimensional seismic surveys has also revolutionized the interpretation of these data. Computer-based interpretation systems, termed workstations, allow the profiles to be viewed on colour screens and key geological horizons to be identified (Figure 12).

Once they have been identified through the use of appropriate algorithms, these horizons can be automatically 'picked' by the computer by recognizing their 'character' throughout the rest of the dataset. Information from wells and on the regional geological setting can also be integrated. The resulting interpretation can then be viewed and manipulated in a variety of ways: vertical sections can be viewed in any direction; time and horizon slices can be generated that can be horizontal, dipping, or undulating; maps of horizons can be produced; and the frequency and amplitude of the seismic reflectors can be analysed to give clues as to the nature of the lithology and the fluid content of the subsurface layers. The three-dimensional survey can be considered as a cube of data, and computer visualization techniques allow the data to be viewed from any direction and, indeed, to be rotated on screen (Figure 13). The latest development is the use of a so-called immersive 'visionarium' environment, in which observers are surrounded by the data, viewing it in actual three dimensions using special spectacles (Figure 14).

Prospect Appraisal Systems

A number of methods have been developed to attempt to translate complex geological data, derived from the geological and geophysical studies described above, into the set of numbers needed for decision-making. The particular appraisal method used depends on the size of the unit to be assessed (from global to part of a structure) and the amount and type of information available (from sparse regional data to detailed drilling results, or data of a more statistical nature such as the number of wells drilled and the amount of reserves found). The methods can be broadly grouped under three main headings: subjective methods, statistical methods, and deterministic models.

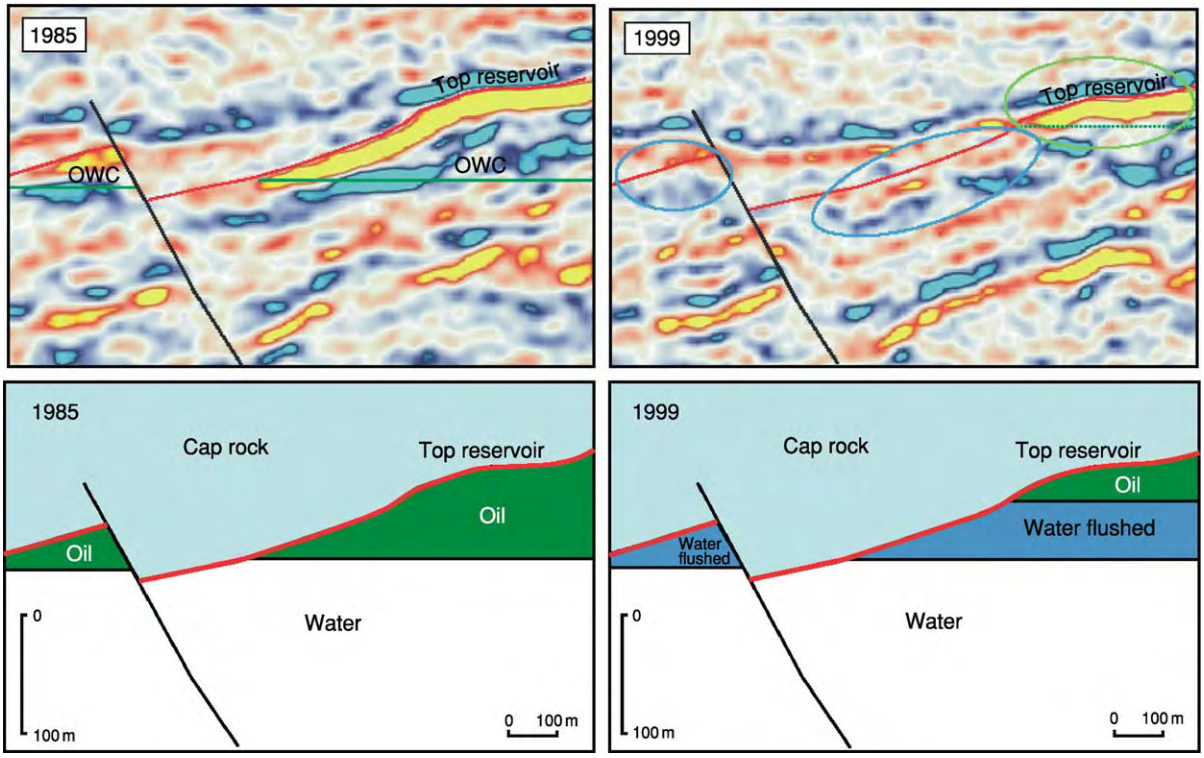

Figure 11 Time lapse (four dimensional) seismic survey over a North Sea field; the changes in amplitude result from a significant depletion of the oil due to extraction. OWC, oil water contact. Reproduced with permission of Millenium Atlas Company Limited.

Subjective Methods

Subjective methods result from the implicit intuitive thought processes of a single individual or group of individuals and can be formidable tools when a substantial body of expertise is available. However, there is the problem of bias: usually people are more certain about the unknown than they can afford to be on the basis of the information available, and some people are consistently pessimistic, while others are optimistic. There is also the problem of consistency of knowledge: local knowledge can override possibly more relevant but less well-known worldwide information.

Statistical Methods

Statistical methods attempt to extrapolate past experience using a variety of statistical techniques. Some depend on the validity of an essentially linear extrapolation, for example a hydrocarbon richness per unit volume of sediments in explored basins, which can then be applied to unexplored basins. Other methods attempt to improve this extrapolation by considering past exploration results, such as the decline of success ratio through time and the decline of field size as a function of exploration effort. In the example shown in Figure 15, the larger fields are discovered first (the so-called 'creaming' effect), but, although the average size of the fields found is decreasing, the number found is still increasing.

One of the best known of such studies is that of M King Hubbert, who in 1956 predicted that US oil production would peak in the early 1970s; this proved to be correct (the so-called 'Hubbert's Peak'; Figure 16).

Disadvantages of these methods are that a certain degree of exploration maturity is required for the necessary historical data to be available, the results may be strictly applicable only to the particular basin or province analysed, and the interrelationships of the variables chosen are not always known and correlations may be fortuitous.

Deterministic Models

Deterministic models attempt to integrate all the relevant geological concepts and research findings on the processes of hydrocarbon generation, migration, accumulation, and retention into a coherent model that will provide quantitative estimates of the hydrocarbon volumes likely to be present and the risks involved. These methods are now widely employed in the industry. The problem is that the information available is usually insufficient for precise estimates of the required variables to be made, and, in such

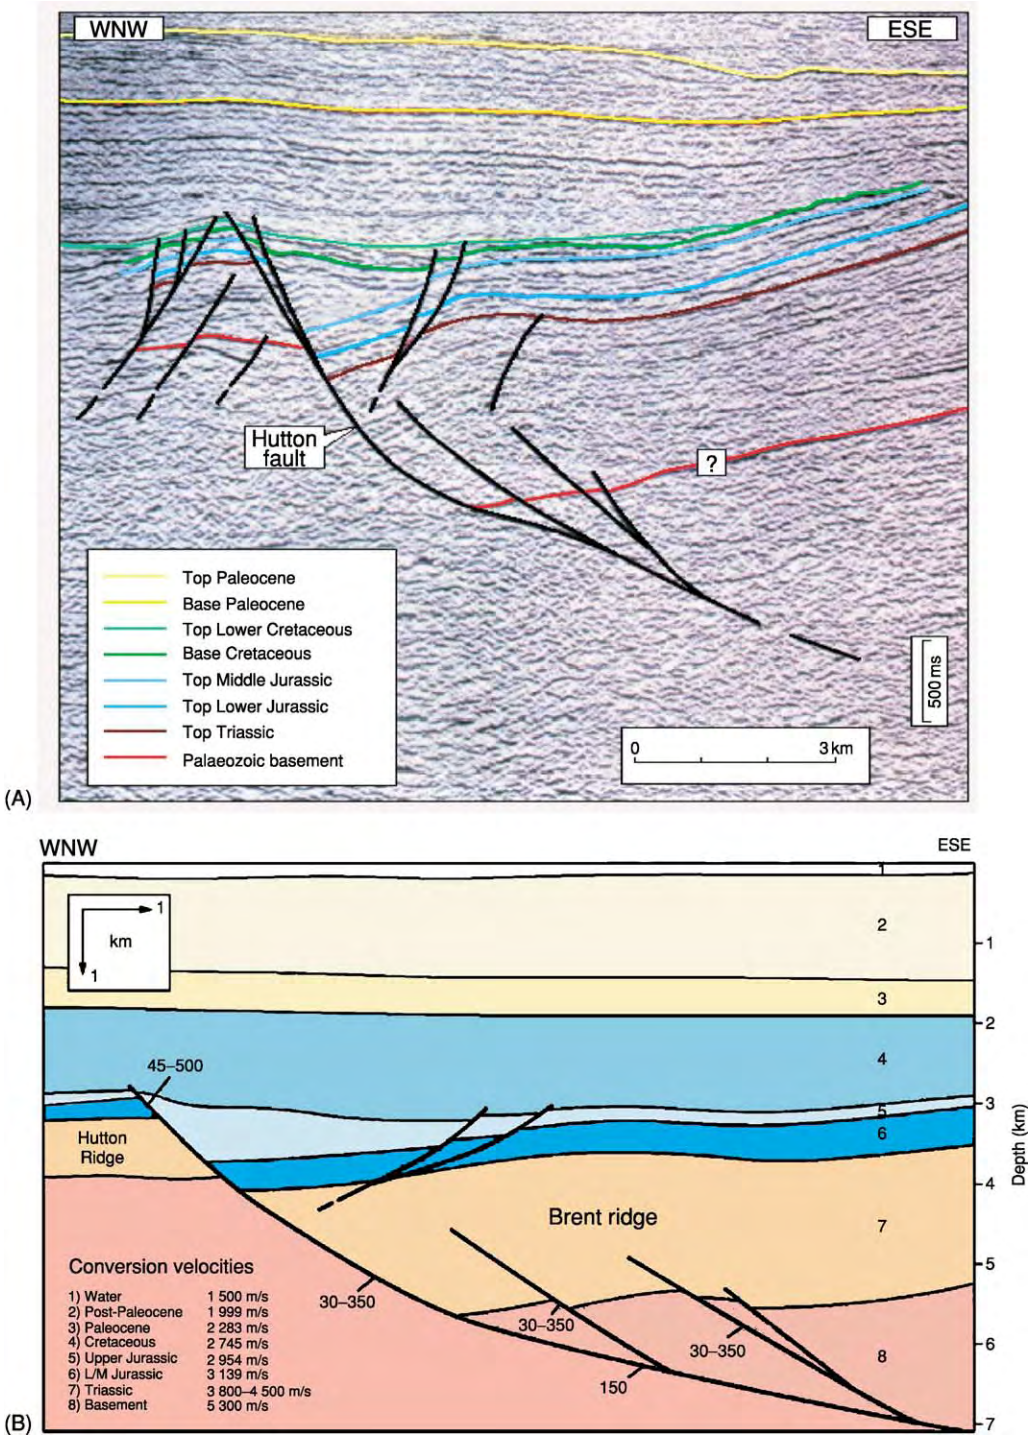

Figure 12 (A) Geological interpretation of a seismic line, and (B) depth converted to show the true fault geometry. Reproduced with permission of Millenium Atlas Company Limited.

cases, a single numerical estimate is often more misleading than helpful. Hence, the inputs will almost always be in the form of probability distributions, and the use of repetitive calculations, each time using an equally likely choice (the so-called 'Monte Carlo' technique; Figure 17) for the input parameters, results in a series of equally likely outcomes, reflecting the uncertainties of both the inputs and the applied formulae. In addition, despite many advances in the understanding of the geological processes involved, any model, although logically consistent and based on the best of present knowledge, is

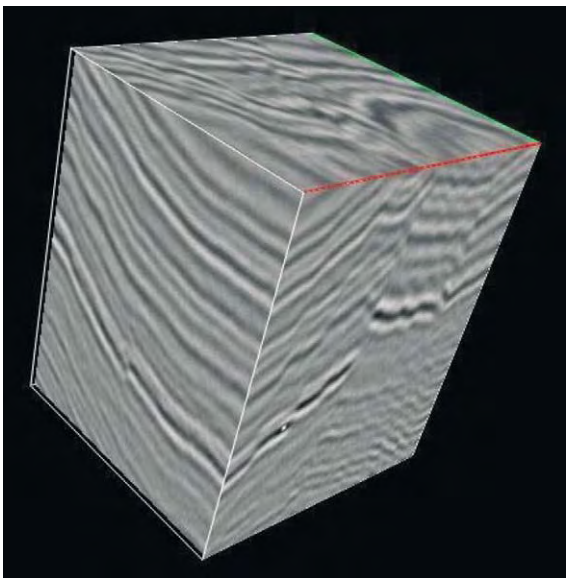

Figure 13 Three dimensional seismic cube which can be re viewed from any direction, or rotation, on the computer workstation screen. Reproduced with permission of Ikon Science Limited.

likely to be only partially correct because there are variables and processes that are unknown, cannot be measured with sufficient precision, or cannot be accommodated in the model. Hence, it is important to calibrate the output from these models against real-life situations.

Exploration Drilling

Assuming that the geological and geophysical work outlined above has identified a 'prospect' – a possible hydrocarbon-bearing structure – it has then to be decided whether to drill an exploratory well, which is the only way to prove the actual presence of hydrocarbons. Factors involved in this decision are the likelihood of hydrocarbons being present in the prospect, the extent – and hence economic viability – of any hydrocarbons found, the cost of development if hydrocarbons are found, and political and economic considerations relating to the concession and the country in which the prospect is situated.

Figure 14 Three dimensional seismic interpretation system (so called 'visionarium').

Reproduced with permission of Nautilus Limited.

In addition to confirming the presence of hydrocarbons, an exploration well provides information from which the size of the accumulation can be assessed, the development of the field planned, and further exploration in the area undertaken. Rock cuttings brought to the surface by the drilling mud and specially taken core samples contribute to an understanding of the geological history of the sedimentary basin and, specifically, of the nature and characteristics of the reservoir rocks. Wireline logging (Figure 18), using special sondes to measure the electrical, acoustic, and radioactive properties of the rocks, allows key physical properties of the rocks, such as porosity and the fluid content – of oil, gas, or water – within the pore space, to be determined. Other logging tools can detect the presence of fractures (which can be important for the flow characteristics of a reservoir), the dip (or inclination) of the rock layers, and sedimentary features (such as cross-stratification). If this information indicates a potentially commercial accumulation, then a flow test can be undertaken, in which the oil or gas is flowed to the surface: from flow and pressure measurements, further insights into the porosity and, particularly, permeability of the reservoir and the likely performance of wells under operational conditions can be gained.

Further surveys and additional drilling are then undertaken to appraise the size of the accumulation and reduce the geological uncertainties; this information is used to plan the development of the field.

Exploration Costs

Onshore, the exploration costs depend very much of the nature of the terrain: operations in remote mountainous or jungle areas are much more expensive than those in flat desert country. Operations in urban and agricultural areas and in areas of environmental sensitivity are expensive, as access can be difficult and strict regulations relating to noise, pollution, and environmental protection must be adhered to. Offshore, costs are less variable, though remote and less climatically favourable locations inevitably attract higher costs (Table 1).

Petroleum Agreements

Apart from the onshore USA, where individuals can have title to the mineral rights, in most countries these rights are vested in the state, and exploration for oil and gas can be carried out only under licences or contracts granted by the state. Petroleum agreements can be divided into two main types: licences (including leases, permits, and concessions) and production-sharing contracts.

Under a licence agreement, a company is granted exclusive rights to explore particular areas. The company finances the exploration campaign and, if the exploration is successful, the development cost and in return is entitled to dispose of the production, sometimes subject to a deduction of a royalty in kind and an obligation to supply the domestic market. The state obtains revenues from the royalty and from taxation, often through special petroleum taxes. A variation on this type of agreement is a joint-venture agreement, where the state shares with the company the risk and expenses of the development phase; generally the company will carry the project at its own cost through the exploration phase.

Table 1 Indicative costs of exploration (for the year 2003) (all values are in US dollars)

Onshore jungle terrain	
Seismic cost per two dimensional kilometre	7 000
Seismic cost per three dimensional square kilometre	12 000 (but can be significantly higher)
Well cost (to 3500 m)	3 5 million
Onshore desert terrain	
Seismic cost per two dimensional kilometre	2 000
Seismic cost per three dimensional square kilometre	4 000
Well cost (to 3500 m)	1.5 2 million
Onshore urban or agricultural environment	
Seismic cost per three dimensional square kilometre	12 000
Offshore	
Seismic cost per two dimensional kilometre	600
Seismic cost per three dimensional square kilometre	5 000
Well cost (to 3500 m)	6 8 million (but can be significantly higher for deep wells encountering high pressure and high temperature, or in remote locations; up to 25 million)

In a production-sharing agreement, the company carries the exploration risk and funds all the development and operating costs. These costs are then recovered from part of the production, known as 'cost oil'. The remaining 'profit oil' is then split in a pre-determined manner between the state and the company.

A further type of agreement is the service contract, in which the state contracts for a service from the company for which the company receives a fee; this can be, for example, a set fee per barrel produced or a percentage of the hydrocarbons produced while providing the service.

Petroleum agreements take many forms, are increasingly complex, and are often a combination of elements from the different types. The main considerations for the company are the investment at risk, its ability to manage the operations, access to oil in the event of success, and the economic return on the investment.

Postscript

The development of new exploration techniques continues to improve geologists' and geophysicists' understanding of petroleum geology and to increase the efficiency of exploration by allowing wells to be sited more accurately and with a greater chance of success. However, even if the geological conditions for the presence of hydrocarbons are promising, exploration remains a high-risk business and investments are made in exploration many years before there is any prospect of producing the oil: those ventures that are successful must generate sufficient profit to pay for the unsuccessful ventures, both past and future. Thus, the fiscal framework established by states is vital to the commercial success of any exploration venture. The interests of governments wishing to develop their petroleum resources and the interests of companies as risk takers have much in common; petroleum-exploration strategies must take these mutual interests into account.

Introduction

The geological activities following the discovery of a petroleum accumulation commence with a thorough analysis of the find in terms of structural definition, reservoir rock characteristics, and accumulation conditions. This is followed by the selection of appraisal well locations and the study of the results. If considered commercially viable, a multidisciplinary team, including specialists of all disciplines in petroleum engineering, designs an initial development plan. At this stage, the volume of petroleum-in-place is estimated and a dynamic model is built to test the production capacity and producible reserves of the field, which may be generated by a series of alternative development plans.

After executing the selected initial development plan, the reservoir model is updated with new data. The increasing information on field performance is used to calibrate the model by history matching. In certain favourable cases, fluid movements can be observed on additional three-dimensional (3D) seismic data (*see* **Seismic Surveys**). Further development activities, such as infill drilling, side tracking, recompletions, or fluid injection schemes, are planned on the basis of the updated model. Detailed field studies by integrated teams of petroleum engineers and production geologists are carried out periodically until the ultimate stages of the field life (Figure 1).

Reservoir performance is a function of the reservoir characteristics and the petroleum properties. The study of reservoir characteristics is the primary task of the production geologist. An overview is given of the influence of various reservoir heterogeneities on fluid flow. To analyse these characteristics, and to quantify the results, requires a wide range of techniques. These cover such a large field of subjects that the work has to be carried out by a group of specialists in seismology, sedimentology, structural geology, geostatistics, and petrophysics. In addition, a good understanding of the principles of reservoir and production engineering is required to be able to function successfully in a multidisciplinary team.

The production geological activities at the various stages of field development have a number of different purposes which all require geological input of some kind (Figure 2). This is illustrated by the different techniques and modelling methods that are employed at each stage (Figure 3). The pace of development of new techniques, in particular integrated computer systems, is very fast. As a result, the production geological activities are centred around workstations being served by a database containing all relevant information (Figure 4).

Historical Development of Production Geology

Production geology as a separate petroleum engineering discipline was only generally recognized in the 1950s. Early field development, with shallow, closely spaced wells and only cuttings and surface outcrop observations, provided little scope for reservoir studies. In the USA and Russia, where grid drilling was and still is in fashion, most companies did very little production geology work in the appraisal stage. In Indonesia, where complicated structures were encountered, the need was felt for more geologist involvement at an early stage.

Around 1915, the Bataafse Petroleum Company (Royal Dutch) started to engage mining engineers with the particular task to improve cooperation between production and geology to achieve a more efficient exploitation of the field. The reports from that time show that structural interpretation and detailed mapping of the producing horizons constituted the main tasks. In these pre-logging and pre-seismic days, correlations were carried out with the aid of cuttings glued to narrow planks.

The wireline logs developed by the Schlumberger brothers in 1927 progressively replaced these early methods. Just before World War II, effective reflection seismic methods came into use, although any sophisticated processing had to wait for the availability of more powerful computers after 1960. This is also the time that production geology, also called 'development geology', began to be more generally employed, although, in most companies, the geologists were still firmly attached to the exploration departments.

In the meantime, sedimentology had made great strides forwards and more attention was given to the internal architecture of the reservoir. Core descriptions and analysis were improved. Research studies of outcrops and recent sedimentation of both

clastics and carbonates were carried out by several major oil companies, in combination with laboratory studies of diagenetic processes. Rock classification systems such as the 'Archie classification' appeared, providing the link between rock texture and permeability. The introduction of induction-, latero-, formation density- and dip-meter logs greatly improved the quantitative assessment of hydrocarbon volumes

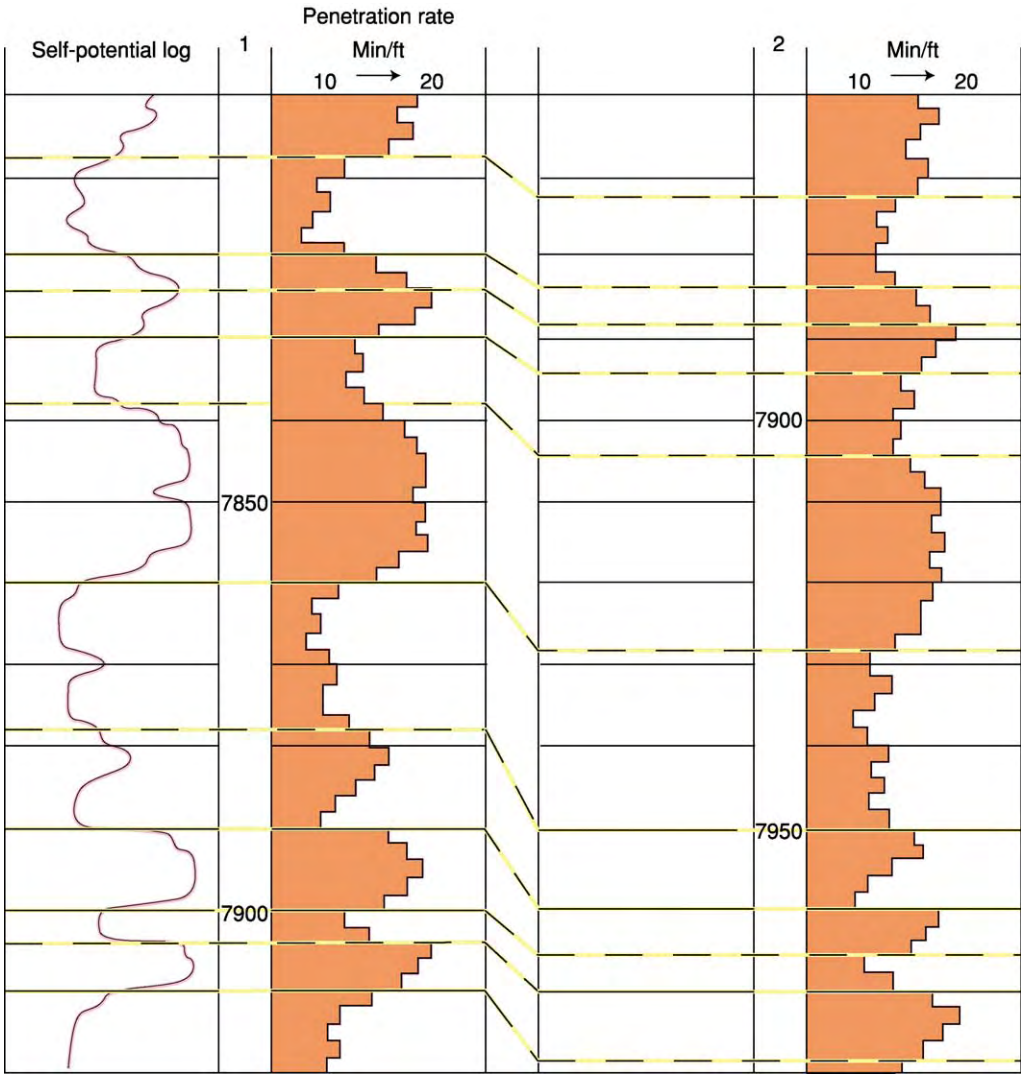

Figure 5 Penetration log correlation.

and distributions. Between 1960 and 1980, most of the presently used production geological methods were developed.

As a typical example of a classical production geological method, Figure 5 shows a penetration log correlation. The different rates of penetration of sandstones and shales (whilst drilling with constant speed and weight) can often be related to spontaneous potential (SP) or gamma-ray (GR) log curves, and thus the progress of wells could be monitored prior to the introduction of modern logging-while-drilling (LWD) much later. Further refinements in structural and reservoir imaging came with the spectacular advance of seismic acquisition, processing, and interpretation. Seismic attribute analysis is now one of the major production geological techniques. Sophisticated borehole imaging logs formed another new source of detailed information. The increase in computer capacity also led to reservoir simulation based on complex heterogeneous reservoir models comprising very large numbers of grid cells, which, in turn, required realistic well-calibrated geological models. This promoted the use of geostatistical methods and stochastic modelling. The present trend is to use a combination of all relevant reservoir data in integrated databases from which visualization can be generated, simulation models can be constructed, and well trajectories can be planned.

Reservoir Characteristics Influencing Fluid Flow and Storage Capacity

Controlling Reservoir Characteristics

The quality of a reservoir is directly related to the available pore space (porosity) and the capacity to

conduct fluid flow through the pores (permeability). Porosity depends on texture (grain size distribution, grain shape, and packing) and the degree of diagenesis (compactions, leaching, cementation). Permeability is a function of the size, shape, and distribution of pore spaces and their interconnectedness. Rocks with a similar texture that have been subjected to similar diagenetic processes will generally show a good correlation between porosity and permeability. However, for the same porosity, significantly different permeabilities may be found in the same reservoir because of facies-related textural differences and/or diagenetic variations.

There are a series of geological features that influence fluid flow and hydrocarbon recovery (Figure 6). Faults, fractures, reservoir architecture, internal zonation of genetic units, low permeability intercalations, sedimentary structures, and pore shape all have an impact on a different scale. The drive mechanism can also be influenced by these factors because they control the pressure support from the aquifer surrounding the reservoir. An accurate evaluation of a reservoir has to take into account all of the relevant heterogeneities at the right scale. The resulting 3D reservoir model forms the basis for volumetric estimates of the trapped hydrocarbons and simulations of

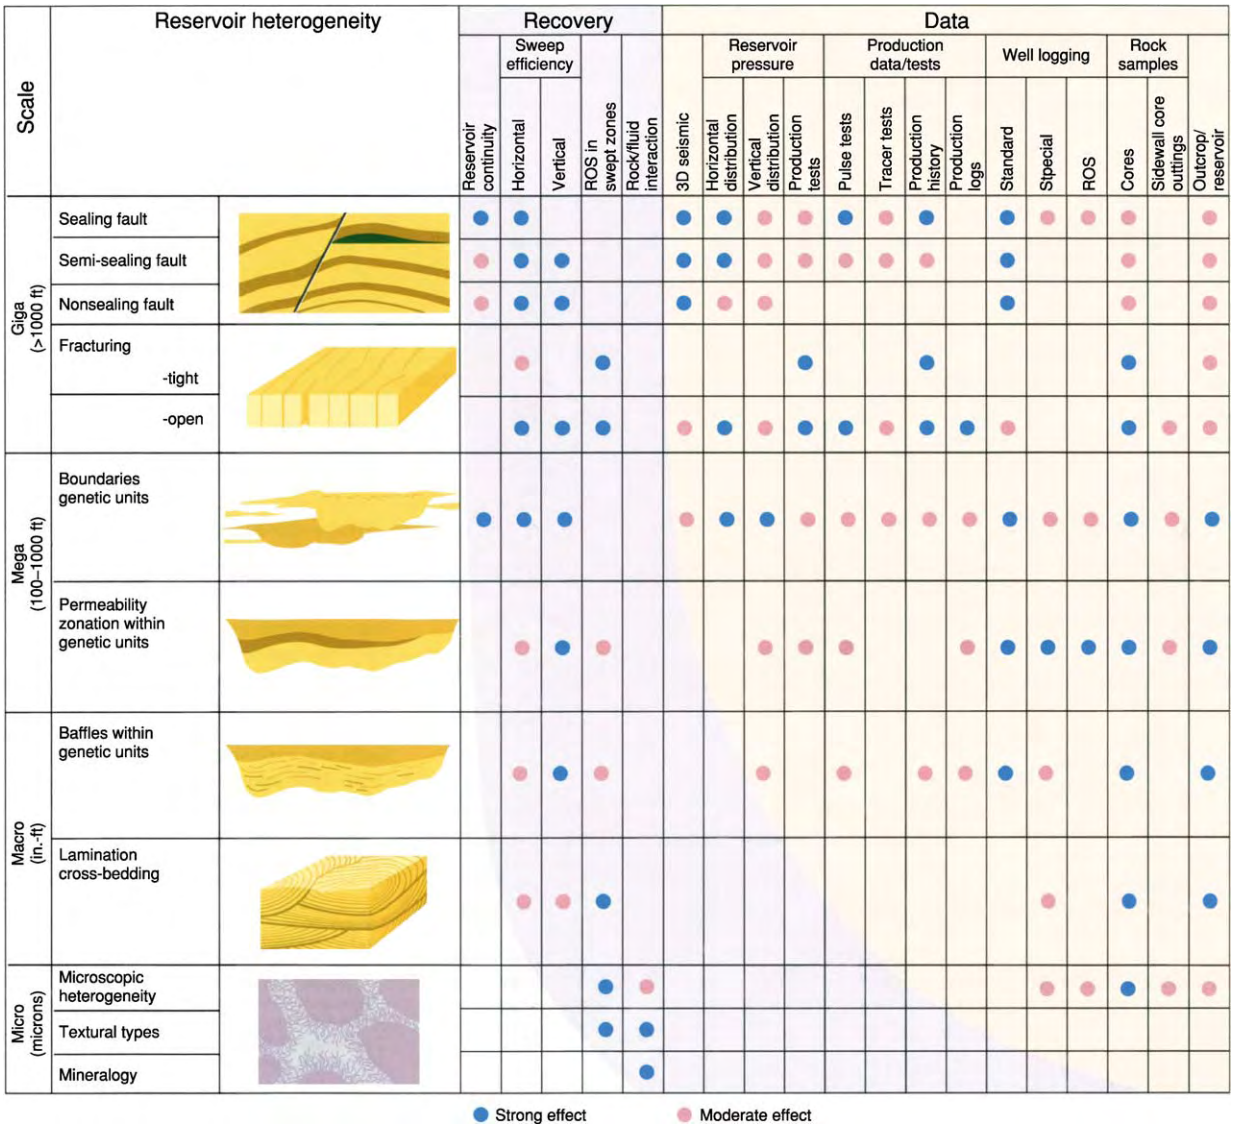

Figure 6 Reservoir heterogeneity influencing fluid flow and hydrocarbon recovery, and relevant data for analysis. ROS, Residual Oil Saturation. Modified with permission from Weber KJ and van Geuns LC (1990) Framework for constructing clastic reservoir simulation models. *Journal of Petroleum Technology* 42(10): 1248 1253, 1296 1297. © Society of Petroleum Engineers.

reservoir performance. In this way, the appraisal campaign can be planned and the optimum development scheme can be determined.

Faults and Fractures

Faults have a significant influence on hydrocarbon migration and trapping. The sealing capacity of a fault can be controlled by cataclasis and diagenesis in the fault zone, juxtaposition against a tight layer, or smearing of clay along the fault. In deltaic settings, where multiple reservoirs separated by shales are common, the determination of the clay smear potential along faults is particularly useful.

Fractures can have a positive or a negative effect on fluid flow. Cemented fractures compartmentalize the reservoir and reduce recovery. Swarms of shear fractures are common along many faults and can significantly reduce productivity over a wide zone. Open fractures, which are mainly associated with folded carbonate reservoirs, can increase productivity enormously, although they may also be the cause of early water breakthrough to the wells.

Clastic Reservoirs

Clastic reservoirs occur in a wide variety of sedimentary settings, ranging from almost homogeneous beds to an intricate 3D network of sinuous sand bodies. From an observation of the existing reservoir configurations, it appears that most clastic reservoirs can be classified into one of three basic architectural types – layer-cake, jigsaw, or labyrinth – which represent a decreasing order of connectivity (Figure 7). Correlation is comparatively easy in layer-cake reservoirs, such as barrier bars or shallow marine sheet sands. Thus, such reservoirs can already be modelled quite realistically in the appraisal stage. At the other end of the scale are the labyrinth-type reservoirs, such as low-sinuosity distributary channel complexes, which require a dense well spacing to achieve a deterministic correlation.

If we add common internal permeability distributions and discontinuity patterns, the impact of the reservoir types on sweep efficiency can be shown (Figure 8). In layer-cake reservoirs, not only the sands but also the shales can be very continuous, preventing vertical flow. High permeability at the base of point bars can lead to early water breakthrough, while the reverse, as in barrier bars, can have the opposite effect. Jigsaw reservoirs, with interlocking sand bodies with contrasting properties and local baffles to vertical and horizontal flow, often show uneven drainage and erratic flood fronts. Labyrinth reservoirs reflect their discontinuous nature in very uneven sweep efficiency and bypassing of major oil volumes.

Carbonate Reservoirs

Carbonate reservoirs are generally more heterogeneous than clastic reservoirs, because the original organic sediments can differ widely in their grain size and composition, but also because of the large influence of diagenesis. The original sedimentary setting can be split into four main types: the deeper chalks and turbidites; the shallow-water build-ups; platform/shoal sediments; and ramp/nearshore packages (Figure 9). These reservoirs are sometimes left with rock characteristics closely related to their original properties, but often considerable changes are effected by the various diagenetic processes. However, in the majority of cases, the original material with a similar texture and composition will be transformed into the same rock type. There may be a complete reversal of the original porosity and permeability distribution. A porous reef may become tight and a low-permeability, fine-grained back-reef may change into a permeable sucrose dolomite (Figure 9).

Several diagenetic processes can increase the heterogeneity markedly. Karstic leaching can be pervasive or restricted to certain zones. Some carbonate reservoirs consist of virtually tight rock in which leached fractures and voids comprise the only effective pore space. Another complicated type, which is very difficult to evaluate, is formed by reservoirs submitted to a mixed process of leaching and dolomitization, forming a network of moldic sucrose dolomite nodules and tunnels through a tight matrix.

For nearly all carbonate reservoirs, detailed microscopic studies are required to unravel their diagenetic history and to identify facies and composing organisms. The rock types have to be classified to be able to analyse and predict the permeability distribution, which, in carbonates, can cover an extremely large range even in a single reservoir (Figure 10).

Small-Scale Heterogeneity

Although the larger scale heterogeneities usually control the production performance, the sedimentary structures and rock texture can cause anisotropy of the reservoir and have a strong influence on residual oil distribution. In cross-bedded reservoirs which have been subject to severe diagenesis, it may be necessary to measure the permeability contrast between the laminae and to take the resulting anisotropy into account in the dynamic fluid flow model. It has also been shown that, even with permeability contrasts between the laminae as low as two, capillary forces can trap of the order of 10% additional oil in comparison with more homogeneous rock. Detailed studies of the capillary pressure curves and relative

permeability to oil and gas for each rock type are necessary. Major lateral differences in apparent oil–water contact can result from variations in rock type.

Techniques

Seismic Methods

The range of methods, techniques, and tools used in production geology has become very large. Seismic techniques are of primary importance in the appraisal stage, but are also used for reservoir monitoring (Figure 11). The traditional use of seismic techniques for structural definition has been much improved by 3D surveys and better processing techniques. Where seismic resolution is good and acoustic impedance contrasts are sufficiently large, amplitude measurements along the beds can reveal depositional patterns as well as oil and gas accumulations (Figure 12).

Besides acoustic impedance mapping, amplitude versus offset (AVO) techniques and shear-wave analysis are now being employed. These techniques are powerful methods to determine lithology, while shear waves are affected by open fractures. Repeat 3D surveys (so-called 4D seismic) can reveal movements of fluid interfaces and saturation changes (Figure 12). Analysis of changes in acoustic impedance and velocity can also be used to estimate pressure changes in the reservoir resulting from hydrocarbon production. This can reveal compartmentalization caused by sealing faults and uneven aquifer drive. Rock stresses can be derived from measurements of shear-wave polarization.

In favourable cases, porosity and pore-fill analysis is carried out via acoustic impedance measurements, calibrated with well data. In this way, volumetric estimates of hydrocarbon-in-place may be made. Of particular importance is to relate the 3D seismic reservoir models to models made from well data correlations with geostatistical methods. Improved calibration of seismic data, attributed using neural network techniques, can provide estimates of facies types and related properties throughout the reservoir. Seismic methods are frequently used for planning well trajectories (Figure 12). Three-dimensional displays and interactive virtual reality techniques are employed for this purpose. The developments in seismic methods for reservoir analysis have been so spectacular in the recent past that further research is likely to result in important advances.

Core Description and Analysis

Facies and rock types have to be identified and characterized from cores and wireline logs. Systematic

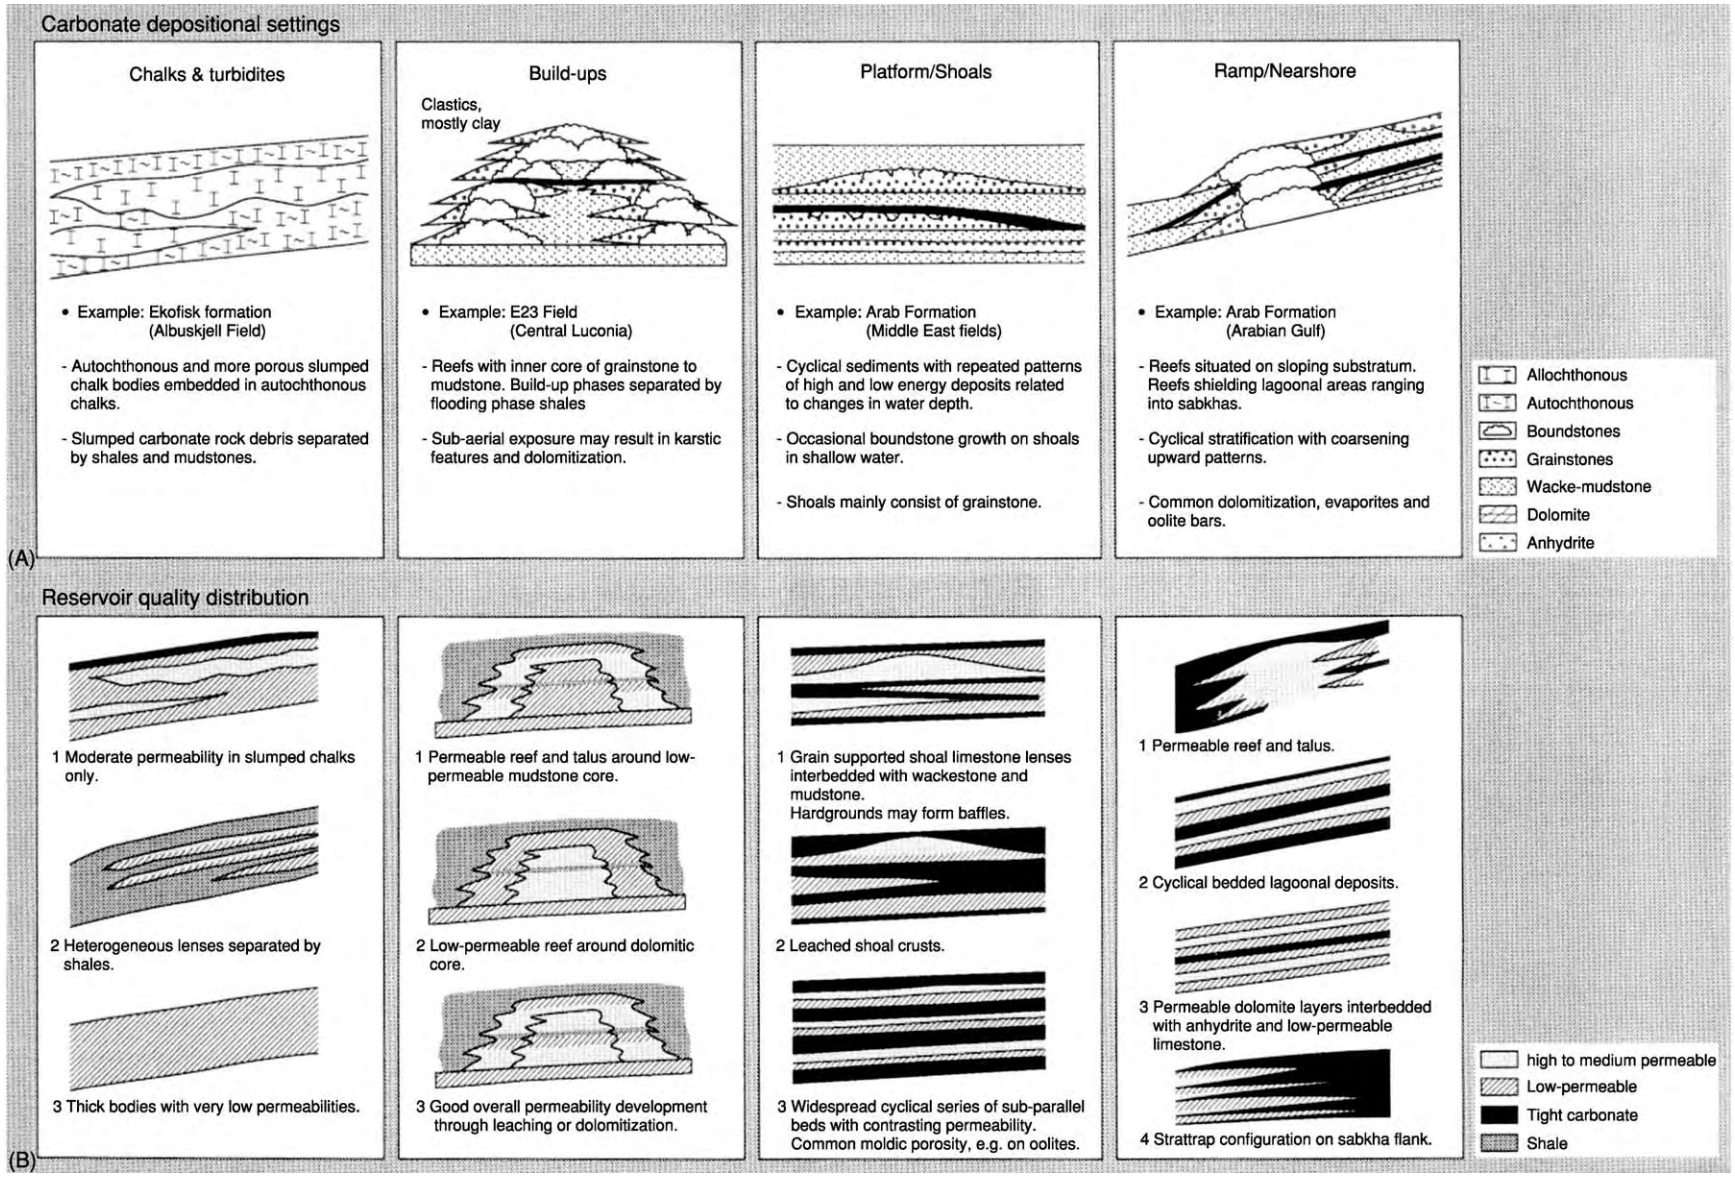

Figure 9 Scheme of the main carbonate depositional settings and common pattern of permeability distribution. Courtesy of Shell.

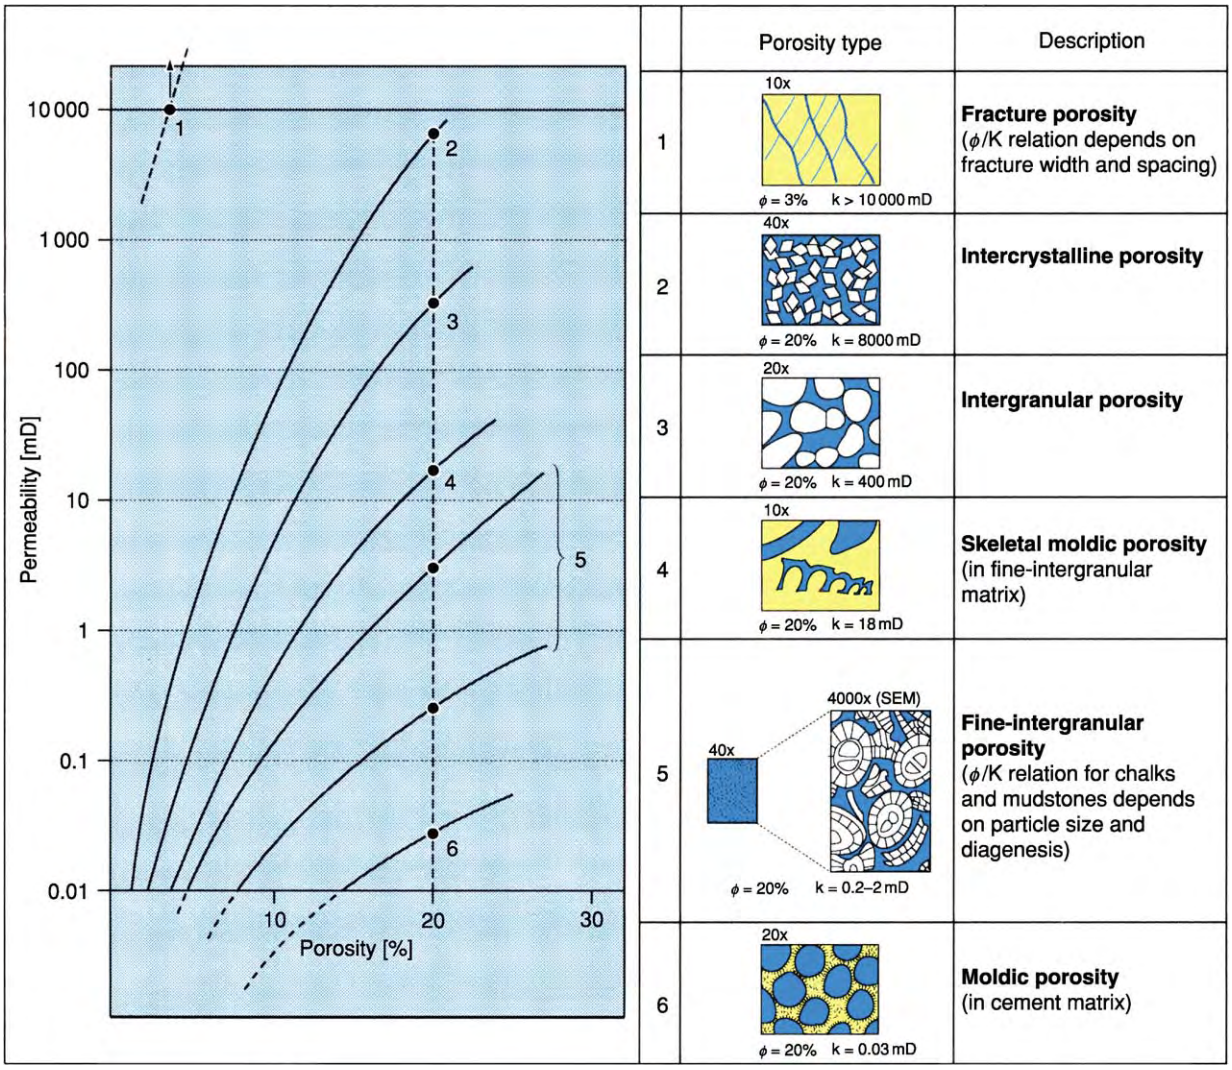

Figure 10 Generalized trends for porosity versus permeability of the main primary and secondary carbonate pore types. Courtesy of Shell.

geologically steered core analysis is the key to the proper understanding of the reservoir composition and the basis for log calibration, static and dynamic modelling, detailed seismic interpretation, and the identification of key heterogeneities. An overview of core analysis methods and applications is given in Figure 13. Core observations under normal light can be augmented by ultraviolet (UV) and infrared photography to reveal remaining oil and sedimentary structures. Standard petrophysical analysis should be carried out with a sample choice and spacing reflecting the reservoir heterogeneity. Probe permeability measurements or cube-shaped samples may be required to analyse permeability anisotropy (Figure 14). The influence of *in situ* stress on reservoir properties and rock compressibility has to be measured.

The core data are used to establish rock types with similar characteristics, such as porosity/permeability relationship, capillary pressure, and relative permeability curves. Each rock type usually represents a specific facies type having a similar lithology and texture. The core data are correlated with the logs to identify typical characteristics that allow the recognition of rock types in uncored wells. This is necessary to delineate facies distribution for well-to-well correlation, as well as to estimate permeability via porosity–permeability transforms. High-resolution borehole imaging logs are very useful for the identification of structural features, sedimentary structures and dips, and trends of individual sand bodies (Figure 15).

A series of electric logs is used to identify rock types in uncored wells. Linear multiple regression of, for example, GR, neutron and density log readings of

known rock types in cored well is used to set up a diagnostic system for uncored wells. Alternatively, neural networks can be trained to carry out this identification. The advantage of the neural network techniques is that the influence of the input parameters is non-linear.

Permeability Distribution

Permeability measurements are amongst the most difficult to derive from well data and yet comprise one of the most useful and relevant measurements in production geology. The permeability distribution in the well is derived from cores and via rock type identification in uncored wells. However, this only provides local horizontal permeability data around boreholes. Cores and logs in horizontal holes can provide lateral permeability development, but only along narrow zones. There are a large number of techniques to augment the permeability database both horizontally and vertically on a range of scales (Figure 16). Production geologists must play an active role in identifying opportunities to measure the permeability, which provides an important control on fluid flow in the reservoir. Vertical permeability on the medium and large scale is particularly difficult to estimate from cores and logs. For this purpose, multiprobe well testers, pulse testing, production logging, and pressure build-up analysis are used.

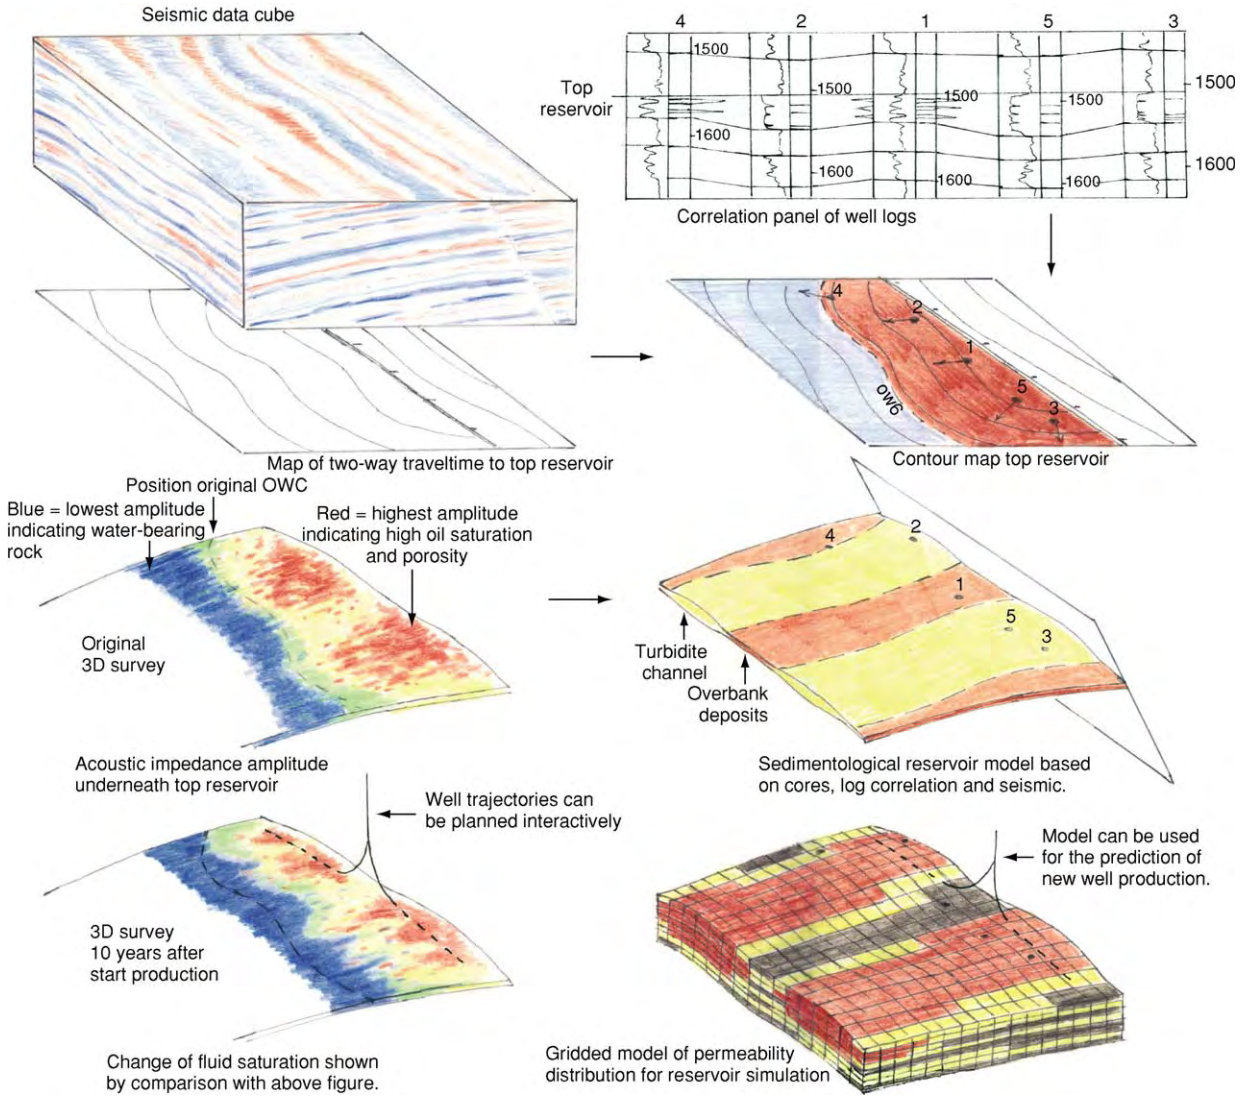

Figure 12 Integrated use of three dimensional (3D) seismic measurements for static modelling purposes.

Fault and Fracture Analysis

Faults are mainly analysed from seismic data, although well-to-well correlation can reveal fault cut-outs. Dip-meter logs can also indicate fault positions by showing drag patterns. The fault types have to be analysed from the deformation pattern seen on seismic measurements and the structural history of the sedimentary basin. The associated sealing capacity of the faults is closely related to the type of fault, fault throw, reservoir lithology, and depth. Cataclastic fault zones tend to be cemented and impermeable after burial to a depth of 1–2 km.

Clay smearing along normal faults is an important process in many deltaic reservoirs. Estimates of the sealing potential can be based on the shale thickness that passed along a fault plane (Figure 17). This can be achieved by a log analysis of wells near the fault and the fault throw derived from the cut-out observed in a well intersecting the fault. If good quality seismic data are available, however, the fault throw distribution can be established. With 3D seismic data, it is possible to sample the acoustic impedance values along both flanks of a fault and to translate these data into synthetic lithological logs. By comparing and correlating the hanging- and footwall stratigraphy, both the 3D distribution of the fault throw and the thickness of the shales that moved across any point of the fault surface can be obtained. The method requires local calibration because the ductility of the shales at the time of faulting can differ markedly.

Fractures are seen on borehole imaging logs. By the use of Stoneley waves (shear waves), open fractures can be identified and the fracture width can be estimated. This provides estimates of the usually very low

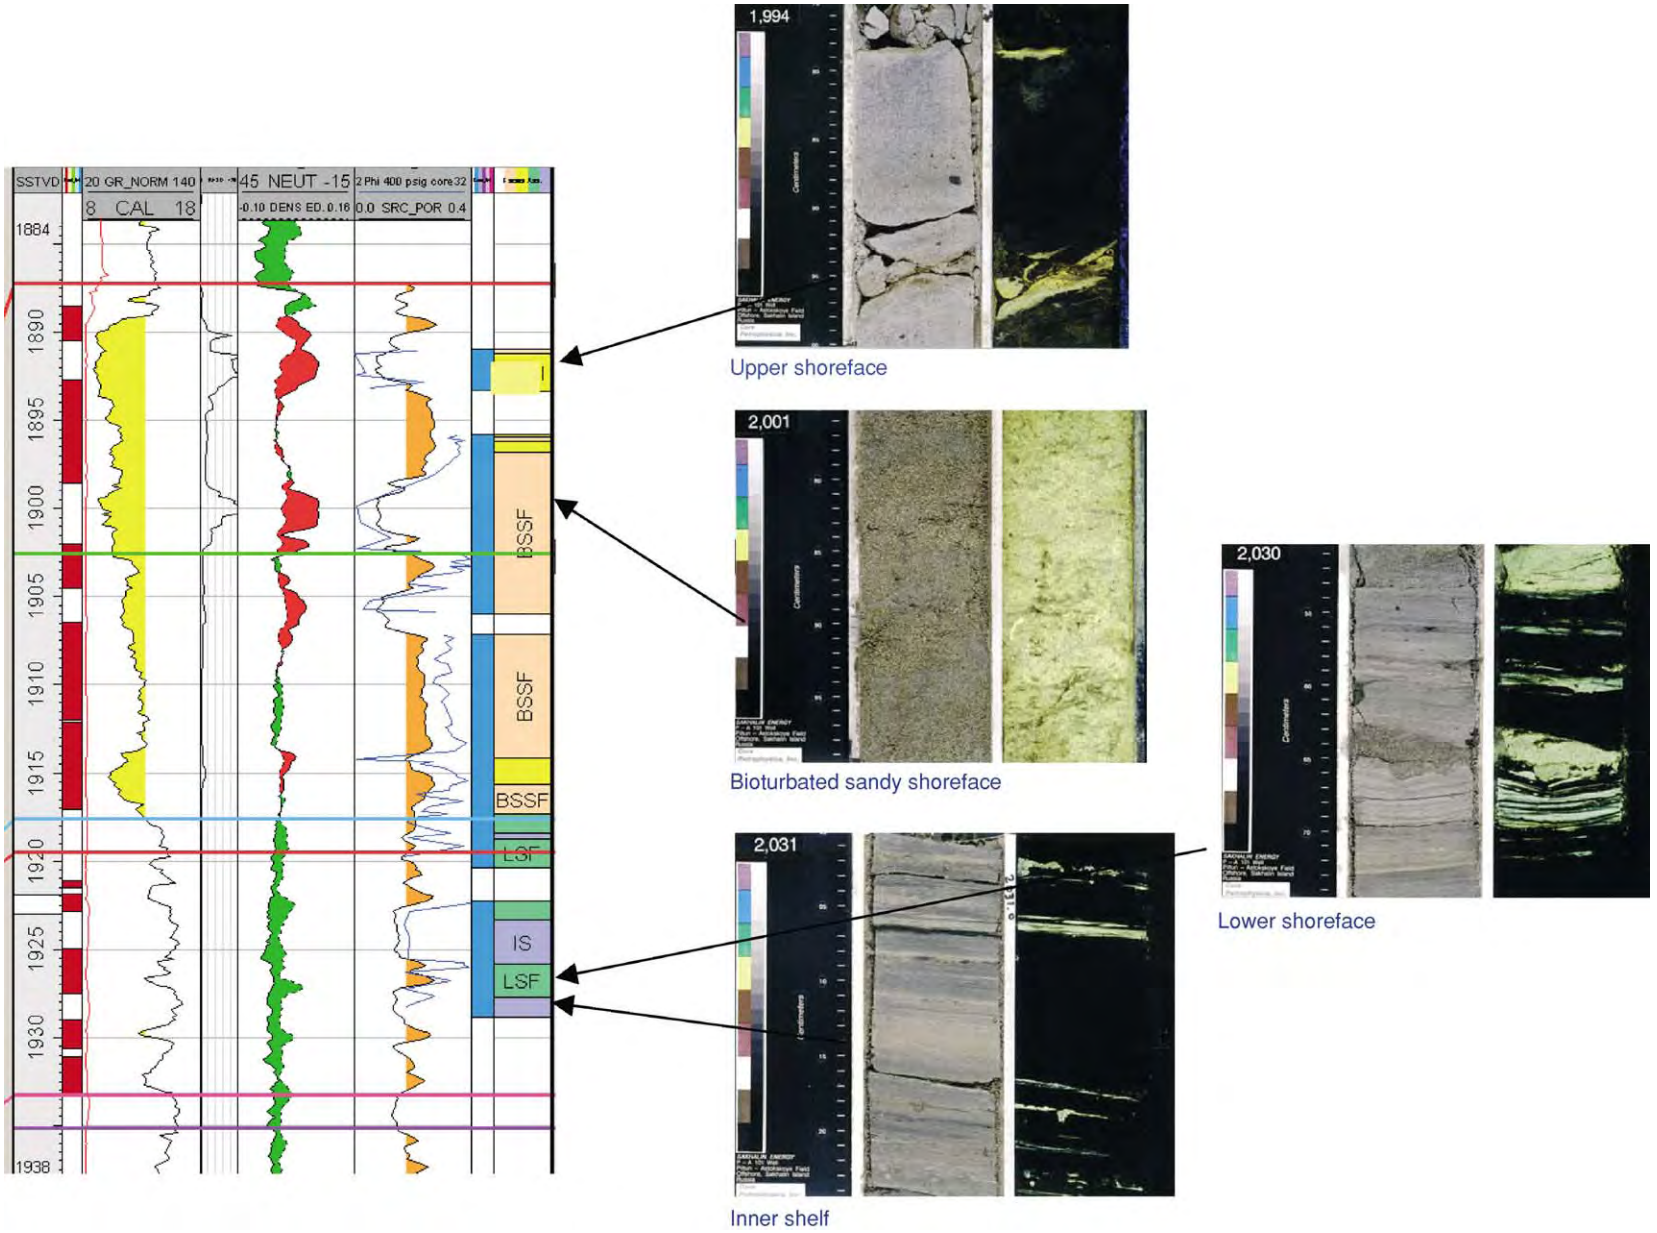

Figure 13 Facies definition from cores and logs. Courtesy of Shell.

fracture porosities. Flowmeter-type production logs can also show open fractures. The shear zones around faults can be analysed with borehole imaging logs in horizontal wells. Fracture density, as a result of tectonic deformation, can be estimated by determining the rate of change of the dip. In fault and fracture analysis, extensive outcrop studies have added enormously to the knowledge of fault zone compositions and fracture distributions (Figure 18).

Correlation and Use of Analogues

The correlation from well to well requires a detailed knowledge of the facies distribution and expectation values of the typical shape and dimensional relationships of genetic reservoir bodies. For this purpose, there is a need for a data bank of such information based on outcrop and field data, complete with their sedimentological setting, including type of basin and climate, to be able to choose a proper analogue example. Such data banks have been compiled by several oil companies, while many universities are engaged in reservoir analogue outcrop studies. The stratigraphy forming the major framework of the reservoir can be interpreted with sequence stratigraphical principles. These principles and, especially, the analysis of sea-level fluctuations can be used to delineate the sedimentary successions, and are a great help in correlating the wells (Figure 19). Sea-level changes have a large influence on the sedimentary processes along time slices of the reservoir and, in carbonates, they also have a strong impact on diagenesis (e.g., leaching and dolomitization).

The well-known techniques of comparing the floral and faunal contents of discrete intervals remain very useful, not only for stratigraphical purposes, but also for facies analysis. The palaeontological and palynological studies can be carried out on drill cuttings whilst drilling, and thus can provide important indications of drilling progress through a known stratigraphical sequence. In combination with LWD techniques, the correct casing setting depth can be determined with sufficient safety margins.

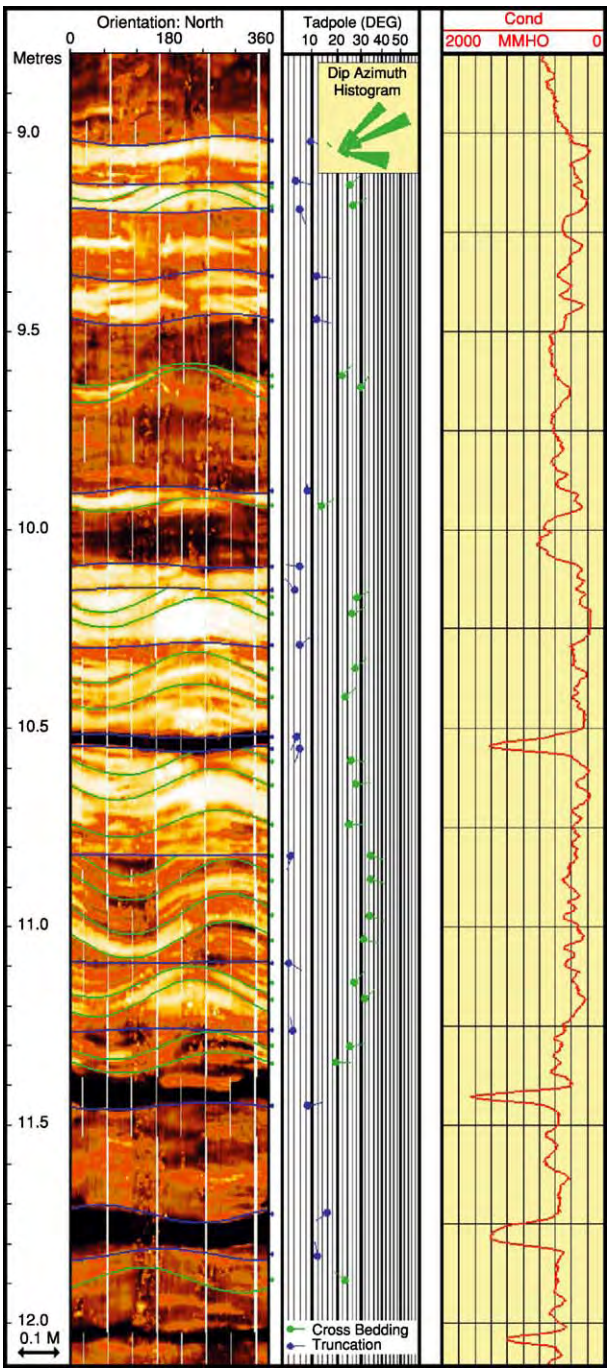

Figure 15 High resolution acoustic borehole images compared with core slab showing aeolian cross bed set. Reproduced with permission from Frikken HW (1999) *Reservoir Geological Aspects of Productivity and Connectivity of Gasfields in the Netherlands*. PhD thesis, TU Delft.

Another useful technique is oil typing via gas chromatography. Detailed comparison of oil samples has proven to be a sensitive indicator of reservoir continuity. Oils that are not in communication either vertically or laterally will show distinctive differences in their chemical fingerprints.

Volumetric Estimates

The static modelling carried out as the basis for volumetric estimates and dynamic modelling requires 3D infilling of the space between the wells. In an early stage, hydrocarbon-in-place estimates are made by

Objective	Scale (m)	Type of measurement
Distribution of horizontal permeability along borehole	0.001–0.01	Probe permeameter on core slabs
	0.01–0.05	Core plugs
	0.05	Grain-size distribution from sidewall samples combined with porosity from logs
	1.2	Nuclear magnetic resonance (NMR) log
	0.5–5	Rock typing in non-cored well and use of porosity/permeability relationship
	1.0–5.0	Pressure build-up from Repeat Formation Tester (RFT) combined with production log
Permeability within well drainage radius	100–500	Well test pressure build-up combined with geological model
	100–500	History matching of well performance after significant production
Vertical permeability of intervals	0.001–0.05	Cube-shaped samples and probe-permeameter
	0.1–0.7	Multi-probe formation tester
	5.0–50	Vertical pulse test
		Computation with geological model using outcrop shale continuity statistics
Lateral and vertical permeability continuity	1.0–50	RFT or multi-probe tester in infill wells
	100–300	Well-test analysis combined with geological model and vertical seismic profile
	200–1000	Horizontal pulse test
Permeability distribution around horizontal wells	0.001–1.0	Core plugs, probe-permeameter, log-derived estimates, production logging
	100–300	Well-test analysis combined with geological model and production logging results

Figure 16 Overview of methods to determine or estimate permeability distribution on a range of scales. Modified with permission from Weber KJ (1995) Visions in reservoir management what next? Chiba: Japan National Oil Corporation.

combining the tentative probability distribution of the controlling parameters: reservoir volume, net-to-gross, porosity, petroleum saturation, and formation volume factor (FVF), the ratio between the net petroleum volume *in situ* and under standard conditions. The cumulative probability distribution curve or expectation curve for the petroleum-in-place is generated with Monte Carlo techniques. The probability distributions of the parameters are randomly sampled and the resulting petroleum-in-place volumes are plotted until the graph hardly changes by additional values (Figure 20).

As an interim step towards 3D modelling, Net-Oil-Sand (NOS) maps can be constructed, which yield better estimates than combining the field averages of all parameters. For thin reservoirs, such maps almost represent 3D models, if the properties of the individual sand bodies can also be plotted (Figure 21).

Geostatistics

Classic statistical methods for the analysis of numerical data sets to determine distributions, standard deviations, and correlations have been used in production geology for a long time. There are, however, a number of problems for which these methods are not suitable. Firstly, one is frequently confronted with sparse data sets which do not allow reliable contouring or correlation. Secondly, there is a need to quantify uncertainty in spatial distributions and also to estimate the possible reduction in uncertainty resulting from drilling an additional well in a given place. Thirdly, one wants to use spatial relationships established for specific types of reservoir body to constrain the models based on well-to-well correlations.

The method which has been developed to handle these problems is called 'kriging', after the originator Daniel Krige, a South African mining engineer. It is based on the reasonable assumption that the unknown spatial distribution of a geological property can be predicted on the basis of the spatial distribution of the measurement of that property. The main tool in this method is the 'variogram', which quantifies the spatial continuity of a property. It is a graph of the variance of the difference of two measurements as a function of their spacing. One can use variograms made on the basis of a data set. If the number of data points is insufficient to define a variogram, one can select a best-fitting variogram or use a variogram that is typical for a modelled property. Known trends can be honoured by using different variograms in different directions.

An example of the above is shown in Figure 22. A map is made of the thickness variation of a reservoir using a best-fitting variogram. Next, the residual

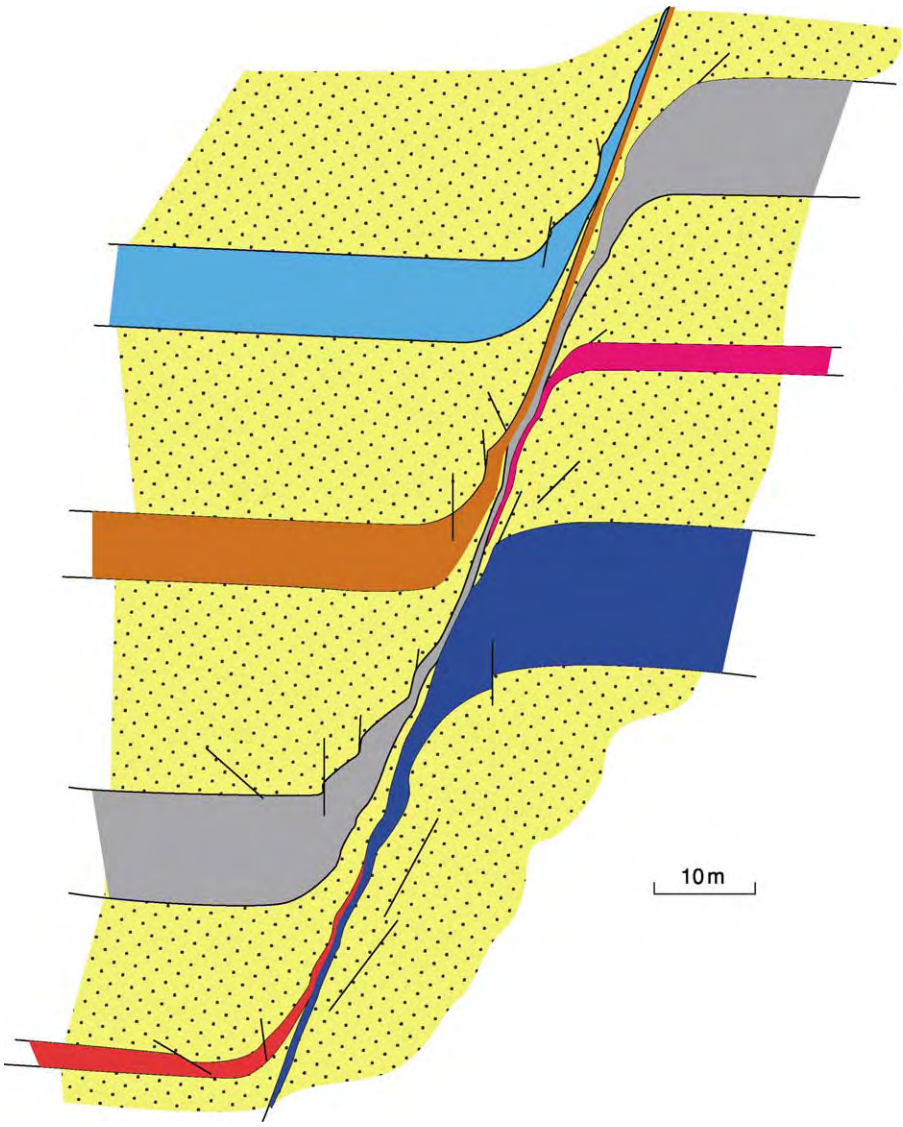

Figure 17 Clay smearing along fault as seen in outcrop. Note discontinuous clay smear of thin (red) shale.

variation between the variogram and the thickness map is computed to show the uncertainty at any point of the map. Finally, one can place a grid over the map and compute the reduction of uncertainty resulting from drilling a fictitious well in any of the grid points. This method can be used to select a next appraisal well.

Further applications of 'kriging' methods include the combination of data from different sources and with different accuracy to estimate a property. In this way, reservoir depth data from wells and from seismic measurements can be merged into one map. Probabilistic reservoir modelling also makes use of variograms to constrain the extent of the bodies within the reservoir. A series of equally probable models can be generated. Here lies one of the most useful applications of analogue data derived from outcrops and densely drilled fields.

Static Modelling

The particular technique used for 3D reservoir modelling depends on the reservoir type. For layer-cake reservoirs, deterministic models can often be made directly from the well-to-well correlations and the rock properties can be interpolated. For labyrinth reservoirs, on the other hand, deterministic modelling is rarely possible without a very close well spacing. Computer systems have been developed to generate a series of equally probable 3D models through 'probabilistic' modelling techniques. Most systems work in three steps. Firstly, correlatable reservoir bodies are determined and incorporated in the

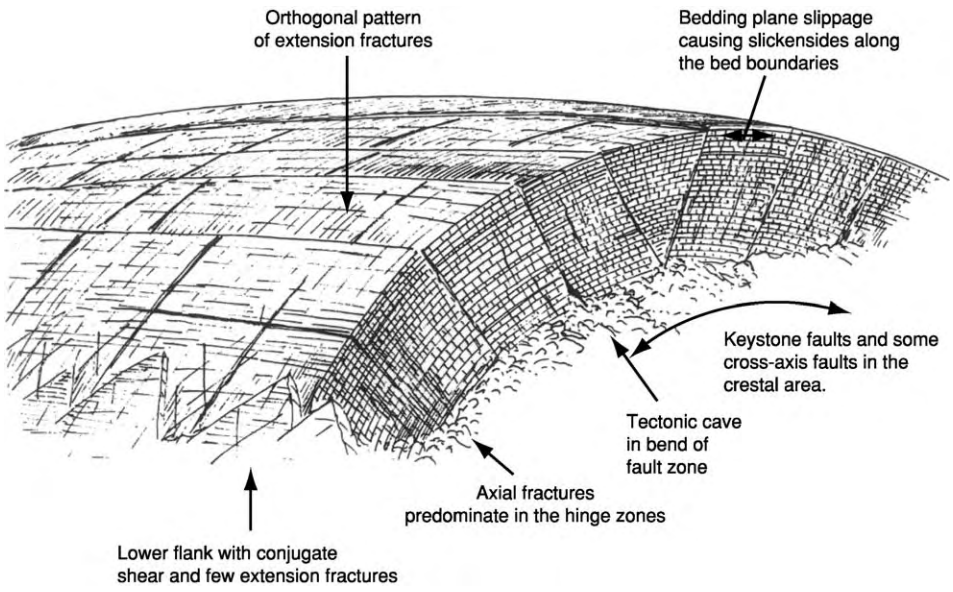

Figure 18 Faults and fractures in anticlinal structure of a thick limestone formation.

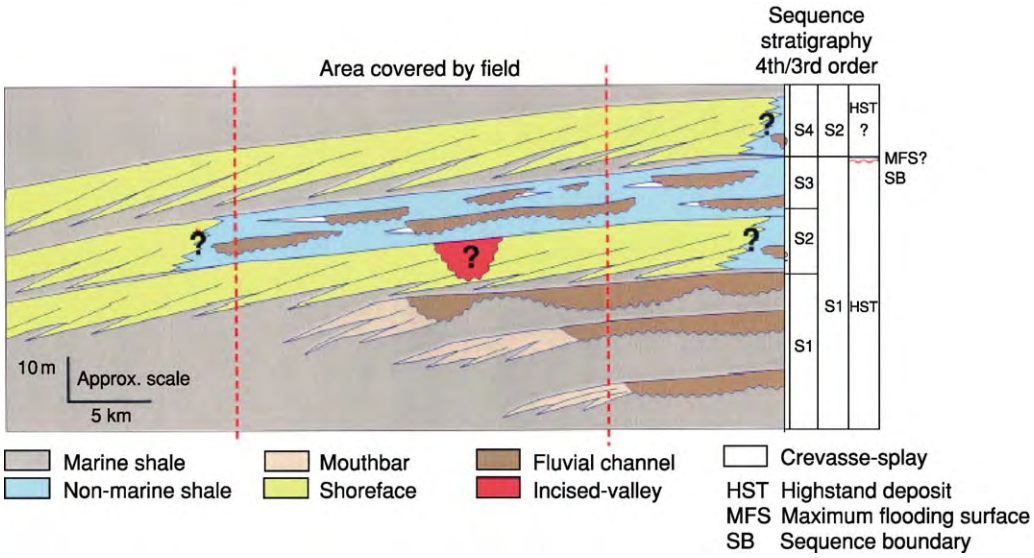

Figure 19 Sequence stratigraphical correlation in reservoir modelling. Courtesy of Shell.

model. Where extrapolations beyond control points are necessary, use is made of an analogue database for the relevant genetic type. Secondly, the uncorrelatable bodies are considered, for which the dimensions are also derived from the database, while body orientations are taken from borehole imaging logs or estimated on the basis of the general geological model. Characteristic variograms for the thickness distribution of genetic sand body types in different orientations relative to their expected trend are also used. Thirdly, especially when the well spacing is rather large, there are smaller or narrower reservoir bodies not penetrated by wells. Such bodies are added using statistical estimates of their occurrence from the wells. Their position and dimensions are conditioned by geological modelling rules and the analogue database (Figure 23). Jigsaw-type reservoirs are also difficult to correlate in the appraisal stage and probabilistic modelling is required. In a later stage, a large part of the architecture may be determined and only limited recourse has to be taken to probabilistic techniques.

The resulting architectural models can be compared with the seismic models and, in favourable

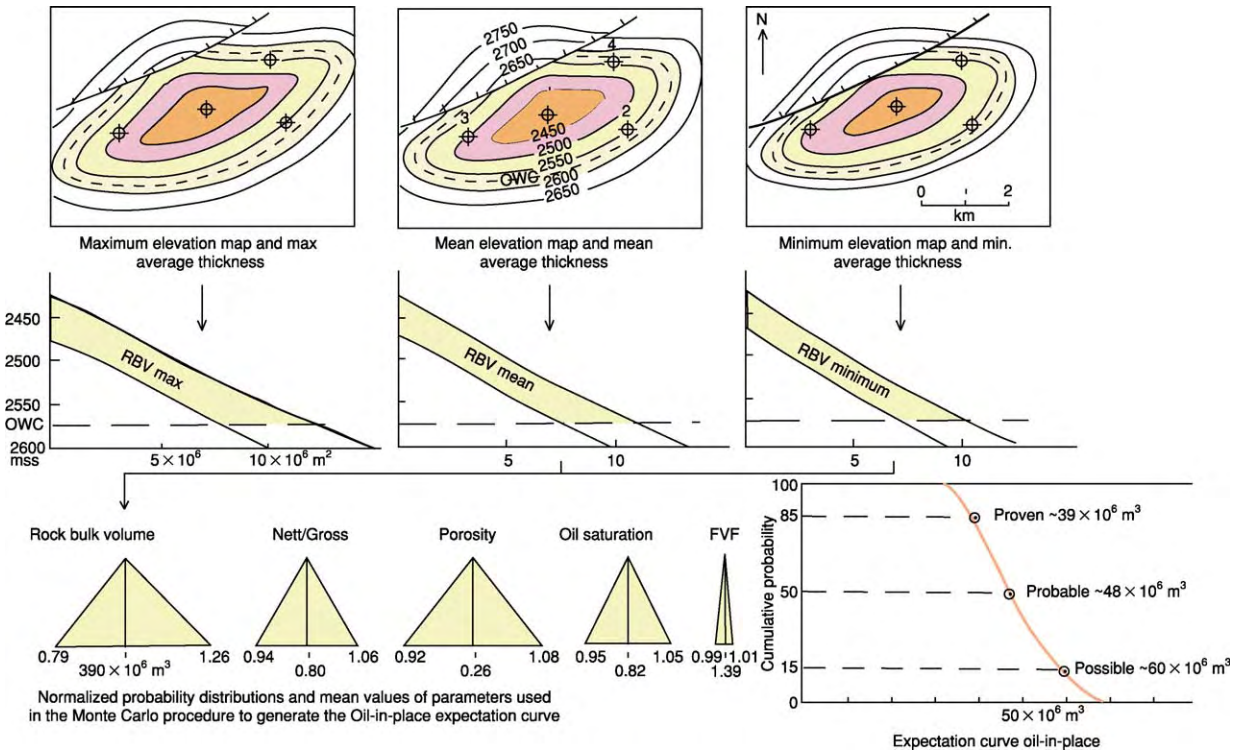

Figure 20 Approach to determine the cumulative probability (expectation) curve for the oil in place volume. RBV, Rock Bulk Volume.

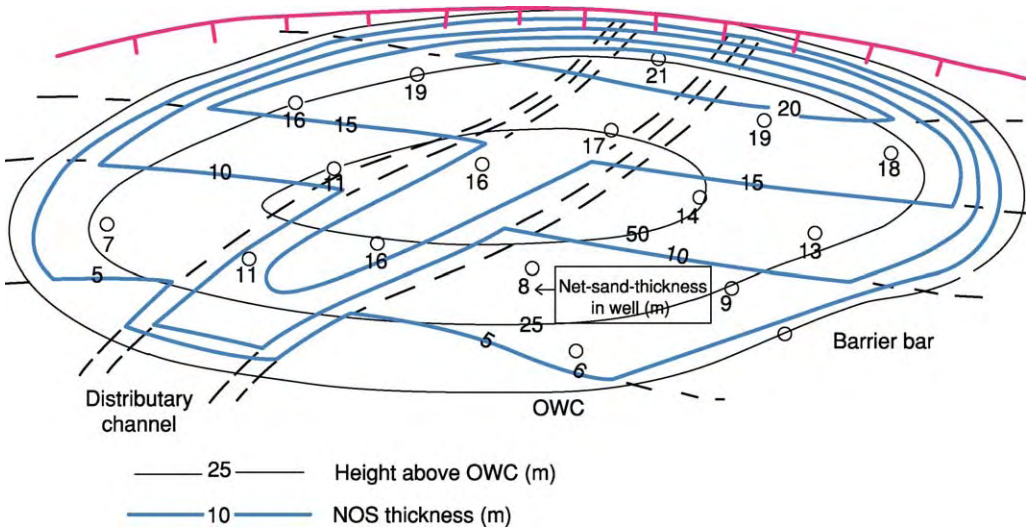

Figure 21 Net Oil Sand (NOS) map of deltaic reservoir.

cases, quantitative correlations can be made. This reduces the spread of possible model configurations. In any case, the permutation of the probabilistic models generated has to be carefully ranked in order of probability by screening them with regard to the presence of geological anomalies. A limited number of 3D models are selected as representing the likely range of variation in the reservoir with respect to hc-volume (hydrocarbon volume), connectivity, architecture, and permeability distribution.

Dynamic Modelling

The profitability of a hydrocarbon reservoir depends crucially on how its development is planned in

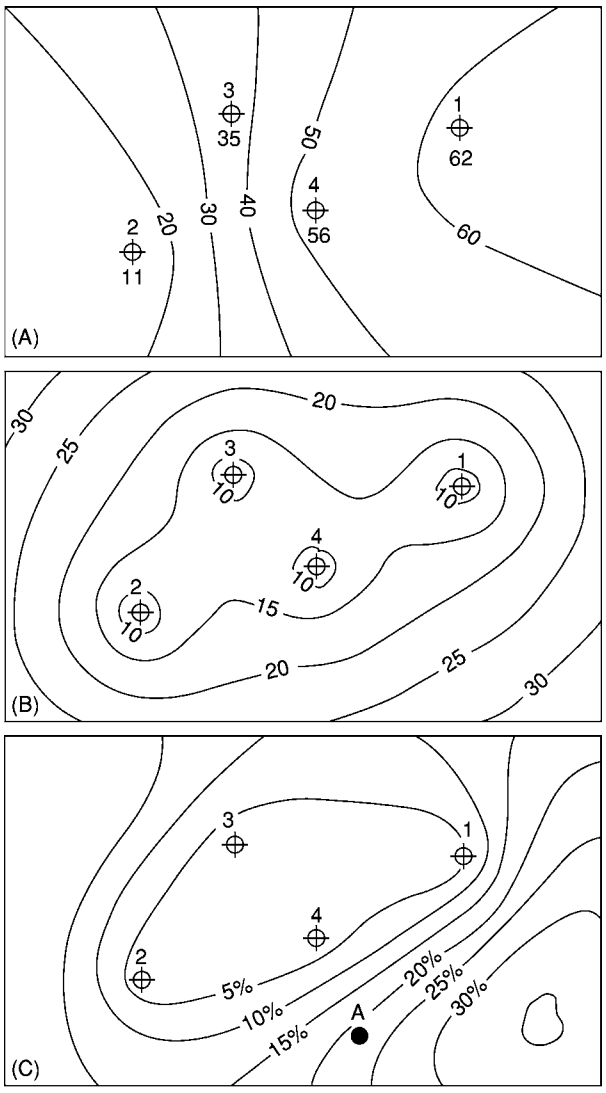

Figure 22 Geostatistical methods in mapping and well planning. (A) Estimated thickness map made with the best fitting variogram. (B) Thickness uncertainty (66% confidence limit) computed from the residual variation between the variogram and thickness map. (C) Expected reduction in estimation variance of the mean thickness after drilling well in location A.

the context of recovery mechanism(s) and infrastructure environment. A key element from the outset of planning is a conceptual model of the hydrocarbon reservoir (ranging from a simple analytical model to a multitude of equiprobable realizations). The reservoir model allows the evaluation of alternatives by providing an estimated range of hydrocarbon volumes that are potentially recoverable under various development schemes.

The majority of the field development plans are based on reservoir simulation models with varying degrees of complexity. Integrated dynamic reservoir models are constructed by reservoir engineers and require input on geological structure and architecture, rock and fluid properties and their distribution, displacement characteristics, and description of the wells and the surface facilities. Static and dynamic modelling programs differ from each other in terms of the number of volume elements they can handle. Like the 3D static modelling packages, the dynamic modelling programs require the reservoir to be segmented into unit cells, each of which has uniform properties, before it can perform computations. Static modelling computations involve the categorization, sorting, and counting of voxel cells; dynamic modelling computations involve the balancing of the fluid masses and pressures within and between 'gridblock' cells. Upscaling programs enable one to aggregate the geological detail (=3D static model) into the bigger elements of a reservoir engineering model (=3D dynamic simulation model) by using a method of permeability averaging (e.g., harmonic, arithmetic, geometric). These programs also produce a corresponding gridblock model of porosity through conventional averaging of voxel porosity values.

It is important that the 3D modeller identifies the key geological characteristics that should not be lost during upscaling (e.g., thin-bedded shales that may act as permeability barriers or baffles) (Figure 24). Not all geological architecture will have equal weighting in terms of its influence on reservoir performance, and therefore the geologist (with the help of a reservoir engineer) must filter through the geological detail in order to determine what is/is not important for reservoir simulation. Iteration between the static and dynamic models is recommended in order to ensure that the relevant detail (flow units and barriers) is not compromised during the upscaling procedure.

Conclusions

The scope of production geological activities and methods has become very wide, requiring an equally diversified group of specialists to cover all topics. Advanced seismic techniques are employed at every stage, from discovery to additional development planning late in the life of a field. The backbone of the profession is formed by expert sedimentologists who can understand and model the architecture of reservoirs, including the features that influence fluid flow. There is clearly a division in clastic and carbonate reservoir expertise because of the difference in sedimentological and diagenetic processes and relevant analysis techniques.

Structural geology is another speciality that should be handled by experts. Again, there are large differences between faults and fractures in clastic and carbonate reservoirs. The advances in seismic resolution

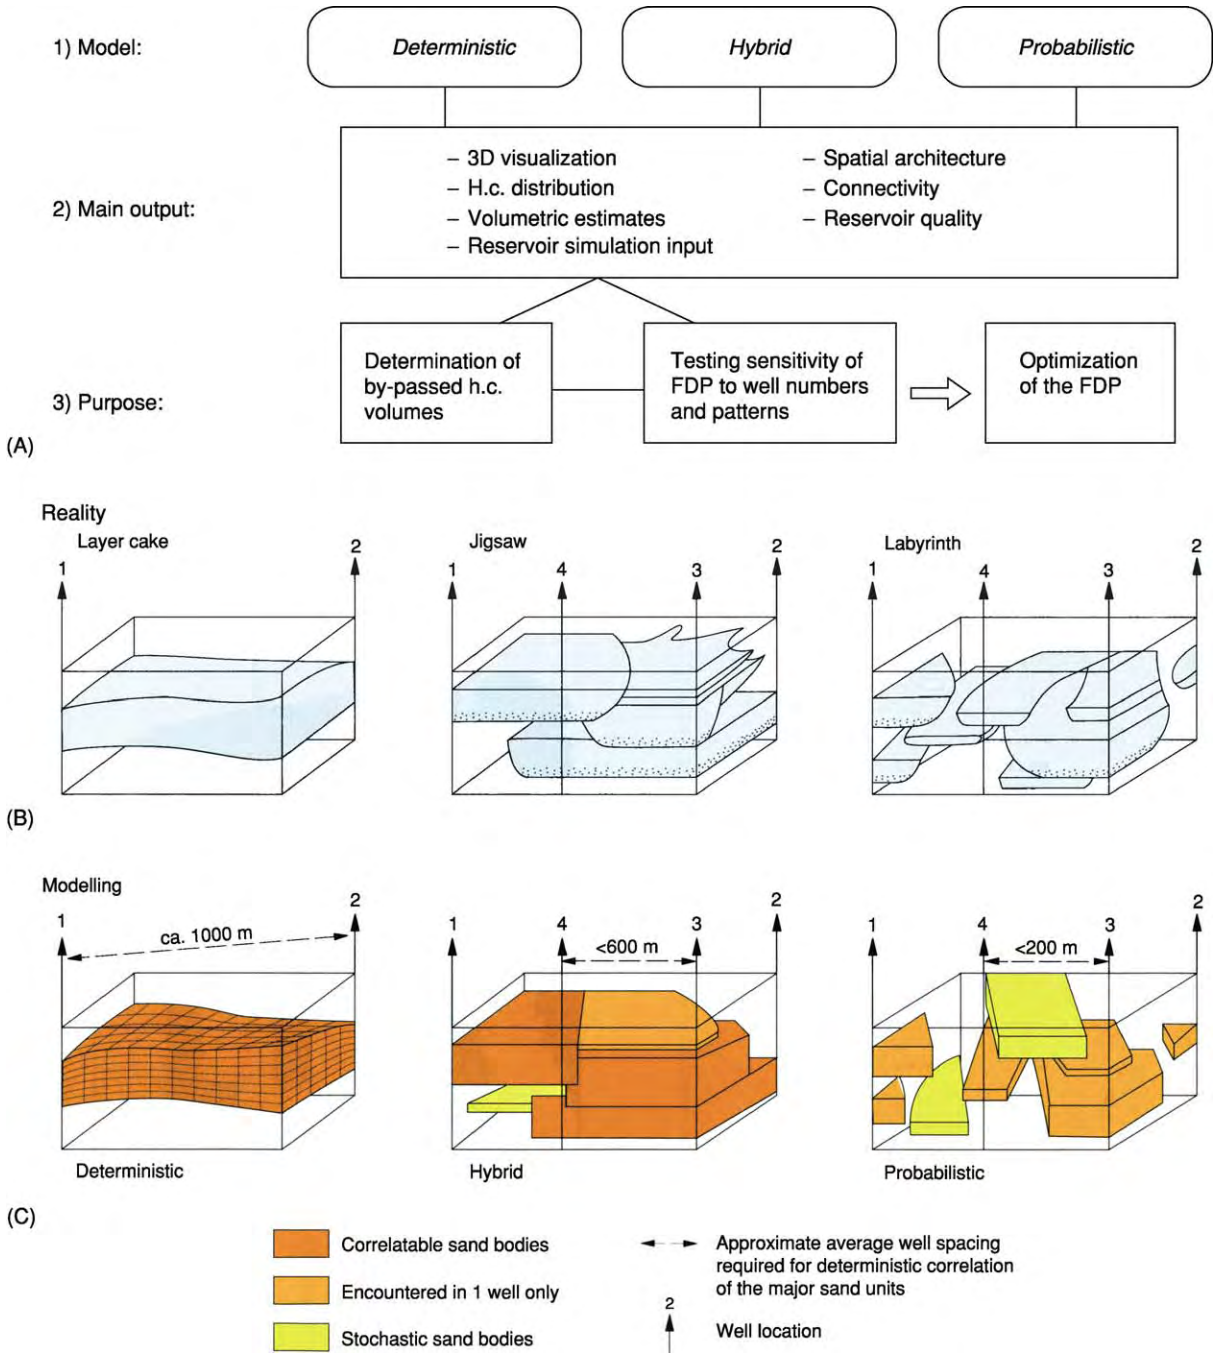

Figure 23 Summary of three dimensional (3D) reservoir modelling. Courtesy of Shell.

on the large scale and borehole imaging logs on the small scale have greatly improved the analysis of faults and fractures. Geostatistical methods are widely used in constructing maps and reservoir models, which reflect the level of uncertainty, but in which analogue information can be incorporated.

The present approach to production geology is heavily dependent on computer systems, and much of the time is spent behind a workstation or personal computer. Modern interactive computer techniques and integrated data systems are used to design models and well trajectories. Visualization plays an important part in this work and virtual reality techniques are already being used. Typical of the modern reservoir management approach is the integrated team composed of various production geology specialists, together with petrophysicists, reservoir engineers, and production technologists.

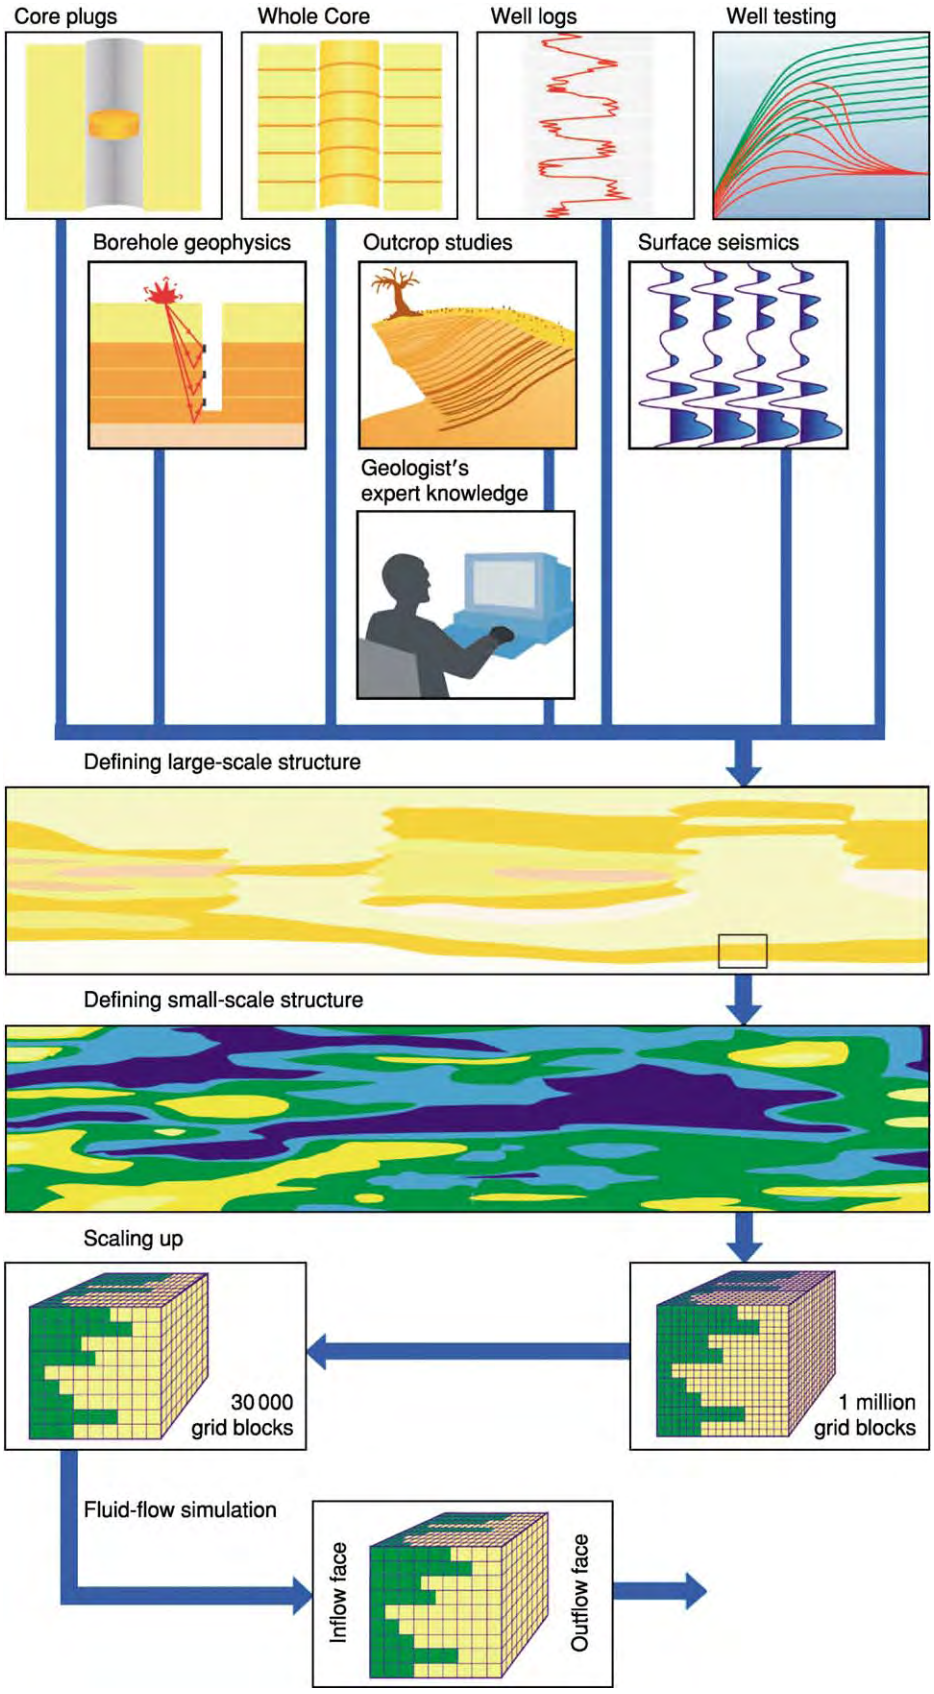

Figure 24 Building a reservoir model with measured data, expert knowledge, and statistics. © Schlumberger Limited, used with permission.

The future will undoubtedly bring important further improvements in seismic techniques. There is a need for more analogue data and sedimentological knowledge to aid in reservoir modelling. The reservoir models will benefit more and more from integration with seismic information, both with respect to reservoir architecture and to fluid content and movements. The high costs of deep-water field appraisal and development will place a premium on the timely construction of realistic reservoir models. On land, there is a large scope for enhanced oil recovery that equally requires reliable detailed reservoir models. Thus, it may be expected that there will be a significant further development in production geological techniques.

Reserves

R Arnott, Oxford Institute for Energy Studies, Oxford, UK

Introduction

Fossil fuels can be broadly categorized as either resources or reserves. Resources include all fuels, both those identified and those as yet unknown. Reserves are that portion of the identified resources which can be economically extracted and exploited using current technology. Petroleum reserves can be labelled under a wide variety of physical, chemical, and geological circumstances. For example, the boundaries between crude oil as a liquid and condensates have long been the subject of controversy. In addition, there are issues of definition as to what to include or exclude from a particular production forecast, as there are as to what can and cannot be reported as reserves because of legal and political considerations. The only near-certainty on the supply side is the actual volume of oil that has been produced. This is because the definitions of petroleum reserves often include assumptions with regard to existing technology and present economic conditions. However, there is no uniformity or stated policy as to the time period over which the existing technology and present economic conditions are anticipated to prevail. As a consequence, there is often fierce debate about how long existing petroleum reserves are likely to last and the economic consequences if future production cannot meet demand.

Definitions of Reserves

Because of the considerable uncertainty surrounding the definitions of reserves, most authors prefer a probabilistic rather than a deterministic approach (Figure 1). An initial declaration of recoverable oil that can, with reasonable certainty, be recovered in the future under existing economic and operating conditions is the usual definition of the 'proven' reserves. However, all fields will also be declared as having additional volumes of 'probable' and 'possible' reserves. The definition of 'proven', 'probable', and 'possible' reserves varies from country to country. 'Proven' reserves are usually defined as being P90 reserves, indicating that there is a greater than 90% chance that the actual proven reserves base will be higher, and a 10% chance that it will be less. Similarly, 'probable' and 'possible' reserves can be defined as P50 and P10 reserves, respectively. The important point here is that, when oil reserve numbers are quoted in the literature, it must be realized that the numbers are probabilistic and, in the case of proven reserves, are more than likely to be exceeded. Therefore, it is wrong for commentators to argue that the volumes of discovered reserves are a fixed entity as, in the case of proven reserves, there will be a 90% chance that the initial reserve number will be exceeded.

Declarations of proven reserves are often only for a specific reservoir. Therefore, when such information is summed, eventually, to the regional and national level, the simple arithmetical addition of a large number of independent values, each representing the 90% probability of a specified volume in a specific reservoir, produces a higher joint probability of the total. It is for this reason that field growth and rates of field growth are well documented in practice.

Resources can be defined as existing reserves plus all of the accumulations of reserves that may eventually become available. These additional reserves might have already been discovered but be uneconomic, or may not yet have been discovered. The distribution of fossil fuels can therefore be viewed as a pyramid, with a small amount of higher quality resource at the top, but with increasingly large amounts of lower grade resource as we move down the pyramid (Figure 2). The costs of retrieving the resource increase lower down in the pyramid, making a larger amount of the resource available at higher prices. The issue as to what defines the total volume of petroleum resources depends on where the pyramid is sliced, and this is a very subjective decision.

There is often a curious circularity in the estimates of undiscovered and ultimate reserves. Undiscovered reserves are the difference between estimates of the discovered and ultimate reserves. However, ultimate resource estimates obviously depend on an estimate of undiscovered reserves. Although there are a number of ways in which to try and surmount this difficulty, the most commonly described method involves an examination of the discovery pattern. In general, there is some regularity to this pattern, with the largest fields being discovered first with attention then switching to the smaller fields. Therefore, in any one basin, the curve (commonly referred to as the creaming curve) relating cumulative discoveries to wildcat wells is usually hyperbolic with the asymptote revealing the level of ultimate reserves. However, this method is not immune to error, especially if larger

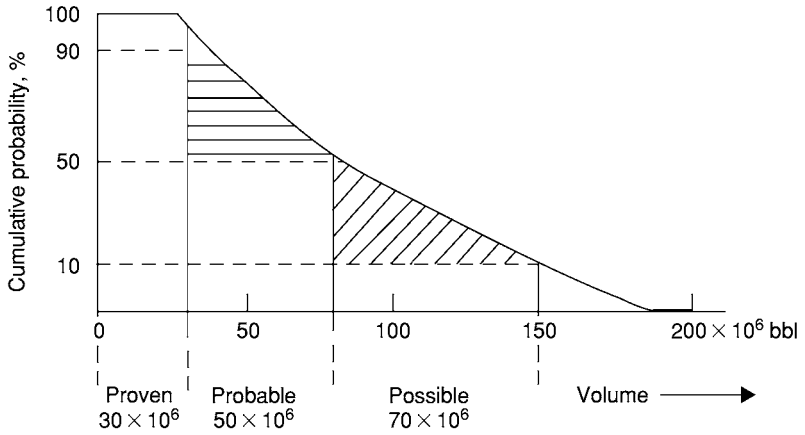

Figure 1 Expectation curve used to find approximate values of proven, probable, and possible reserves. bbl, barrels.

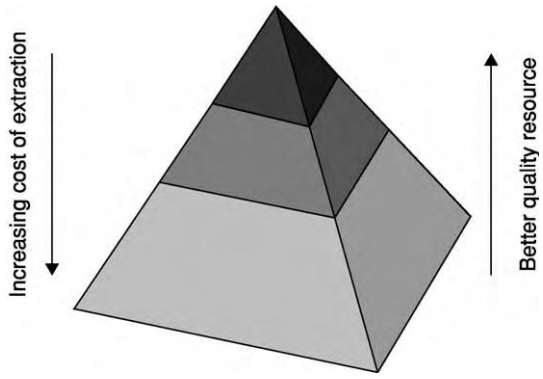

Figure 2 Resources visualized as a pyramid, with a small volume of prime resources that are of high quality and easy to extract, and a large volume of resources of lesser quality that are more difficult or expensive to extract.

fields are discovered late in the life of a particular basin. In the case of the UK sector of the North Sea (Figure 3), the asymptote has moved over time as the older fields have grown in size through better recovery techniques and reservoir definition. As a consequence, estimates of the total resource base have almost doubled in size from the initial values.

Predictions of Ultimate Recoverable Reserves

Numerous authors have attempted to predict the magnitude of the ultimate recoverable resource base. What is interesting about these estimates is that they all essentially identify those crude oil reserves that will be produced over the next 40–50 years. In other words, every assessment tends to slice lower through the resource pyramid (Figure 2). Estimates of the ultimate resource vary significantly depending upon the relative optimism or pessimism of the subsurface geotechnical assessment, as well as the definition of what is the minimum size of economic importance.

Recent estimates of the ultimate recoverable reserves of oil (Figure 4) vary between 1.5 and 3.8 trillion barrels. It is interesting to note that, despite the range of estimates, the mean estimate has remained stable at 2 trillion barrels for at least the past 20 years, suggesting that technology has reached an asymptote. Of course, not all of the estimates are based on the same set of data, as different estimates slice the resource pyramid at different levels. The most pessimistic estimate only includes conventional oil reserves and excludes all other oil types (for example, heavy oil, tar sands, secondary recovery). In contrast, the optimistic estimate by the United States Geological Survey (USGS) only excludes from its estimates oil from tar sands, oil from polar regions, and oil shales. However, nearly all estimates rely on existing technology and do not attempt to predict the impact of future technological developments. As a result, the estimates can only be regarded as static estimates at a fixed point in time under a particular set of technological and economic circumstances.

The actual volume recovered will depend on a number of factors, not least whether the reserves are economic to extract. Political, economic, and technological constraints all play a role in deferring or accelerating production. In addition, there is interplay with other sorts of fuel, which is likely to have a significant impact on determining the rate of extraction.

Historical evidence from producing fields highlights the fact that reserve estimates are dynamic as circumstances change and knowledge and technology progress. An understanding of the potential importance of the growth of reserves can be gained from considering the current estimate of the global oil resource base and the current average recovery factor. Using consensus estimates that the global average

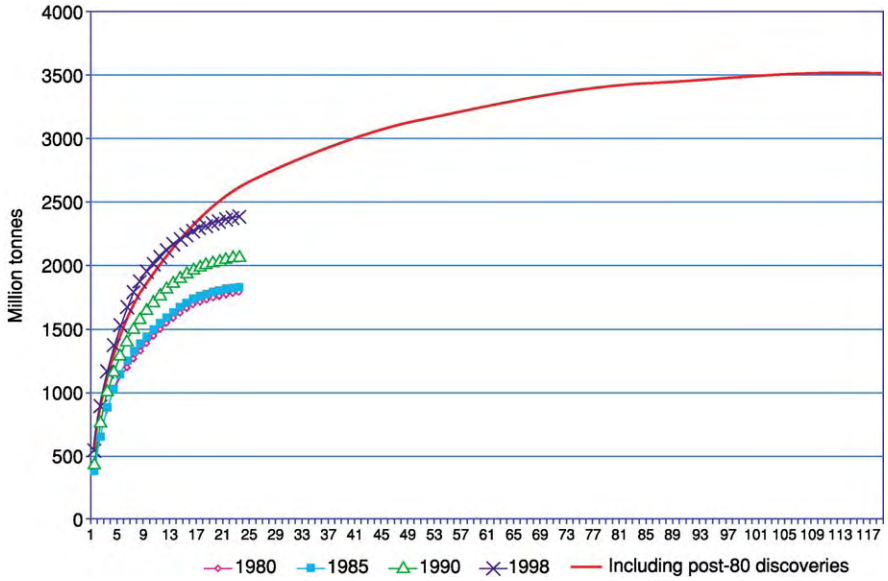

Figure 3 Creaming curves for the UK sector of the North Sea showing the impact of reserves creep on the older fields. The upper curve includes all fields that had been discovered and were producing by 1998. The symbols represent estimates of the same 25 fields made at different times (1980, 1985, 1990, and 1998). The figure shows the change in estimated size of these discoveries. The full line shows the addition of a further 100 discoveries made up to 1998 and which are currently in production.

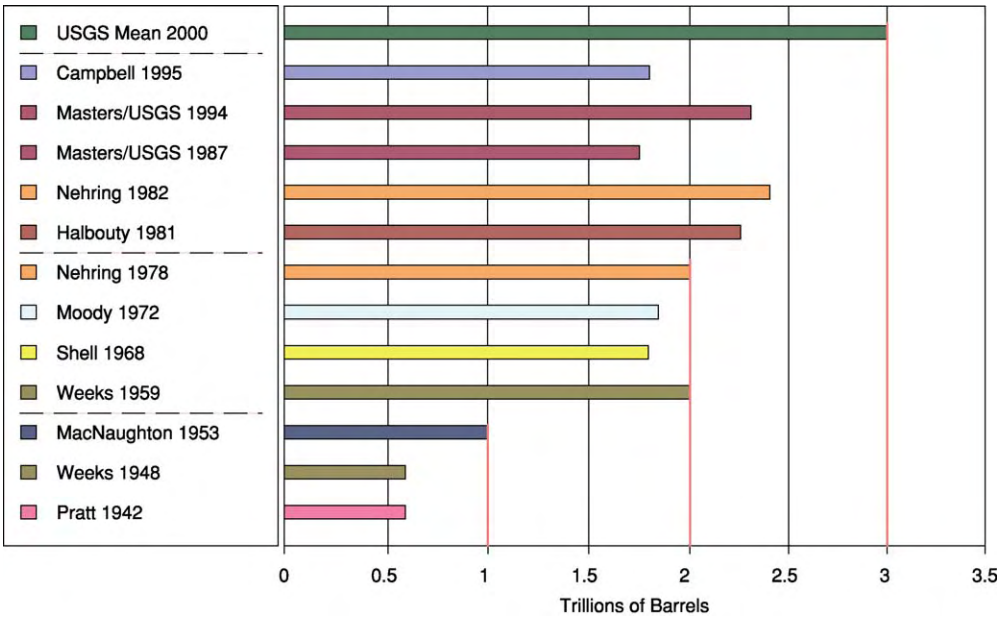

Figure 4 Published estimates of world ultimate oil recovery (trillions of barrels). This chart shows the various published estimates of ultimate oil recovery through time. Earliest estimates made in the 1940s suggested an ultimate recovery of around 0.5 trillion barrels. However, the average estimate since Halbouty (1981) has been around 2.0 trillion barrels. USGS, United States Geological Survey.

oil recovery factor is around 35% (Figure 5), and that the current resource base of reserves is around 2 trillion barrels, original oil in place would be nearly 6 trillion barrels. Therefore, every 1% increase in global oil recovery would lead to an additional 55 billion barrels of oil being produced. Moving the average global recovery factor up to 45%, a not unrealistic target, could increase global recoverable reserves by around 550 billion barrels.

Over the past 50 years, estimates of global recoverable oil reserves have risen annually, except for two small falls in the late 1970s, despite annual increases in oil production (Figure 6). This has led to a great deal of attention being paid to reserve reporting by

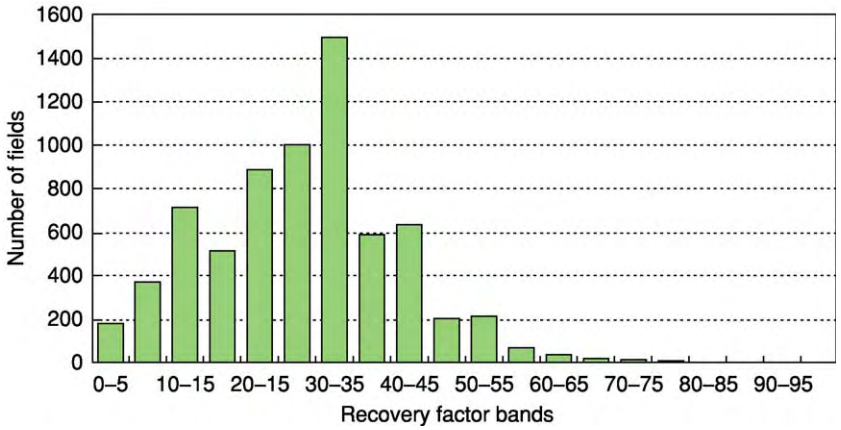

Figure 5 Distribution of recovery factors in all currently producing oil fields.

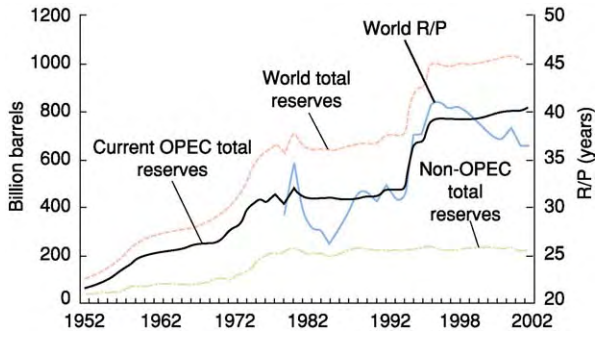

Figure 6 Global estimated reserves and reserves to production (R/P) ratios by year. OPEC, Organization of Petroleum Exporting Countries. R/P, reserves to production ratio.

companies and countries. Individual Organization of Petroleum Exporting Countries (OPEC) members have been accused of inflating reports of reserves because export quotas were originally based on estimates of recoverable reserves. The huge reserve revisions reported by many OPEC companies in 1987 have been used by some to undermine confidence in published numbers. In reality, it is possible that previous OPEC estimates were too conservative, having been inherited from private companies before nationalization.

Although the absolute level of reserves has risen only slightly over the past 5 years, within that total, upward revisions to existing fields and discoveries have exceeded 150 billion barrels, 30% more than actual consumption. The USGS recently published a mean estimate of 612 billion barrels from increased recovery, significantly increasing their estimate of the world's ultimate recoverable reserves. In the UK sector of the North Sea, reserves have grown by an average of 35% from the time of field approval (Annex B) to the present day or abandonment (Figure 7).

Estimates of the total resource base remaining depend not just on new discoveries being made and brought on stream, but also on the amount of reserves used due to depletion of existing fields. Over 70% of current world oil supply comes from oil fields that were discovered prior to 1970, and 14 of these fields produce over 20% of the world's total supply. Even though data for many of these fields are very hard to come by, the decline rates for these fields are likely to become of increasing importance in the future. However, the effect of depletion is often overstated as forecasters often assume a depletion rate of 10–20%, and no further investment. As an example, estimates of non-OPEC production have always tended to indicate that production is at or near its peak, and yet overestimation of depletion rates has led to successive estimates being proven to be incorrect (Figure 8).

The Peak Oil and Depletion Debate

Ever since oil was first produced in significant quantities over 140 years ago, debate has taken place on whether petroleum will run out within the foreseeable future. Historically, near-term supply concerns arise when the relative rate of production capacity growth falls short of expected rates of demand growth. Through time, however, changing attitudes to oil supply and demand have led to varying perceptions of whether the resource is in short supply or not. It is also noticeable that changes in perception can take place over a very short period of time depending on a particular event on either the supply side or the demand side. The discovery of super giant oil fields in Texas in the 1930s gave rise to perceptions of a huge glut in oil. This perception was sustained by the discovery of major reserves in the Middle East. However, by the early 1970s, there was a clear paradigm

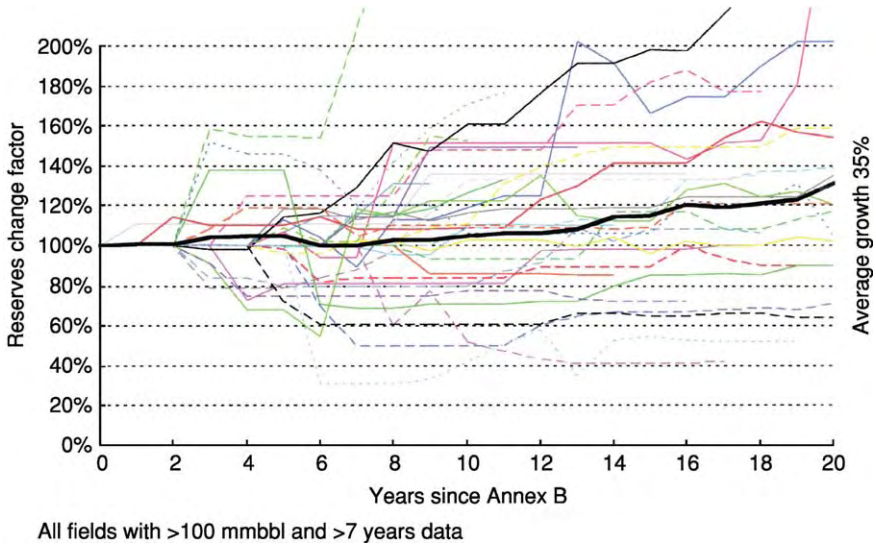

Figure 7 Growth of reserves in UK oil fields. This chart shows the change in reserve estimates of UK oil fields with time, since their 'Annex B' approval. Some field estimates have decreased, but most have increased very substantially. The average of all the fields (full line) has grown by 35% over 20 years.

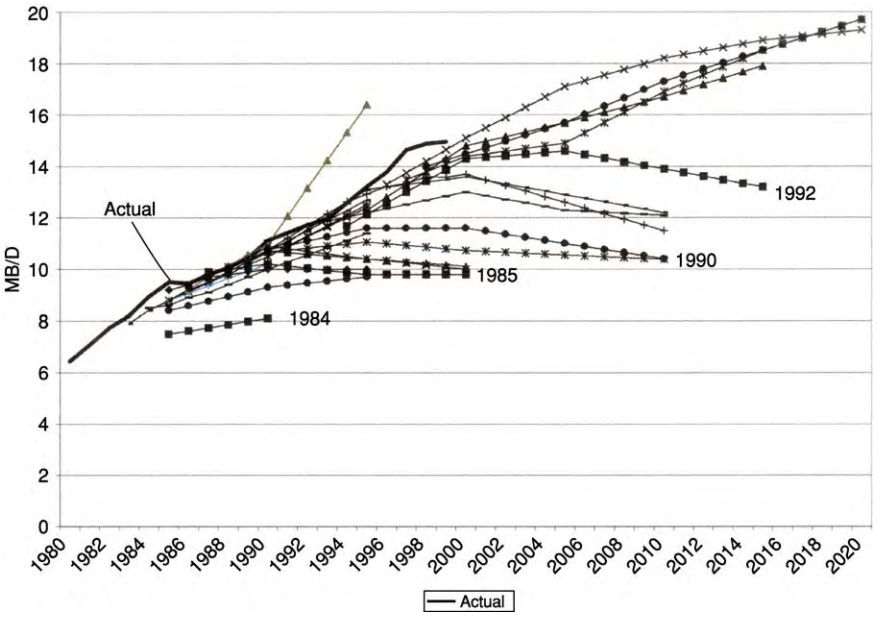

Figure 8 Forecast of non Organization of Petroleum Exporting Countries (OPEC) Third World oil production over time made by the United States Department of Energy. The chart shows that estimates of non OPEC production have consistently proved to be conservative through time. For example, the forecast made in 1990 for the year 2000 is now some 4 million barrels per day lower than actual production. MB/D, million barrels per day.

shift as part of a trend towards pessimism about resource availability as studies began to emerge that oil production outside the Middle East had peaked. This was triggered when US production levels started to fall from peak levels by the end of the 1980s. In the 1990s, the introduction of new development techniques to boost recovery rates, coupled with the revolution in computers which transformed seismic acquisition and processing, the technical innovations that enabled deep-water development, and the opening up of new petroleum provinces that were previously closed due to political constraints, all led to a period of optimism that weakened concerns about the exhaustibility of reserves. More recently, these

concerns have been raised again as the oil industry worldwide struggles to replace its reserves and achieve targeted rates of production growth.

Much of the published literature on the depletion debate falls into two camps. On the one hand, there are those who warn of the imminent danger of a collapse in oil supply and the economic consequences of that occurring. On the other hand, there are those who argue to varying degrees that there is no limit to oil supply in the near future. What is common to both camps is the extensive reference to the work of King Hubbert.

Hubbert gained prominence in the American geological community because he anticipated the peak and subsequent fall of US oil and gas production. At the heart of his prediction was the assumption that all resources are finite, and that eventually all resources will be depleted and exhausted over a period of time that is determined by the rate of production.

Hubbert argued that the complete cycle of exploitation must have the following characteristics. Beginning at zero, the rate of production tends initially to increase exponentially. Then, as difficulties of discovery and extraction increase, the production rate slows in its growth, passes one or more maxima and, as the resource is progressively depleted, declines eventually back to zero. He argued that this cycle of production would be bell shaped when plotted against time. The approximate rule here is that peak production will correspond to the mid-point of depletion and that this usually occurs about 20–25 years after the discovery of the mid-point. Although some production curves do have a shape that approximates such a 'normal' distribution, there is no inherent reason why production should follow such a pattern, and some production curves show very strong asymmetry. For example, when production is dominated by a small number of large fields, peak output tends to precede the depletion mid-point. Where the discovery pattern is more dispersed, or where offshore fields are significant, the production peak usually comes after the mid-point.

Hubbert's basic assumption was that, if known past and prospective rates of production are combined with a reasonable estimate of the amount of fuel initially present, one can calculate the probable length of time that the fuel can be exploited. In other words, the area under the complete production curve would be equal to the size of the resource. However, estimating the amount of oil and gas that will ultimately be discovered and produced in a given area is full of uncertainty, as we have seen. The Hubbert curve might have fitted US production, but, on a global scale, the modelled curve no longer fits the historical data (**Figure 9**). Up until the mid-1970s, the modelled production matched the actual production, but, after the supply shocks, which led to sharp oil price rises, annual increases in demand for oil fell from around 7% to just 2% per annum.

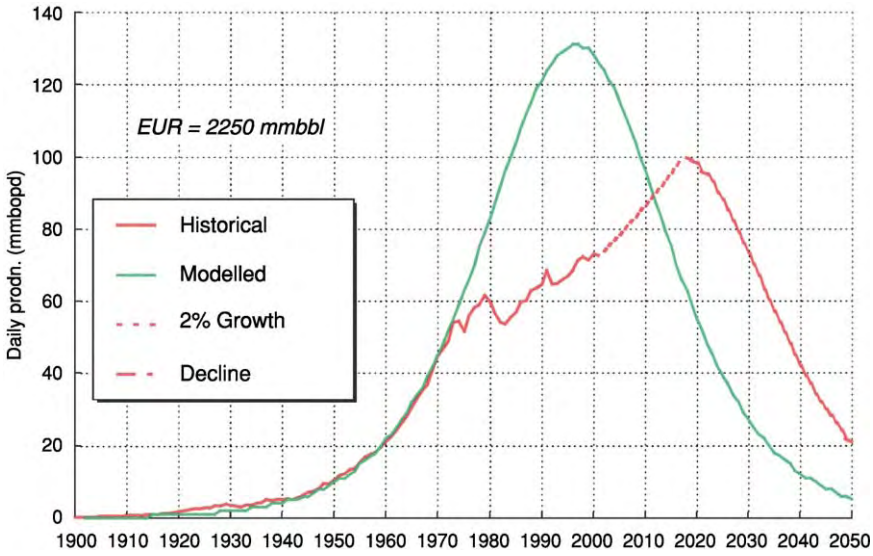

Figure 9 World production and the Hubbert peak. This chart shows a theoretical Hubbert curve based on production up to the oil price shocks of the 1970s. The resulting high oil prices led to a decrease in demand for oil. As a result, the slope of the oil supply curve departs from the predicted Hubbert curve after 1973. Assuming oil demand growth of 2% from 2003, and an ultimate reserve base of 2.25 trillion barrels, the peak in oil production could be reached in 2018. The chart highlights the impact that changes in demand can have on predictions of when global oil production will peak. mmbbl, billion barrels; mmbbpd, million barrels per day.

Models of Resource Depletion

There are, in essence, two main models that have been applied to the estimations of the volume of remaining reserves and the rate of depletion. On the one hand, there is the model for an open market and, on the other, the model for a closed market. The closed market model, in essence, treats the global oil reserves as a finite or 'fixed stock', whereby market depletion would ultimately result in higher prices. In the open market model, the cost of new energy sources is forecast to fall because of technological innovation, economies of scale, and the development of efficient systems of transportation. With lower costs, new energy sources become competitive with existing energy sources and ultimately lead to their replacement. The open market model could ultimately lead to lower energy costs through time through the potential substitution of fuels, in particular natural gas.

The open market model has stronger affinities to actual market examples. The US energy market is an open market, which has benefited from a long-term reduction in energy prices despite rising demand. Coal substituted for firewood; petroleum substituted for whale oil for illumination purposes, and eventually coal for transportation; gas substituted for coal in domestic heating; and gas and coal are currently competing in the electrical generation sector (Figure 10).

The End of the Petroleum Era?

With any finite resource, there will come a time when unfavourable economics will not permit further extraction. Worries concerning the long-term supply of petroleum began shortly after production started in 1859. The huge growth in energy markets after World War II also led to renewed fears that fossil fuels would be exhausted. In the 1970s, many people argued that the growth in world population and industrial production would lead to the total depletion of oil within 50 years of the forecast. The fact that the deadlines for these scenarios have now passed, and oil production and reserves continue to rise, shows that these forecasts were all overly pessimistic.

The resource exhaustion spectre was initially raised largely on the basis of a comparison of the current year's oil production with the so-called proven reserves of oil. However, this type of evaluation is inadequate as proven reserves represent nothing but the working stock of the oil industry. For example, the 'optimum' reserves life of 10 years is merely an expression of confidence from private and state oil companies as to where oil will come from in the future in order to fund investment in new infrastructure. Therefore, the current reserves life of oil is deemed to be irrelevant, especially in the context of a global reserves life that has risen to around 40 years from 1940 to 1975 despite the significant increase in global production.

The debate has now moved on from reserves life to a focus on the point in time when global production starts to decline. Supporters of this 'peak oil' school of thought forecast serious economic and social consequences in the aftermath of this occurring.

They highlight the fact that most of the world's major oil discoveries were made during the 1960s and 1970s and that, since that time, the discovery rate has declined (Figure 11). Using examples from various basins around the world, not least the USA, it is argued that peak oil production usually occurs around 25–30 years after peak exploration success. Using this as a proxy, it is predicted that oil production will peak within the next 10 years and, given that there are no near-term substitutes to oil, an economic crisis will ensue.

The Economic Viewpoint

One key assumption made by the supporters of 'peak oil' is that the resource base is finite. However, the amount of oil that can be recovered depends not only

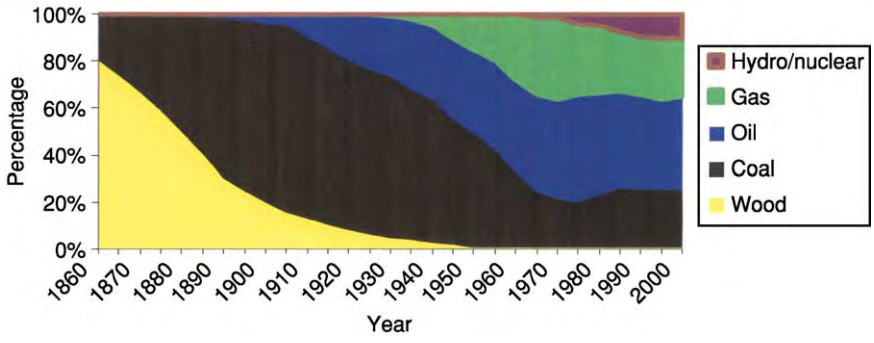

Figure 10 United States primary energy consumption by fuel, 1860 2000.

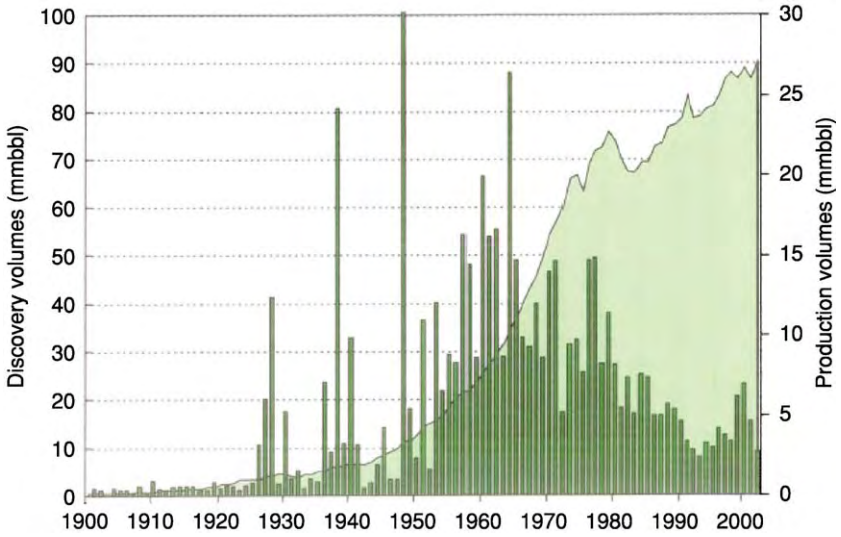

Figure 11 Discovery volumes and world oil production, 1900 2000. mmbbl, billion barrels.

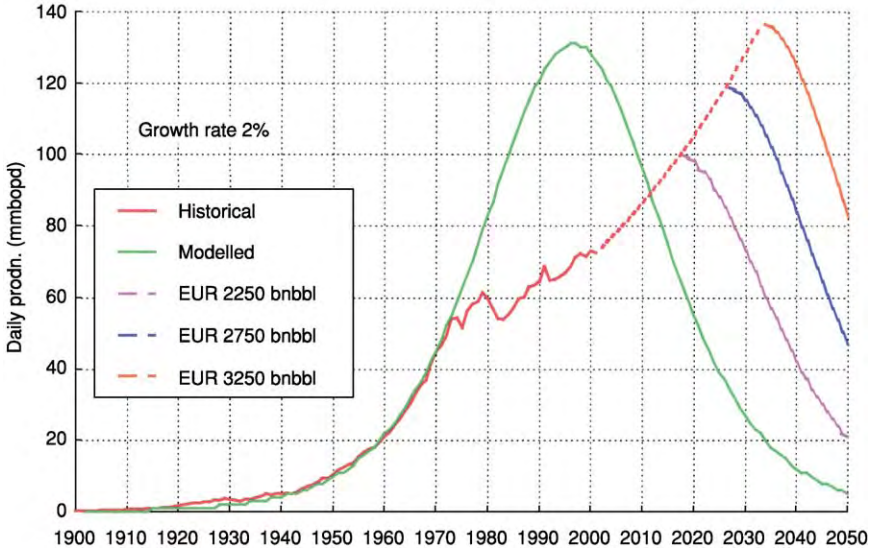

Figure 12 The effect of changing the resource base on the timing of peak oil. bnbbl, billion barrels; mmbopd, million barrels oil per day.

on the total resource base of oil, but also on dynamic variables, such as price, infrastructure, and technology. The level of peak production will also increase if recoverable reserves rise and, as a consequence, the timing of peak oil will be pushed further into the future (Figure 12).

Economists argue that oil reserves are not a 'fixed stock' and that energy has not been getting scarcer in basic economic terms, but rather has been getting more plentiful. The fall in the long run cost of oil production has been used in support of this argument. It is also argued that there is no such thing as an exhaustible natural resource and that the total petroleum reserves in the Earth are an irrelevant non-binding constraint. If oil becomes uneconomic to produce, the industry will disappear and whatever is left in the ground will remain unknown: a geological fact of no economic interest.

On the demand side, it has been proven wrong to project current rates of growth well into the future. For example, in the late 1970s, the history of nearly 30 years of an average 7% per annum rate of growth in oil demand still played a powerful role in determining attitudes to the longevity of oil resources. This was at a time when growth rates had already fallen to around 1% per annum and when most

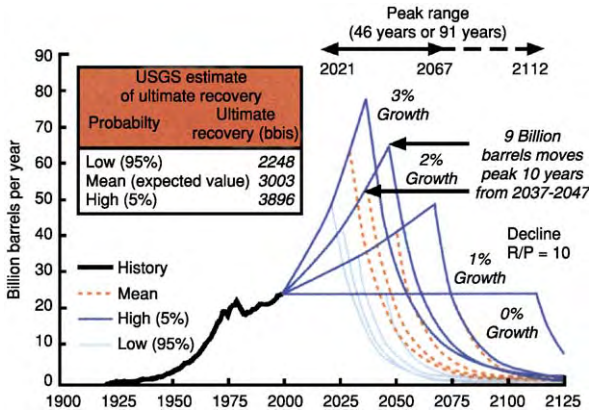

Figure 13 Conventional oil supply model showing the timing of peak oil with four rates of oil demand growth. R/P, reserves to production ratio; USGS, United States Geological Survey.

economists were forecasting a maximum growth rate of 3%. Changes in forecast to oil demand therefore have a major impact on the timing of peak oil; a difference of just 3% in average annual demand growth for oil gives a 46 year range in the timing of peak oil (Figure 13). Similar arguments can be applied to changes in the level of investment and the rate of depletion.

The Real Debate

The amount of fossil fuel on our planet is finite, certainly within the time-frame of civilization. However, does this necessarily mean that we will run out of petroleum reserves imminently or at all? Or will we develop alternative sources of energy long before the planet's petroleum reserves have been extracted? The changing pattern of world oil supply has meant that many of the predictions that oil would run out by the turn of the twentieth century have been proven wrong. Fears of impending scarcity of non-renewable energy have all been proven to be groundless as important changes on both the supply and demand sides have occurred.

The history of those who predict future trends in the depletion of petroleum reserves is one of persistent tension between those who assert that the best decisions are based on quantification and numbers, determined by the patterns of the past, and those who base their decisions on more subjective beliefs about the uncertain future. Ultimately, oil is a finite resource, but the real debate is not so much whether we are likely to significantly diminish the petroleum reserve base within the next few decades, but whether prices will fluctuate sufficiently to enable energy substitution. Volatility in the price of oil will sharpen the debate and could actually cause near-term unjustified changes in investment patterns by industry and governments alike.

PLATE TECTONICS

R C Searle, University of Durham, Durham, UK

Introduction

In the theory of plate tectonics, it is assumed that the Earth has a thin, brittle, outer layer, or 'lithosphere', which is broken up into a small number of tectonic 'plates'. These plates are further assumed to be rigid and undeformable, but capable of independent motion relative to each other on the surface of the Earth. The different relative motions of the plates are considered to be responsible for much of the varying geological activity on the Earth. The plate motions are describable in simple geometric terms and, once they have been determined, usually from a limited number of observations; they can be used to predict the type, magnitude, and direction of relative motions across plate boundaries anywhere in the world, both present and past. The power of plate tectonics theory arises both from its unifying view of global tectonics and from its powerful predictive ability. The subject of plate tectonics, *sensu lato*, is sometimes divided into 'plate kinematics', which deals with plate motions and their geometry, and plate tectonics *sensu stricto*, which deals with the geological consequences of the motions.

Tectonic Plates, Lithosphere, and Asthenosphere

The fundamental assumption underlying plate tectonics is that the outer part of the Earth consists of a small number of thin, rigid plates which are curved to fit the spherical shape of the Earth. The plates are considered to suffer no internal deformation, and only to deform and interact with each other along their boundaries, which are considered to be very narrow compared with the plate dimensions.

This view arose in the 1960s, largely as a result of the newly observed pattern of global seismicity provided by the World Wide Standard Seismograph Network. This showed that, over much of the world, earthquakes occur in narrow bands no more than a few tens of kilometres wide, whilst the large areas between these bands are essentially aseismic (Figure 1). The assumption was made that the aseismic areas are largely devoid of deformation and behave rigidly, and the bands of seismicity mark the plate boundaries. In simple plate tectonics theory, the plate boundaries are considered to have negligible width, although in practice they are associated with narrow but finite bands of geological activity (*see* **History of Geology Since 1962**).

Early workers on plate tectonics theory divided up the Earth's surface into about 12 major plates (Figure 2), although since then considerable numbers of smaller 'microplates' have been recognized.

The rigid outer layer of the Earth, which comprises the plates, is known as the 'lithosphere', from the Greek '*lithos*' meaning stone. Below this is a weaker layer, the 'asthenosphere' (Greek '*asthenia*', weakness), which deforms relatively easily and allows the plates to slide around. It is important to understand that these are terms describing the mechanical behaviour of the Earth and not its composition. In particular, the lithosphere does not normally correspond to the crust, but comprises both the crust and the uppermost part of the upper mantle, which usually behave together in a brittle manner (*see* **Earth:** Mantle; Crust). The lithosphere ranges in thickness from a few kilometres at mid-ocean ridge axes (where it may be entirely crust) to around a hundred kilometres in old ocean basins, and perhaps several hundred kilometres under continental cratons (where it is predominantly mantle). The asthenosphere constitutes a relatively weak layer of mantle below the lithosphere, capable of plastic deformation. The thickness of the asthenosphere is less well defined than that of the lithosphere, but may range from around 50 km in some places to several hundred kilometres, and may even encompass the whole upper mantle. Furthermore, except in the case of some subduction zones (see below), tectonic plate boundaries do not follow the boundaries between continents and oceans. An individual plate typically comprises regions of both continental and oceanic crust. For example, the South American plate consists of the continent of South America plus the western half of the South Atlantic Ocean (Figure 2).

The different mechanical behaviours of the lithosphere and asthenosphere are explained by the different deformation mechanisms that occur at different temperatures and pressures. At relatively low temperatures, most rocks deform elastically and suffer brittle failure (faulting) when their elastic limit or 'strength' is exceeded. This strength increases with pressure and hence depth (Figure 3). However, as the temperature increases, solid-state creep becomes increasingly important. Deformation by this mechanism becomes easier at higher temperatures, and the rock weakens exponentially (Figure 3). The depth at which brittle deformation gives way to ductile creep

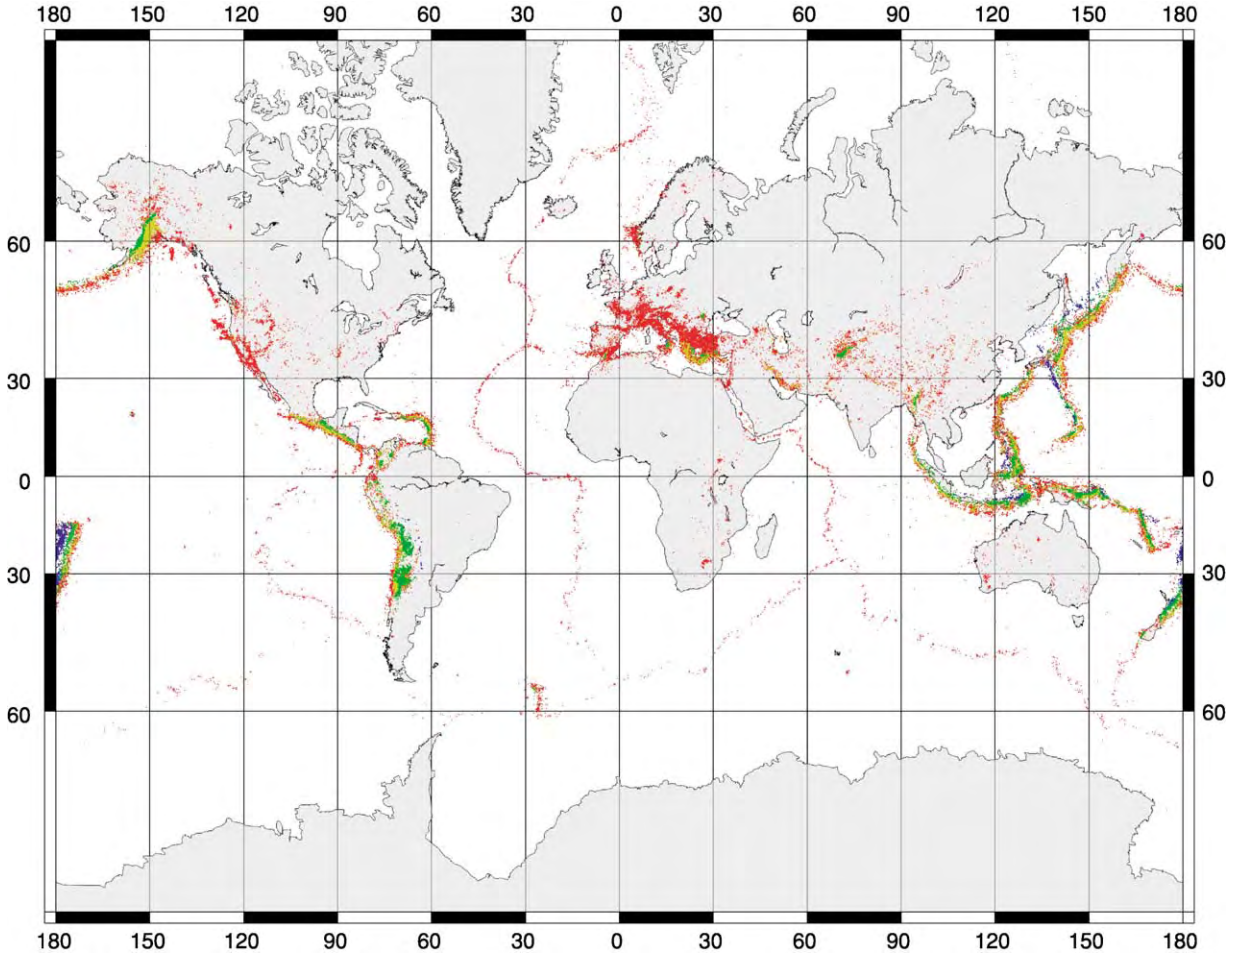

Figure 1 Distribution of shallow (0 33 km, red), intermediate (33 70 km, yellow; 70 300 km, green), and deep (300 700 km, blue) earthquakes of magnitude 4.0 or greater recorded between 1990 and 1996. Reproduced from D. Sawyer, http://www.geophysics.rice.edu/plateboundary/intro.html.

depends mainly on the composition of the rock, the rate of strain, and the geothermal gradient. Laboratory measurements of the mechanical properties of rocks and minerals predict depths of the brittle–plastic transition in the range suggested for the base of the lithosphere by observations of the Earth.

Evidence for the existence of the lithosphere and asthenosphere comes from a variety of sources. Seismic waves generated by earthquakes, particularly shear or S waves, show very little attenuation of their energy whilst travelling through the lithosphere, but are attenuated somewhat more in the asthenosphere (*see* **Tectonics:** Earthquakes). The velocities of these waves through the Earth show a marked decrease in the region of the asthenosphere. The effective viscosity of the Earth's mantle, as inferred from, for example, the rate of uplift of continental areas following the retreat of glaciers, shows a decrease in viscosity in the asthenosphere.

In general, crustal rocks are weaker than mantle, and, because oceanic crust is much thinner (around 6 km) than continental crust (approximately 35 km), oceanic lithosphere has a much greater component of mantle rocks and is correspondingly stronger. For this reason, oceanic areas tend to behave in a more rigid way than continents. In particular, continental mountain belts often display deformation over quite broad zones compared with oceanic plate boundaries (Figure 1).

Plate Tectonics

Although plate boundaries are primarily defined by the earthquakes along their boundaries, they are also marked by distinctive morphological features, narrow bands of tectonic activity, and, especially at transform boundaries (see below), by individual major faults. The active plate boundary may be only

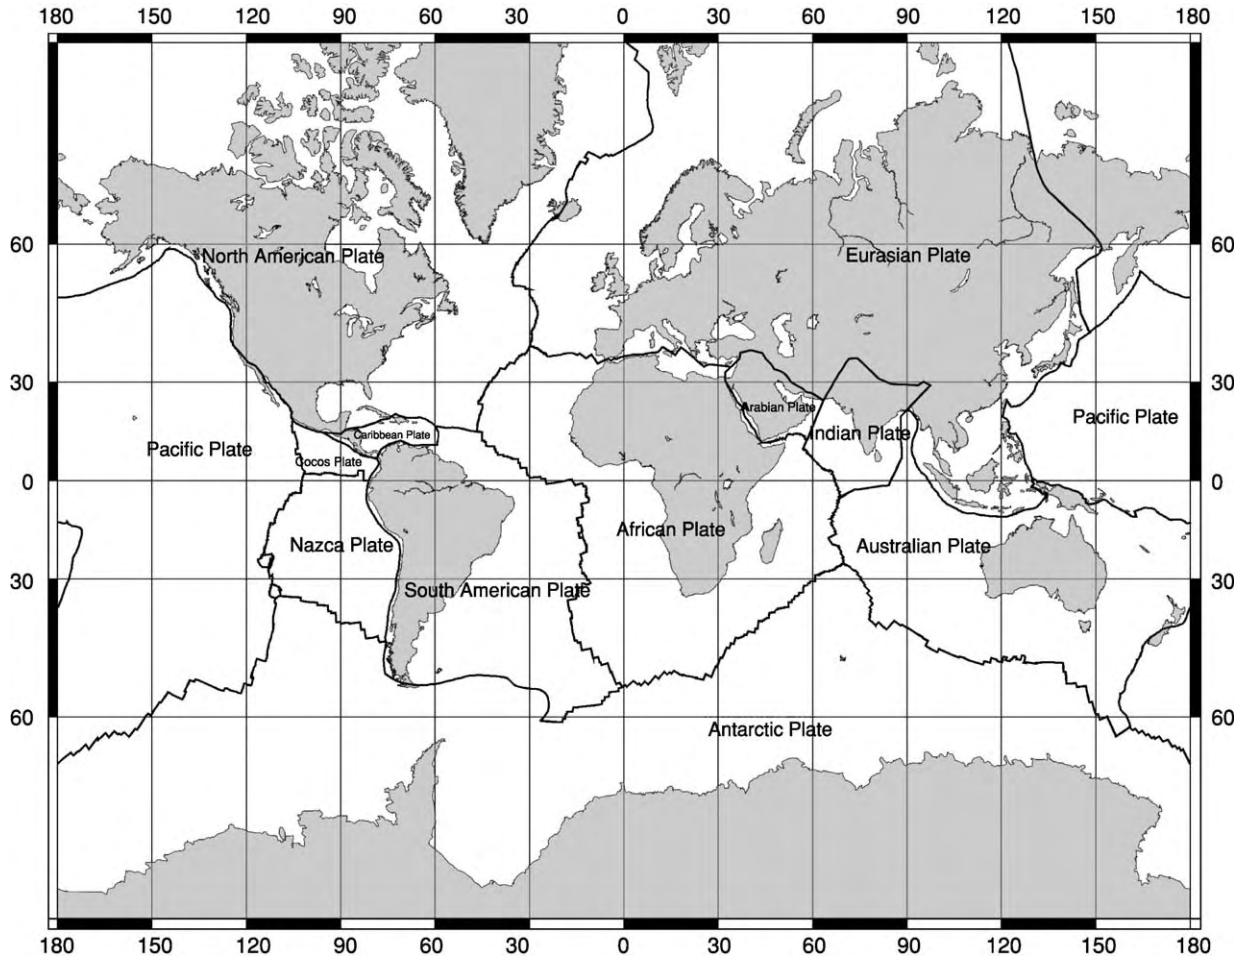

Figure 2 Major plates of the world and their boundaries. Reproduced from D. Sawyer, http://www.geophysics.rice.edu/plateboundary/intro.html, after D. Mueller, University of Sydney, Sydney, Australia.

a few kilometres wide, and rarely more than a few tens of kilometres.

Three types of plate boundary are recognized, corresponding to the three types of relative motion (Figure 4): 'divergent' (also 'ridge' or 'accretionary') plate boundaries, 'transform' (or conservative) plate boundaries, and 'convergent' ('subduction' or destructive) plate boundaries. In general, any type of plate boundary can join any other type.

Divergent (Ridge) Boundaries

Divergent boundaries occur only at mid-ocean ridges, and are the sites of creation of new lithosphere by seafloor spreading (*see* **Tectonics:** Mid-Ocean Ridges). The Mid-Atlantic Ridge and East Pacific Rise are typical examples. These boundaries are characterized by extensional tectonics dominated by normal faulting and extensional earthquake focal mechanisms. Generally, a divergent plate boundary is approximately orthogonal to the plate separation or spreading direction, but this is not essential, and ridges with greater or lesser extents of obliquity are fairly common.

The mid-ocean ridges associated with these plate boundaries arise because new plate is created at the boundary; thus, the plate gets older with increasing distance from the plate boundary and, as it does so, it cools, becomes denser, and thermally contracts. The plate boundary is thus the youngest, hottest, and shallowest region, forming the crest of the mid-ocean ridge. The detailed morphology of the plate boundary appears to depend on the temperature of the underlying mantle, which is mainly controlled by the spreading rate. For 'slow spreading ridges' (with a plate separation rate of less than about 60 km per million years), there is usually a 'median valley', a few kilometres deep and a few tens of kilometres wide, formed by rifting (Figure 5). At 'fast spreading ridges' (separation faster than 70 km per million years), the plate is too hot and weak to support rifting, and instead there is a volcanically built axial high.

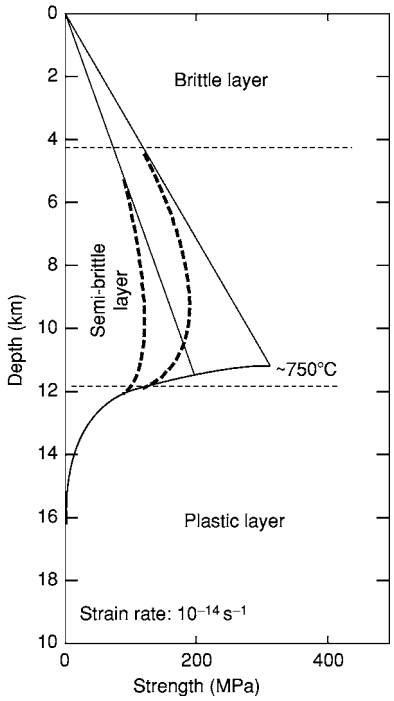

Figure 3 Calculated strength envelopes for material subject to brittle, semi brittle, and plastic deformation with increasing depth. Reproduced from Searle RC and Escartín J (2004) The rheology and morphology of oceanic lithosphere and mid ocean ridges. In: German C, Lin J, and Parson L (eds.) *Thermal Regime of Ocean Ridges and Dynamics of Hydrothermal Circulation. American Geophysical Union, Geophysical Monograph*, Fig. 8. Washington, DC: American Geophysical Union.

Ridges are formed by melting of dry mantle at depths of ~60 km, producing basaltic magma. Basaltic volcanism is widespread at mid-ocean ridge plate boundaries.

Plate tectonics theory allows for asymmetrical spreading (one plate accreting faster than the other). However, although temporary asymmetrical spreading is common, the net effect averaged over millions of years is usually approximately symmetrical. The precise reasons for this are not fully understood.

Transform Boundaries

Transform boundaries are those in which plates slide past one another with essentially no convergence or divergence; they thus conserve the areas of the adjacent plates. Because of this, they have the important property that they are exactly parallel to the direction of relative plate motion, and can be used for its estimation. Transform boundaries are characterized by strike-slip faulting and earthquakes with strike-slip mechanisms. A typical example of a transform boundary is the San Andreas Fault Zone in California, USA (Figure 6).

In simple plate tectonics theory, a transform boundary consists of a single fault called a 'transform fault', although, in practice, there is often a zone of such faulting some tens of kilometres wide. Because there is no large-scale convergence or divergence at these boundaries, there is also relatively little vertical relief,

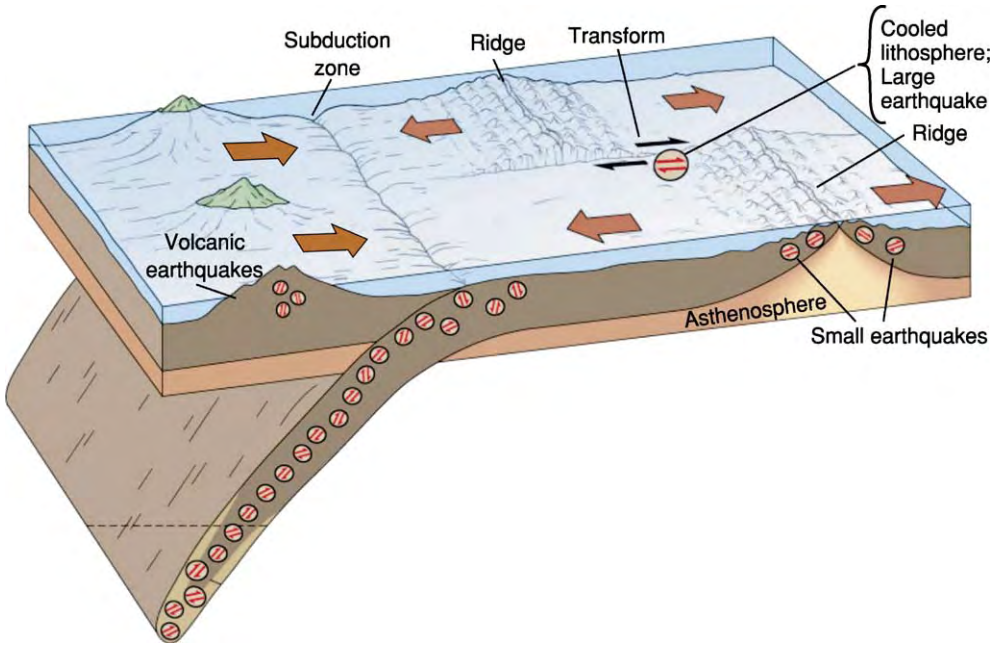

Figure 4 Diagram illustrating the three principal types of plate boundary (ridge, transform, and subduction), their general morphology, and the distribution of earthquakes. Large arrows show relative plate motion. Circles with double arrows indicate the general distribution of earthquakes. Modified from Davidson JP, Reed W, and Davis PM (2002) *Exploring Earth*, Fig. 8.13. Upper Saddle River, NJ: Prentice Hall.

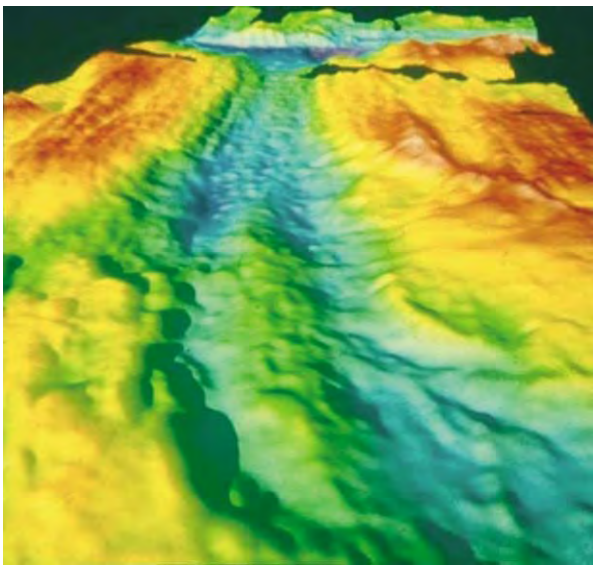

Figure 5 Oblique view of the topography of the Mid Atlantic Ridge Median Valley near 24° N, based on multibeam echosoun der measurements. The view is towards the south, with the cross cutting Kane Transform Fault in the distance. The width of the distant view is approximately 50 km, width in the foreground about 20 km, and distance from the foreground to the horizon about 100 km. Depths less than 2500 m, red; greater than 4200 m, blue. The median valley is approximately 30 km wide. There is evi dence of fault scarps on the valley walls. The ridge in the centre foreground is a linear volcano sitting above the plate boundary and representing the current axis of plate accretion. Image produced by M. Jones, University of Durham, Durham, UK, using data from Purdy GM, Sempere JC, Schouten H, Dubois DL, and Goldsmith R. (1990) Bathymetry of the Mid Atlantic Ridge, 24° N 31° N Amap series. *Marine Geophysical Researches* 12: 247 252; and Pockalny RA, *et al.* (1988) *Journal of Geophysical Research* 93: 3179 3193.

although small valleys and scarps usually mark the trace of the transform fault itself. Transforms link other plate boundaries, and can thus 'transform' one type of tectonic boundary (e.g., extensional) to another (e.g., compressional), hence the name. Many transform faults offset mid-ocean ridges, producing (in map view) a staircase pattern of alternating ridge and transform boundaries (Figure 2). Such offsets range from a few tens of kilometres to over a thousand kilometres in length. Transform boundaries occur in both continental and oceanic lithosphere.

Convergent Boundaries

Convergent plate boundaries in the strict plate tectonics sense occur only at the deep-sea trenches and related 'subduction zones' (*see* **Tectonics:** Convergent Plate Boundaries and Accretionary Wedges). Areas of active mountain building on continents (e.g., the Alpine–Himalayan zone) are zones of plate convergence, but are characterized by broad and almost continuous zones of deformation. This is partly because continental lithosphere is weaker and more easily deformed than oceanic lithosphere, and partly because it is less dense and so is not readily removed by subduction (see below). Plate tectonics does not provide a very useful description of such broad continental convergence zones.

Where one of the converging plates consists of oceanic lithosphere, it will be overridden by the other and pushed down into the asthenosphere in a process known as subduction (Figure 7). This can occur because oceanic lithosphere (unlike continental lithosphere) has a similar density to the underlying asthenosphere. Where both plates are oceanic, either one may be subducted under the other, and sometimes, depending on local conditions, the 'polarity' of subduction may reverse (i.e., the subducted plate breaks off and subsequently becomes the overriding one, whilst that which was overriding begins to subduct).

The plate boundary at a subduction zone is marked by a deep trench, the deepest and probably most famous of which is the Mariana Trench in the western Pacific, whose base is over 11 km below sea-level (*see* **Tectonics:** Ocean Trenches). As the slab subducts, it is deformed and generates earthquakes. These occur in a narrow band, known as the Wadati–Benioff zone, that follows the position of the subducting slab, and constitutes some of the best evidence for the existence of subduction zones. Subduction zones are very complex, and contain local regions of both compressional deformation (mainly at the actual plate boundary and in the leading edge of the overriding plate) and extensional deformation (mainly where the subducting plate bends to begin its descent). Earthquake mechanisms reflect this, and also show variation in mechanism with depth in the subducting plate. Some of the world's largest earthquakes are associated with subduction zones.

As the slab descends, it heats up and gives off water trapped in the crustal rocks. The presence of this water lowers the melting point of the surrounding mantle and, at a depth of some 100 km, magma is generated that rises through the overriding plate to create a volcanic arc, a hundred or so kilometres behind the trench (depending on the angle at which the slab is descending).

As with ridges, oblique subduction is allowed by plate tectonics theory, and is relatively common.

Plate Kinematics

Rotation Poles

The great strength of plate kinematics is that it can describe plate motions in terms of simple geometry,

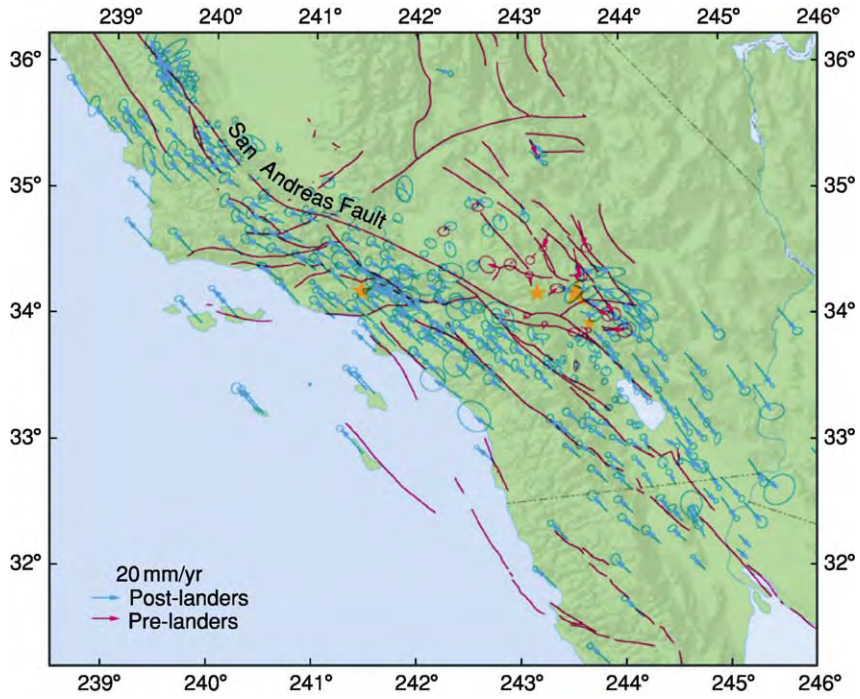

Figure 6 Map of major faults (red) and movement measured over 1 year by a Global Positioning System (GPS) (arrows) over part of the San Andreas Fault Zone in California, USA. Reproduced from Davidson JP, Reed W, and Davis PM (2002) *Exploring Earth*, Fig. 8.24. Upper Saddle River, NJ: Prentice Hall.

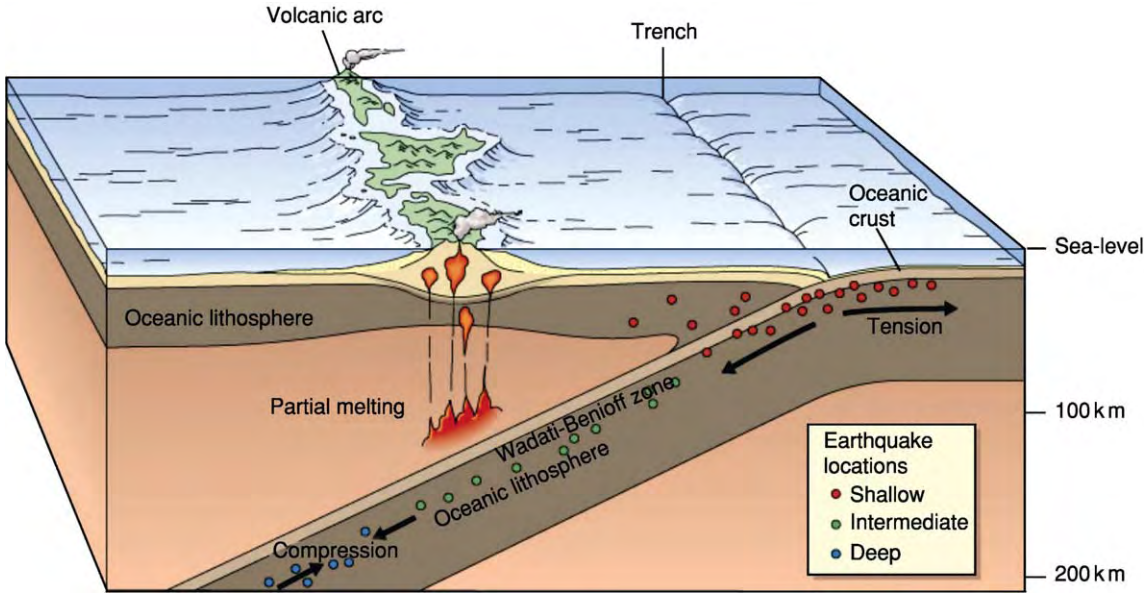

Figure 7 Diagram of a typical ocean ocean subduction zone. Reproduced from Davidson JP, Reed W, and Davis PM (2002) *Exploring Earth*, Fig. 10.3a. Upper Saddle River, NJ: Prentice Hall.

and hence make precise predictions of relative motions anywhere on the globe. At the heart of this geometry is a concept called Euler's theorem, which states that any displacement of a rigid body on the surface of a sphere can be described in terms of a single rotation about a specified axis (Figure 8). Such axes cut the Earth's surface at pairs of points called 'rotation poles' (or 'Euler poles'). Once the poles and the angular rotations are specified, the whole motion is completely determined. Thus, the

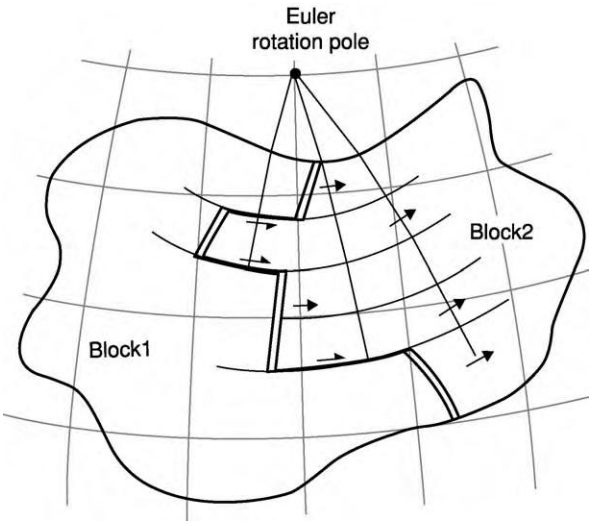

Figure 8 A Euler rotation pole describing the motion between Block 1 and Block 2. Plate boundary shown by double lines (mid ocean ridge) and bold single lines (transform faults). Circles (medium lines through transforms) and great circles drawn orth ogonal to them and passing through the pole are analogous to latitude and longitude in the geographic coordinate system. Light lines show the geographic coordinate system for comparison. Reproduced from Lowrie W (1997) *Fundamentals of Geophysics*, Fig. 6.30. Cambridge: Cambridge University Press.

motion of a given plate is specified in terms of its Euler pole and a corresponding angular rotation rate.

In practice, determining the motions of individual plates relative to some common reference frame is not easy, but determining 'relative' motions between pairs of plates is quite straightforward. These relative motions can also be described by rotation poles, although then the pole position must be specified relative to one or other of the pair of plates. Such relative rotation poles are the basis of most descriptions of plate kinematics.

As Euler poles define the 'directions' of the rotation axes, and the angles or rates of rotation define their 'magnitudes', rotations can also be described as vectors. Vector and matrix algebra can then be used to calculate plate motions, greatly simplifying and speeding up such calculations, which can be performed easily on computers.

It is important to distinguish between so-called 'instantaneous poles', which describe motion at an instant only, and 'finite rotation poles', which may describe the net result of motion over long periods of time. In descriptions of current plate motions, 'instantaneous' is usually taken to be about the past 1–3 million years. Motions over longer periods can be approximated by successions of so-called 'stage poles', each of which may describe the motion over a period of a few million years.

Like the geographic poles, we can imagine the Euler poles as centres of coordinate grids (Figure 8). 'Small circles' centred on the poles are the equivalent of lines of latitude, and plate relative motions are everywhere parallel to these small circles. Along any given small circle, the angular separation rate is constant, and increases with the distance from the rotation pole to the circle. 'Great circles' represent the shortest distance between two points on the surface of a sphere. Great circles that pass through the pole of rotation are equivalent to lines of longitude in the geographic system, and cut the small circles at right angles.

Measuring Plate Motions

Plates move at average rates of a few tens of millimetres per year. Thus, relatively indirect methods have usually been used to determine plate motions, although in recent years various geodetic measurements have been developed that are sufficiently precise to provide direct measurements of plate motions.

The most common way of determining plate separation rates is to use the linear magnetic anomalies (Vine–Matthews anomalies) produced during seafloor spreading to determine plate ages. These anomalies are produced as the Earth's magnetic field episodically reverses its direction, and the reversing field direction is recorded in the basalts of the oceanic crust as they cool after eruption at the mid-ocean ridge axis. This varying rock magnetization causes small variations, or 'anomalies', in the magnetic field above the seafloor, and these are readily observed by towing a magnetometer behind a ship or low-flying aircraft. Because the reversal process is irregular, the resultant magnetic anomalies have a characteristic pattern, which has been calibrated against crustal age through radiometric dating of samples of the magnetized rock. If the pattern of reversals can be recognized, the crust that is the source of the anomalies can thus be dated. The magnetic anomalies mark isochrons of crustal creation; therefore, by measuring the distance between a recent magnetic isochron on one plate and its conjugate on the other, the 'instantaneous' divergence rate, and hence the rotation rate, can be determined. (The commonly quoted 'spreading rate' is the rate at which a single plate accretes; for symmetrical spreading, it is half the divergence rate.) As the spreading or divergence rate varies with the distance from the Euler pole, in principle, the distance to the pole can be determined by measuring the spreading rate at several places along the plate boundary.

The best measure of the direction of relative plate motion is the azimuth of transform faults which, as stated above, are exactly parallel to the relative motion direction. Transform faults thus follow small

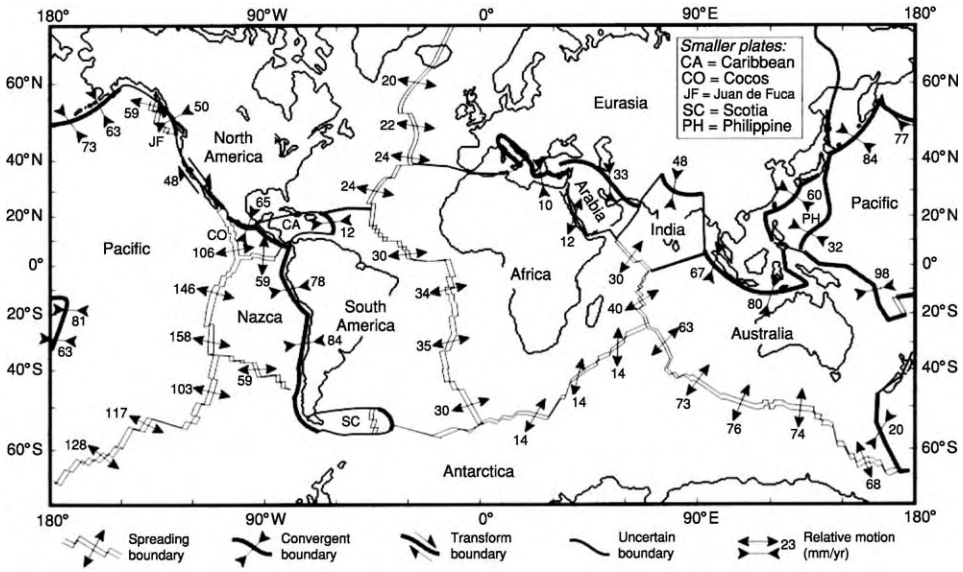

Figure 9 Map of plate boundaries showing the relative velocities across them from the data of DeMets C, Gordon RG, Argus DF, and Steins (1990). Reproduced from Lowrie W (1997) *Fundamentals of Geophysics*, Fig. 1.11. Cambridge: Cambridge University Press.

circles about Euler poles. A great circle at right angles to a small circle passes through the pole. Thus, if the azimuths of several transforms along a plate boundary are determined, great circles can be constructed normal to them, and should intersect at the Euler pole (Figure 8). Transform faults are readily recognized by their morphology (for example, a narrow linear valley for ridge–ridge transforms along mid-ocean ridges).

In practice, both spreading rates and transform azimuths are used together to solve for pole positions, sometimes supplemented by other data, such as earthquake focal mechanisms, to estimate relative motion directions. Euler poles may be calculated for individual plate pairs, for groups of plates, or for the global plate system (Figure 9). The most recent determination of global plate motions was performed by C. DeMets and others from Northwestern University, Illinois, USA, and provides a remarkably precise and self-consistent description of these motions (see 'Further Reading').

As stated above, an important attribute of plate kinematics is its ability to predict plate motions. An interesting example of this is the possibility of determining convergence rates across subduction zones. Even at ocean–ocean subduction zones, one plate is destroyed, together with the record of magnetic lineations carried on it. Thus, there was no direct way of measuring such motion until the recent development of sufficiently precise geodetic methods. However, the relative motions of the plate pair can be determined by global fits as described above, and then the motion at any point on the common plate boundary, including subduction zones, can be calculated from the Euler pole data.

In recent years, geodetic methods have been developed to the level at which they can begin to measure plate motions directly. Where plate boundaries exist on land (such as the Mid-Atlantic Ridge in Iceland or the San Andreas Fault in California, USA), standard geodetic methods, such as electronic distance measurement, can be used at a local scale (over ranges of a few kilometres). On a slightly larger scale of tens to hundreds of kilometres, precise relative position determinations (to precisions of a few millimetres) can be made by careful use of the Global Positioning System satellite network. Relative positions between widely separated continents can be determined by Very Long Baseline Interferometry, in which the variation in phase of radio signals from distant quasars is used. Repeat measurements by these methods over times of a few years can now resolve plate motions, and give results that, in general, agree well with the more traditional determinations.

The rotation rates of the major plates about their Euler poles range from about 2.1° per million years for the Cocos–Pacific pair, to about 0.1° per million years between Africa and Europe or Africa and Antarctica, and only 0.03° per million years for India–Arabia. Many of the minor plates (so-called 'microplates') rotate much faster than this, at tens of degrees per million years. In terms of linear rates, the fastest plate divergence rate at present is on the East Pacific Rise between the Pacific and Nazca plates, at

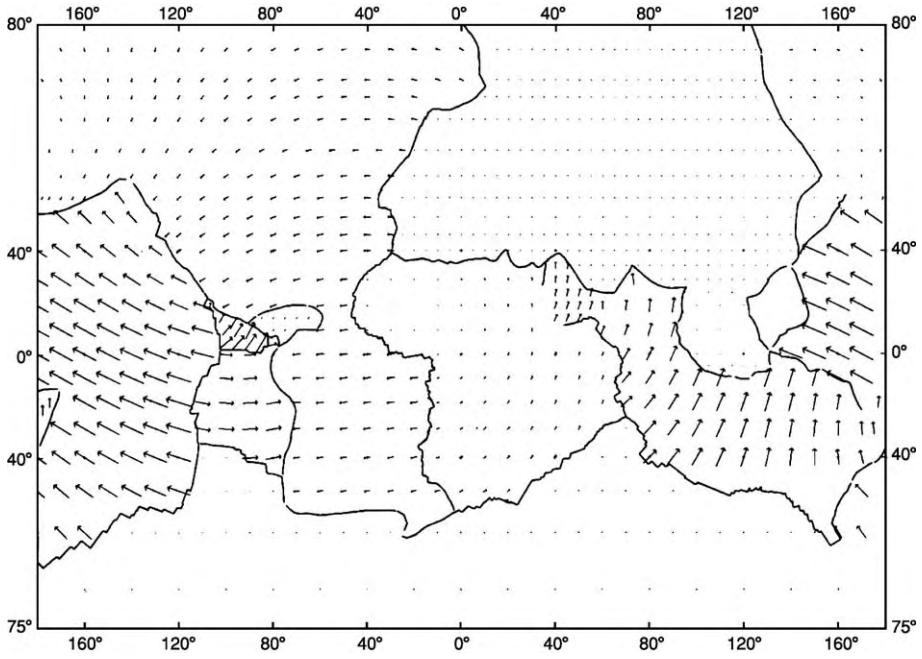

Figure 10 Map of plate boundaries and absolute motion vectors. Arrow lengths are proportional to the plate speed, with the longest (in the western Pacific) corresponding to speeds of about 100 mm per year. Reproduced from Fowler CMR (1990) *The Solid Earth: An Introduction to Global Geophysics*, Fig. 2.20. Cambridge: Cambridge University Press.

about 160 km per million years (or 160 mm per year). At the slow end, the North America–Eurasia plate boundary passes very close to its Euler pole in northern Siberia, where the relative motion becomes essentially zero.

Absolute Plate Motions

So far, we have dealt only with relative motions, which are fairly easy to determine. There is also interest in determining so-called 'absolute' plate motions, where the motions of all plates are related to some common reference frame. The possibility of doing this arises from the proposed existence of mantle plumes, which rise as narrow columns of relatively hot rock from deep in the mantle, possibly from the core–mantle boundary. They reach the Earth's surface in so-called 'hotspots' where they are manifest by clusters of intense volcanic and seismic activity. Well-known examples occur in Iceland and Hawaii, but there are thought to be many tens of such hotspots and associated plumes.

Hotspots leave clear trails on the Earth's surface, which comprise lines of volcanoes or volcanic seamounts and zones of thickened volcanically produced crust. The Hawaii–Emperor seamount chain, trending north-west from Hawaii, is an excellent example, but there are many other subparallel seamount trails in the south-western Pacific which are thought to have resulted from plumes. If points along the hotspot trails are dated (e.g., by radiometric dating of volcanic products), the relative motion between the plumes and the plate, and between given plumes, can be determined. We can also calculate the motions of individual plates relative to the average plume motion.

When this is performed, the relative motion between many of the hotspots turns out to be quite small, and significantly less than the average relative motions between plates. From this, and the fact that plumes are thought to rise through the mantle, it seems reasonable to assume that the average plume motion relative to the mantle is quite small, although it should be admitted that this has remained difficult to test in detail, and there are those who even question the existence of plumes. Nevertheless, if it is assumed that the average motion of hotspots relative to the mantle is zero, plate motions can then be given in the supposedly fixed mantle reference frame. These are referred to as absolute plate motions. They can also be described in terms of Euler poles, and are shown in Figure 10.

Mechanisms and Plate Driving Forces

Plates as Parts of the Mantle Convection Cycle

Plate motions are ultimately driven by the Earth's heat energy, and they are intimately related to the

mantle convection that is driven by this heat. One view of plates is that they simply represent the surficial parts of mantle convection cells: as hot, ductile mantle rises to the surface, it cools and becomes brittle – a plate – and then moves as a rigid block over the surface before being subducted, gaining temperature and becoming ductile again. Recent results from seismic tomography suggest that, around the rim of the Pacific, sheets of cold material descend below subduction zones deep into the lower mantle, implying a strong coupling of mantle motion and subducted plates.

However, the coupling is not perfect. There are some parts of the mid-ocean ridge (divergent plate boundaries) where it seems that the deeper mantle (below the asthenosphere) may be descending rather than rising. One such place is the so-called Australo-Antarctic Discordance south of Australia. Moreover, some plates, such as Africa, are almost entirely surrounded by ridges and have very few subduction zones on their boundaries. In such cases, a rigid coupling of plates to convection cells would imply the unusual scenario of upwelling along an expanding ring, with a downwelling column inside it. In fact, one of the advantages of plate tectonics is that it allows partial decoupling of plate motions from deeper mantle flow via the ductile asthenosphere.

The Forces Acting on Plates

Another way to look at the problem of the driving mechanism is to consider the forces acting directly on the plates. There are many possible forces, but amongst the most important are ridge push, slab pull, trench suction, and mantle drag. Ridge push arises from the tendency of the plates on a mid-ocean ridge flank to slide down the slopes of the wedge of thermally expanded asthenosphere that lies beneath the ridge. Slab pull arises from the negative buoyancy of the subducted plate which tends to drag the rest of the plate down with it. Trench suction is an additional force tending to pull plates together at subduction zones as a result of local convection driven by the subduction. Mantle drag is the frictional force between the base of the plate and the underlying asthenosphere.

It is possible to estimate some of these forces, at least approximately, and their relative importance can also be assessed by considering the observed stresses in plates and inferred absolute plate velocities. The latter is particularly instructive. Absolute velocities are largely independent of the total area of the plate, and so it is unlikely that mantle drag is an overall driving force, as was once thought (i.e., plates do not ride as passive passengers on top of mantle convection cells). However, plate velocities are inversely correlated with the area of continental lithosphere, suggesting that large areas of continent act as a brake (perhaps because such lithosphere is very thick or because subcontinental asthenosphere is cold and rather viscous). The fastest plates are those, mainly in the Pacific, which have large lengths of subduction zone along their boundaries, implying that slab pull and/or trench suction are important driving forces, as also suggested by calculation. There is a modest correlation with the effective length of ridge on the plate, indicating that ridge push is a driving force, but less strong than trench pull; this also tends to be backed up by calculations. Observations of intraplate stresses are also consistent with these conclusions.

Tests of Plate Tectonics

There have been numerous tests of plate tectonics theory. Its self-consistency, direct measurements of predicted plate motions, earthquake focal mechanisms, and distributions of earthquakes have all played their part in confirming the theory.

Overview

L R M Cocks, The Natural History Museum, London, UK

Introduction

Since the Precambrian–Cambrian boundary can now be dated at 543 Ma ago, and since the Earth is estimated to have been formed at about 4500 Ma ago, it follows that the Precambrian represents about seven eighths or 88% of geological time. However, that fact was not at all obvious to early geologists who, 200 or so years ago, had no idea of the age of the Earth. Between about 1820 and 1845, Earth history was divided into various named systems, with the Cambrian the oldest, based on the successive assemblages of distinct fossils contained in the sedimentary rocks and on the Law of Superposition, which states that rocks are older than other rocks now above them (assuming that they have not been structurally overturned). Igneous rocks were either undated or dated relatively as younger than the sedimentary rocks through which they had been intruded. Since no unambiguous fossils were then known from rocks below the Cambrian, all such rocks were and are simply termed the Precambrian. It was not until the invention and progressive refinement of radioisotopic dating in the twentieth century that the true ages of both the Precambrian and the rocks above it began to be understood.

Divisions of the Precambrian

Unlike the Phanerozoic (Cambrian–Holocene), there are no formal subdivisions of the Precambrian. However, the Precambrian is normally divided into two: the earlier Archaean and the younger Proterozoic. The Proterozoic has itself been divided into three, and the Precambrian is thus divided as follows (the ages are obviously approximate):

Neoproterozoic – 1000 Ma–543 Ma,
Mesoproterozoic – 1600 Ma–1000 Ma,
Palaeoproterozoic – 2500 Ma–1600 Ma, and
Archaean – *ca*. 4000 Ma–2500 Ma

No Earthly rocks are known that are older than about 4000 Ma, so there is no universally used name for the period between the formation of the Earth at about 4500 Ma and the formation of the oldest known rocks of the Archaean, although the Hadean is a term used by some. The Neoproterozoic is divided into the Riphean (1000–600 Ma) and the Vendian (600–543 Ma), and the Vendian is sometimes termed the Ediacaran.

The Precambrian in this Encyclopaedia

A large number of articles in this encyclopaedia deal in various ways with aspects of the Precambrian, and thus this article is devised to help the reader to locate the appropriate entry through cross-referencing. Thus there follows a brief guide to the key aspects of the Precambrian, under the headings the origin of the Earth, major Precambrian outcrops, Precambrian sediments and climate, the origin of life and Precambrian fossils, Precambrian orogenies and Precambrian terranes and palaeogeography.

The Origin of the Earth

Our galaxy and the universe appear to have been formed about ten thousand million years (10 Ga) ago, but our star – the Sun – and its Solar System do not seem to have been formed for a long time after that, at about 4.5 Ga. The article on Earth structure and origins (*see* **Earth Structure and Origins**) describes how this process is thought to have occurred. The oldest known individual minerals are found within

zoned zircons from Western Australia, which give an age of nearly 4.4 Ga. However, the oldest known rocks are the Acasta Gneisses of Canada, which are about 4.0 Ga old; this age is closely followed in other areas, for example the 3.9 Ga Napier Complex of Antarctica. The oldest cratons so far identified form parts of the South African and West Australian shields (*see* **Shields**) and are dated at about 3.2 Ga.

Major Precambrian Outcrops

Although slivers of Precambrian rocks are found in many terranes consisting mainly of younger rocks (*see* **Terranes, Overview**), the great majority of Precambrian outcrops are found in the old shield areas of North America (principally the Canadian Shield, North American Precambrian Continental Nucleus (*see* **North America:** Precambrian Continental Nucleus; Continental Interior), South America (largely underlying Brazil and the adjacent areas), Africa (several areas) (*see* **Africa:** Pan-African Orogeny), Northern Europe (the East European Craton (*see* **Europe:** East European Craton)), Siberia (the Angara Craton, Central Asia (*see* **Asia:** Central), and Russia (*see* **Russia**)), India (*see* **Indian Subcontinent**), Antarctica (*see* **Antarctic**), and Australia (*see* **Australia:** Proterozoic). Several of these shield areas are made up of more than one shield unit; for example, three individual shields can be identified within Australia, and another three are found within Antarctica. From late in the Proterozoic and for all of the Palaeozoic, the South American, African, Indian, Antarctic, and Australian shields were grouped together to form the supercontinent of Gondwana (*see* **Gondwanaland and Gondwana**).

Precambrian Sediments and Climate

The Earth's atmosphere in Archaean and pre-Archaean times was a reducing one, consisting largely of carbon dioxide, nitrogen, water vapour, and inert gases, with subsidiary amounts of hydrogen, methane, and ammonia. A critical event in Earth history was the change just before about 2.2 Ga in the atmosphere from reducing to oxidizing, termed the Great Oxidation Event. The sediments reflect that profound change; for example, a characteristic sediment of many Archaean and Early Palaeoproterozoic shields is the banded iron formation (*see* **Sedimentary Rocks:** Banded Iron Formations). This sediment type is first known from the Isua Supracrustal rocks of Greenland, dated at 3.8 Ga, and these chemically precipitated deposits, which contain up to 35% iron, reach their maximum distribution between 2.8 Ga and 2.5 Ga, the end of the Archaean. They are often associated with greywackes deposited by turbidity currents in 'greenstone belts', which are extensive sedimentary mudstones and coarser rocks (usually metamorphosed) with high percentages of iron and other minerals. Following the change in the atmosphere from reducing to oxidizing, there are no true banded iron formations, although comparable granular iron formations are known from a few areas, notably Lake Superior, Canada (dated at about 1.9 Ga), and, much later (Late Neoproterozoic), the Yukon and Namibia.

Each grain of clastic sediment at the bottom of the oceans today has been through several (an estimated average of five) cycles of erosion and sedimentation during Earth history. Since there was no vegetation on the land and soils only developed progressively with time, Precambrian erosion rates were much higher than those of today. Nearly all Early Archaean sediments were volcanogenic, usually basic or intermediate in chemical composition, but today these account for only about 20% of sediments, most of the earlier ones having broken down into their individual mineral components. Since quartz is more resistant to weathering than most other minerals, the proportion of quartz in sedimentary rocks has progressively increased, reaching today's figure of approximately 50%. Limestones became common for the first time in the Proterozoic and often contain algal stromatolites. These Precambrian limestones had a higher magnesium content than average modern limestones, which resulted in a higher proportion of dolostones. A form of coal termed schungite is found for the first time in rocks aged about 2.0 Ga, and, although now metamorphosed, it probably formed initially from local accumulations of blue-green algae. Chert is known from Archaean rocks onwards and occurs in the form of layers within banded iron formations and as nodules within dolomites; however, these cherts are of inorganic or secondary origin, and primary cherts, formed from siliceous organisms such as radiolaria, are not known until the Late Neoproterozoic.

Precambrian climates have formed the topic of many research projects. As can be seen from the desert sediments that many Precambrian rocks contain, the climates were often very hot; however, at other times, glacigenic deposits were widespread. These Precambrian glaciations occurred in several phases, and some workers believe that the Earth was at one time completely covered in glaciers, the so-called 'snowball Earth', but that concept is controversial, although palaeomagnetic evidence indicates that some glacigenic rocks in Australia must have been close to the then equator.

The Origin of Life and Precambrian Fossils

It is not known when life originated here on Earth; however, as far as can be deduced, life originated only once. Prokaryotes, which include bacteria (*see* **Biosediments and Biofilms**), are apparently simpler than eukaryotes, since they lack a nucleus, and were probably the first organisms. Because early organisms were largely soft-bodied, the early fossil record is tantalizingly incomplete. As detailed in the article on Precambrian prokaryotes (*see* **Precambrian:** Prokaryote Fossils), the changes in overall carbon isotopes seen after 3.5 Ga indicate that biological systems were in place by that time. This was well before the Great Oxidation Event at about 2.2 Ga, and thus early life forms must have lived in a reducing environment.

Laminated structures known as stromatolites have been described from rocks as old as 3.4 Ga in Australia and South Africa; however, it appears likely that the earliest stromatolites were inorganic in origin. In contrast, stromatolites deposited after about 3.0 Ga were apparently organic in origin. Although the range and diversity of these complex organisms peaked in the Middle Mesoproterozoic and Neoproterozoic, their descendants are still to be found living today, most famously at Shark Bay, Western Australia. The role of stromatolites and other early organisms in taking carbon dioxide out of the atmosphere and replacing it with free oxygen played a major part in the change of the atmosphere during the Great Oxidation Event at about 2.2 Ga.

As the Precambrian progressed, life forms became more diverse (*see* **Precambrian:** Eukaryote Fossils), although they rarely exceeded 1 mm in size. A major evolutionary event took place in the later Proterozoic Vendian period (*see* **Precambrian:** Vendian and Ediacaran), when much larger macroscopic fossils, albeit still without hard parts, evolved; these are known as the Ediacara fauna. That fauna has been found on most of the larger Late Precambrian terranes, but apparently became extinct at or near the Precambrian–Cambrian boundary.

Precambrian Orogenies

In the Archaean there were many orogenies, but in most cases their detailed ages and lateral extents have not yet been fully determined, and long periods of orogeny are often conflated under a single name. For example, various orogenies have been recognized as occurring during the formation and subsequent fusion of the three cratons that make up present-day Australia. However, the 2.6–2.4 Ga Sleafordian Orogeny of Australia marked the assembly of the South Australia craton and spanned the Archaean–Palaeoproterozoic boundary (*see* **Australia:** Proterozoic). In central Canada the Trans-Hudson Orogeny extended from 2.2 Ga to 1.7 Ga, peaking at 1.9 Ga (*see* **North America:** Precambrian Continental Nucleus). Some workers correlate the 1.9–1.8 Ga Barramundi Orogeny of the North Australian craton with the Trans-Hudson Orogeny of North America, and the two together form a key element in the assembly of the Rodinia supercontinent (see below). In Antarctica there are at least three different Archaean–Palaeoproterozoic cratons that formed between 3 Ga and 1.6 Ga (*see* **Antarctic**).

The best-known Precambrian orogeny in the Mesoproterozoic is the Grenvillian Orogeny (*see* **Grenvillian Orogeny**), which occurred between 1.3 Ga and 1.0 Ga and probably resulted in the assembly of the superterrane of Rodinia. The Grenvillian Orogeny is principally represented in eastern North America and consists of an earlier accretionary stage between 1.3 Ga and 1.2 Ga, widespread magmatism from 1.2 Ga to 1.1 Ga, and a continent–continent collision at about 1.0 Ga. The 1.3–1.1 Ga Albany Fraser Orogeny of the South and West Australian cratons has been interpreted as part of the Grenvillian Orogeny.

During the final part of the Neoproterozoic, the Timanide Orogeny (*see* **Europe:** Timanides of Northern Russia) affected today's northern Europe and resulted in the accretion of a substantial number of terranes to the old craton of Baltica. In addition, the Cadomian Orogeny affected most of the terranes now in southern Europe; this continued until about 530 Ma, in the Early Cambrian.

Precambrian Terranes and Palaeogeography

It is not known exactly when continental and oceanic crust became differentiated on the Earth's surface, but the process is thought to have started before the Archaean. The oldest known cratons are dated at about 3.2 Ga, and it is not until after the formation of these cratons that we can be sure that wide shallow continental-shelf seas actually existed. Although there are glimpses of early terranes, for example between 3.0 Ga and 1.6 Ga (Archaean–Palaeoproterozoic) several Antarctic cratons were stabilized, there is no clear image of global palaeogeography prior to the Late Mesoproterozoic.

The existence of a Precambrian superterrane was suggested in the 1970s, as geologists noted a number of 1.3–1.0 Ga mountain belts now on different continents, and later the name Rodinia was adopted for

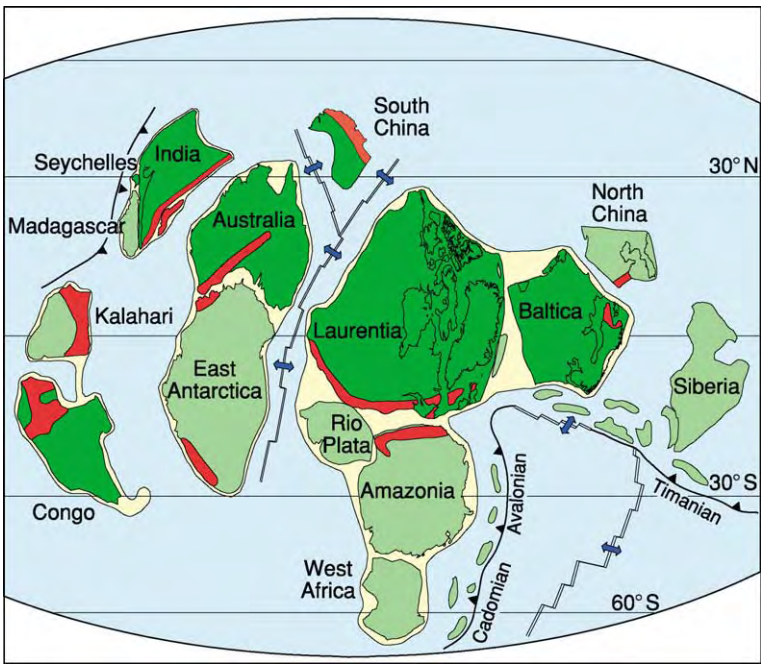

Figure 1 Palaeogeographical reconstruction at 750 Ma, just after the initial breakup of the Rodinia superterrane. The dark green shading represents terranes with good palaeomagnetic data, in contrast to the light green from with palaeomagnetic data is poor or absent. The red areas are the tectonic belts. Modified by Trond Torsvik, Trondheim, from Torsvik (2003).

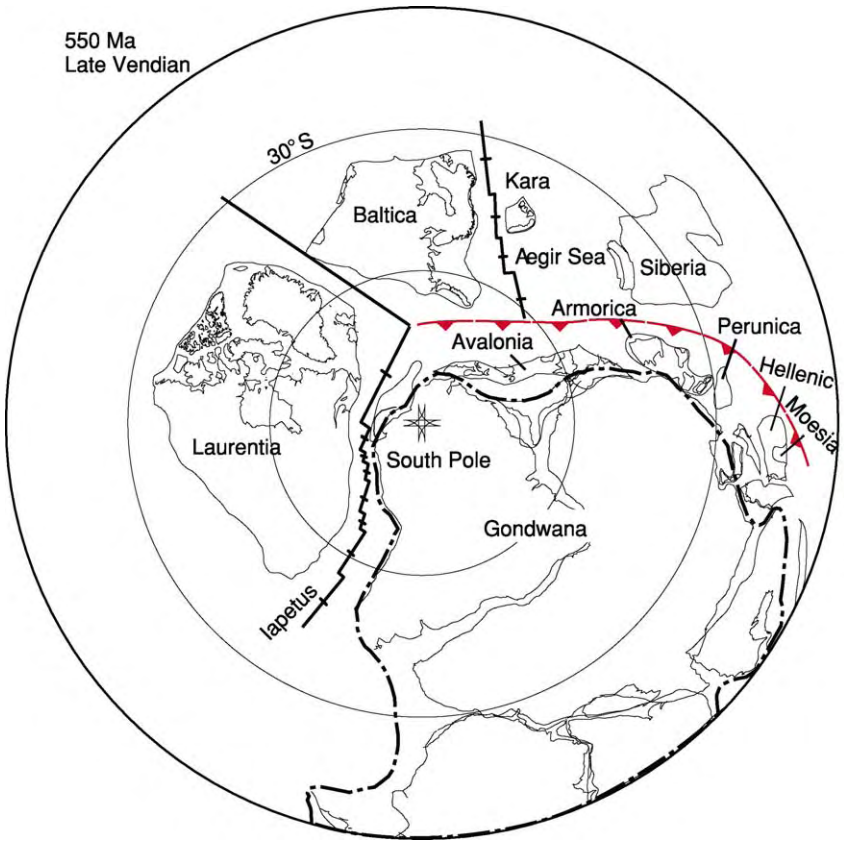

Figure 2 Palaeogeographical reconstruction at 550 Ma, near the end of the Neoproterozoic. New diagram by Trond Torsvik, Trondheim.

this terrane. There is now a progressively convincing scenario emerging of the slow assembly of the superterrane of Rodinia during the Mesoproterozoic between 1.3 Ga and 1.1 Ga. After relative stability for a long period, Rodinia started to break up at about 850 Ma. That breakup is documented by several events; for example, the 760 Ma Areyonga event in Australia may represent rifting between Australia and the new terrane of Laurentia. Similarly, Laurentia appears to have separated from Antarctica at about 750 Ma (**Figure 1**). However, South America, Africa, peninsular India, Australia, and Antarctica stayed together and, with further smaller accretions, remained together to form the superterrane of Gondwana in the Late Neoproterozoic, a process that was complete by the Early Cambrian. Between 580 Ma and 555 Ma there was massive plutonism in Scandinavia, and flood basalts in the Ukraine occurred at 576 Ma; these events may document the separation of Baltica from Laurentia. Gondwana remained a united superterrane until after the breakup of Pangaea in the Early Mesozoic.

Figure 2 shows a probable palaeogeography for the Late Neoproterozoic. The progressive rifting between Laurentia (North America) on the one hand and Gondwana and Baltica on the other resulted in the opening and steady widening of the Iapetus Ocean between the two sets of terranes, an opening that continued until about the end of the Cambrian. In addition the opening of the Ran Ocean marked the division between Baltica and Gondwana, and the Aegir Sea separated Baltica from Siberia. Most of the other side of the globe was occupied by the vast Panthalassic Ocean.

Eukaryote Fossils

S Xiao, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

Eukaryotes, archaeobacteria, and eubacteria are the three domains of living organisms (Figure 1). Most life forms that we can see with the naked eye are multicellular eukaryotes, which include animals, fungi, plants, and seaweeds. Many eukaryotes (for example, dinoflagellates, ciliates, and amoebae) are, however, single-celled and microscopic.

Eukaryotes are cytologically distinct from prokaryotes (archaeobacteria and eubacteria). A typical eukaryotic cell contains membrane-bound intracellular structures such as a nucleus, mitochondria, and, for photosynthetic eukaryotes, chloroplasts. Eukaryotes are also distinctively characterized by DNA-associated histone, eukaryotic gene regulation, and tubulin- and actin-based structures known as cytoskeletons, which help to maintain and manipulate the shape of the cell.

Nuclei, mitochondria, chloroplasts, histone, and cytoskeletons are rarely preserved in the fossil record, making it a serious challenge to recognize fossil eukaryotes, particularly single-celled ones. It has been suggested that cell size may be a useful guide: eukaryotes tend to have larger cells than prokaryotes. The size range of eukaryotic cells, however, overlaps considerably with that of prokaryotic cells. Cell size alone therefore is only indicative, not conclusive, evidence of eukaryotic affinity. Morphological complexity provides more reliable evidence. Because of the supportive function of cytoskeletons,

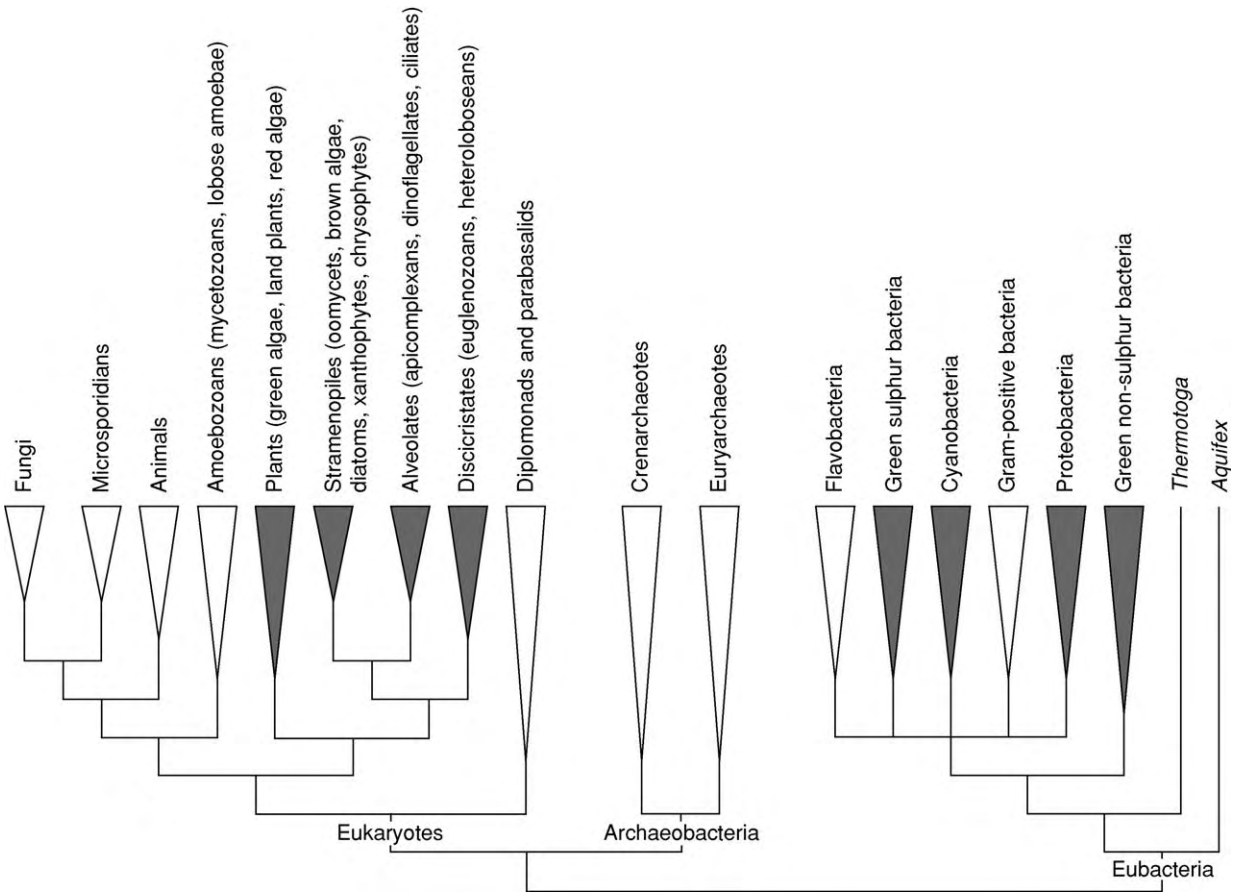

Figure 1 Phylogenetic relationships among the three major domains (eubacteria, archaeobacteria, and eukaryotes) and phylogen etic structure within the eukaryote domain. Shaded clades include photosynthetic members. Simplified from Woese CR, Kandler O, and Wheelis ML (1990) Towards a natural system of organisms: proposal for the domains Archaea, Bacteria, and Eucarya. *Proceedings of the National Academy of Sciences of the USA* 87: 4576 4579 and Baldauf SL, Roger AJ, Wenk Siefert I, and Doolittle WF (2000) A kingdom level phylogeny of eukaryotes based on combined protein data. *Science* 290: 972 977.

many eukaryotes maintain complex cell morphologies that can be preserved in the fossil record. For multicellular organisms, eukaryotic morphologies extend to cell organization and differentiation. Through intercellular interaction (e.g. via plasmodesmata and pit connections), controlled cell division, and genetic regulation, multicellular eukaryotes can have well-organized cell arrangements and some degree of cellular differentiation, which distinguishes them from prokaryotes. In addition, eukaryotic biochemistry may leave fingerprints in ancient rocks in the form of molecular fossils or biomarkers. Steranes, for example, are good eukaryote biomarkers. Steranes are derived from steroids, and the biosynthesis of steroids is almost exclusively a characteristic of eukaryotes.

Not only the size range but also the morphological disparity of eukaryotes overlaps with that of prokaryotes. Many eukaryotes, particularly single-celled ones, can be morphologically simple and volumetrically small. It can be very difficult to distinguish such eukaryotes from prokaryotes. This is a significant challenge because the majority of Precambrian microfossils are morphologically simple. Many of them are featureless filamentous or spheroidal structures, less than a few tens of micrometres in size, preserved in cherts or shales. The default interpretation of these microfossils is that they are prokaryotes. This is not an unreasonable interpretation for many, particularly if they can be shown to be microbial mat builders. For others, however, a eukaryote interpretation is equally plausible; there is simply not enough morphological detail to allow an unambiguous interpretation. These fossils are not the focus of this article. The discussion below takes a more conservative approach, focusing only on the Precambrian fossils that can be reasonably interpreted as eukaryotes. In addition, the discussion will concentrate on marine sediments; there are no known convincing eukaryote fossils in Precambrian terrestrial sediments.

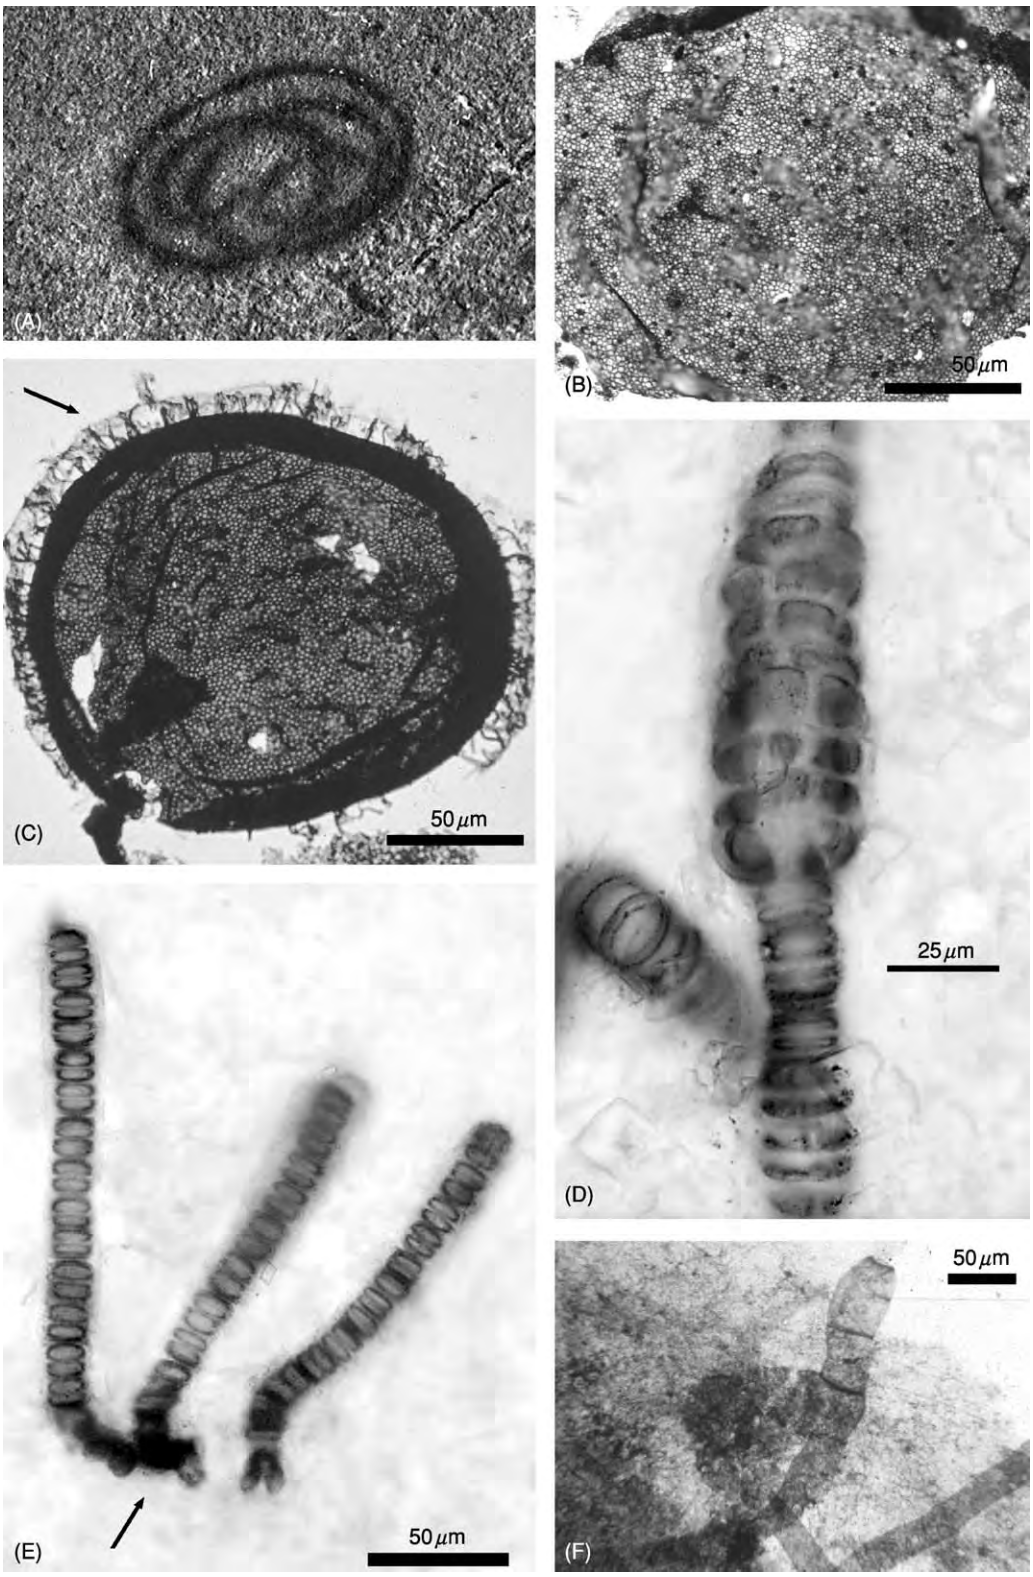

Figure 2 Palaeproterozoic (A) and Mesoproterozoic (B F) eukaryote fossils. (A) Coiled ribbons from the Negaunee Iron Formation, Michigan, USA. Specimen is about 2 cm in maximum dimension. Reproduced with permission from Xiao S, Knoll AH, Kaufman AJ, Yin L, and Zhang Y (1997) Neoproterozoic fossils in Mesoproterozoic rocks? Chemostratigraphic resolution of a biostratigraphic conundrum from the

Archaean (3800–2500 Ma) Eukaryotes

Phylogenetic relationships among the three domains (Figure 1) indicate that the eukaryotes may have a history that extends back as far as those of the other two domains. Since there are microbial fossils in the Archaean, the possibility of Archaean eukaryotes is intriguing. Indeed, we can follow the footprints of eukaryotes into the Archaean. Steranes, which are eukaryote biomarkers derived from steroids, occur abundantly in the ~2600 Ma Marra Mamba Formation and the ~2715 Ma Maddina Formation in northwestern Australia. But so far no eukaryote microfossils have been found in Archaean rocks.

The presence of steranes in Archaean rocks, however, does not necessarily imply that all of the features (mitochondria, cytoskeletons, and histone) that collectively define living eukaryotes evolved in the Archaean. It is possible that the biosynthesis of steroids appeared early in eukaryote history. These Archaean organisms may represent ancient branches that are more closely related to the eukaryotes than to the other two domains but that diverged before the last common ancestor of all living eukaryotes evolved. In other words, they may represent stem-group eukaryotes.

Palaeoproterozoic (2500–1600 Ma) Eukaryotes

Eukaryotic biomarkers continue to occur in Palaeoproterozoic and younger rocks, for example in the McArthur Group (approximately 1600–1700 Ma) in northern Australia. But it is in the Palaeoproterozoic rocks that the earliest morphological evidence for eukaryotes has been found. Such morphological evidence appears in two forms: macroscopic carbonaceous compressions and organic-walled microfossils.

Among Palaeoproterozoic carbonaceous compressions, the coiled ribbons (Figure 2A) of millimetric width and centimetric length from the *ca*. 2000 Ma Negaunee Iron Formation of Michigan are probably the most famous because of the ancient age of the formation. The Negaunee ribbons resemble the Mesoproterozoic fossil *Grypania spiralis*. Millimetre-sized discoidal to elliptical compressions resembling *Chuaria* and *Tawuia* are known from the *ca*. 1800–1900 Ma Changzhougou Formation and Chuanlinggou Formation in northern China. The slightly younger (*ca*. 1700 Ma) Tuanshanzi Formation in northern China contains millimetre- to centimetre-sized carbonaceous ribbons and blades. Although the cellular details of these fossils are not preserved, their macroscopic and stable morphologies suggest that they are probably the earliest eukaryotic fossils known so far.

The Changzhougou Formation and Chuanlinggou Formation in northern China also contain organic-walled microfossils (or acritarchs) and multicellular eukaryotes. The Chinese acritarchs are spherical vesicles with simple morphology but relatively large size (about 100 μm in diameter). They are commonly referred to the genus *Leiosphaeridia*. They are interpreted as single-celled resting cysts of ancient eukaryotes. The relatively thick and resistant vesicles of the resting cysts allowed their preservation in carbonaceous shales. The cellular details of another fossil, *Qingshania magnifica*, described from the Chuanlinggou Formation, are preserved, and the organism shows evidence of cellular differentiation – the expanded terminal cell at one end of the clavate filament was probably a reproductive cell. *Qingshania magnifica* may well be a multicellular eukaryote.

Palaeoproterozoic eukaryotic fossils do not have distinct morphological features that would allow them to be placed into extant eukaryotic clades. Like the Archean molecular fossils, the Palaeoproterozoic fossils may also reflect stem-group divergence in the early history of eukaryotes.

Mesoproterozoic (1600–1000 Ma) Eukaryotes

Morphologically simple acritarchs such as *Leiosphaeridia* continue to dominate Mesoproterozoic microfloral assemblages, and *Grypania spiralis*, *Chuaria*, and *Tawuia* are also known in Mesoproterozoic successions. However, several morphologically complex acritarchs first appeared in the Mesoproterozoic. In addition, the first crown-group eukaryotes (that is, fossils that can be phylogenetically resolved to an extant eukaryote clade) also occur in the Mesoproterozoic. This indicates that crown-group eukaryotes began to diversify in the Mesoproterozoic. By the

end of the Mesoproterozoic, several algal groups had already diverged.

Acanthomorphic acritarchs (or acritarchs bearing spines) and acritarchs with patterned vesicles are known in the 1400–1500 Ma Roper Group of northern Australia and the >1000 Ma Ruyang Group of northern China. The Roper and Ruyang assemblages include such acanthomorphs as *Tappania plana* and *Shuiyousphaeridium macroreticulatum* (**Figure 2C**), as well as acritarchs with polygonally patterned (*Dictyosphaera delicate* and *Shuiyousphaeridium macroreticulatum*; **Figure 2B** and **2C**) or striated (*Valeria lophostriata*) vesicles. Some of these fossils have wide geographical and long stratigraphical ranges. For example, *Valeria lophostriata* and *Tappania* occur in Mesoproterozoic and Neoproterozoic rocks in Laurentia, Australia, India, and northern China. As no prokaryotes are known to have comparable levels of morphological complexity, these acritarchs are probably eukaryotic. Some of these acritarchs (for example *Dictyosphaera delicate*) preserve an organic $\delta^{13}C$ signature that is consistent with eukaryotic photosynthetic biochemistry, but it is unclear which algal group (e.g. chlorophytes, rhodophytes, or stramenopile algae – a group that includes chrysophytes, xanthophytes, diatoms, and brown algae; **Figure 1**) they belong to.

One of the earliest eukaryotic fossils that has been confidently attributed to a modern algal group is *Bangiomorpha pubescens* (**Figures 2D** and **2E**) from the 1200 Ma Hunting Formation in arctic Canada. This is a multicellular filamentous fossil that shows evidence of holdfast differentiation and sexual reproduction. It is interpreted as a benthic bangiophyte red alga. Another phylogenetically resolved eukaryotic fossil is *Palaeovaucheria clavata* (**Figure 2F**), interpreted as a xanthophyte alga, from the upper Mesoproterozoic Lakhanda Group in south-eastern Siberia. Xanthophyte algae are members of the photosynthetic stramenopiles whose plastids were derived from a secondary endosymbiont (probably a red alga). The occurrence of *Bangiomorpha pubescens* and *Palaeovaucheria clavata* in Mesoproterozoic rocks suggests that not only must crown-group eukaryotes such as red algae have diverged but also the secondary endosymbiotic event leading to stramenopile algae must have occurred by the end of the Mesoproterozoic.

Neoproterozoic (1000–540 Ma) Eukaryotes

The Neoproterozoic era includes several major milestones in eukaryote evolution. The diversity and morphological complexity of eukaryotes increased appreciably in the Neoproterozoic, and several phylogenetically and ecologically important eukaryotic groups make their first appearance in the Neoproterozoic fossil record. These include heterotrophic protists, biomineralizing protists, and, towards the end of this era, animals. Molecular-clock estimates also indicate that land plants and fungi may have diverged in the Neoproterozoic, but so far this has not been confirmed by palaeontological evidence.

Major environmental crises occurred in the middle Neoproterozoic. Between about 720 and 600 Ma, the Earth experienced at least two global glaciations (also known as 'snowball Earth events'), during which glaciers reached the tropical oceans. More glaciations may have occurred in the Neoproterozoic, but these were not nearly as extreme. It is therefore convenient to divide the Neoproterozoic into three intervals: Early (1000–720 Ma), Middle (720–600 Ma), and Late (600–543 Ma) Neoproterozoic.

Early Neoproterozoic

A quick look at several fossiliferous units of Early Neoproterozoic age gives us a broad picture of eukaryote diversity at that time. The Early Neoproterozoic Little Dal Group (850–780 Ma) in northwestern Canada, the Chuar Group (>742 Ma) in the Grand Canyon, and the Huainan Group and Huaibei Group (*ca*. 740–900 Ma) in northern China contain some of the best-preserved carbonaceous compressions in the Early Neoproterozoic. *Chuaria* and *Tawuia* (**Figures 3A** and **3B**) are abundant in these successions. In addition, *Longfengshania stipitata* – a benthic alga with an ellipsoidal head, a stipe, and a simple holdfast – has been described from the Little Dal Group and from the Changlongshan Formation (*ca*. 800–900 Ma) in northern China. Individuals of *L. stipitata* sometimes occur in clusters (**Figure 3C**), like a bunch of inflated balloons tethered together. These carbonaceous compressions are probably multicellular eukaryotes, although *Chuaria* and *Tawuia* have been interpreted as colonial cyanobacteria by some palaeontologists.

Acritarchs, particularly those with more complex morphologies, became more diverse in the Early Neoproterozoic (**Figure 3D**). More than 20 acritarch species with complex morphologies have been described from Early Neoproterozoic successions. Except a few (e.g. *Tappania* and *Valeria lophostriata*), they are not known in the Mesoproterozoic. The Wynniatt Formation (*ca*. 800–900 Ma) of arctic Canada, the Svanberfjellet Formation (*ca*. 700–800 Ma) in Spitsbergen, and the Mirojedikha Formation in Siberia, for example, contain some of the best-preserved acritarchs in the Early Neoproterozoic. The Svanberfjellet

Formation has also yielded the earliest known green algal fossil–*Proterocladus* (Figure 3E).

Biologically controlled mineralization and the formation of skeletons is an evolutionary event that significantly enhances fossil preservation. All fossils discussed in the preceding sections are non-biomineralizing eukaryotes. The earliest known biomineralizing protists are probably from the Early Neoproterozoic. Silicified scale-shaped microfossils (less than 100 μm in diameter) from the Tindir Group (age poorly

constrained, but possibly 620–780 Ma) of north-western Canada can be compared to chrysophyte skeletons. Vase-shaped microfossils (Figure 3F) from the Chuar Group and other Early Neoproterozoic successions (e.g. the Visingsö Formation in Sweden and the Draken Conglomerate Formation in Spitsbergen) have been interpreted as testate amoebae whose mineralized tests are typically preserved in casts and moulds.

The Chuar testate amoeba fossils add another dimension to our consideration of the Neoproterozoic biosphere, and that is heterotrophy. Because testate amoebae are heterotrophic protists, the Chuar vase-shaped microfossils suggest that the Early Neoproterozoic biosphere was ecologically complex. Of course, heterotrophic eukaryotes must have evolved earlier. In fact, the earliest eukaryotes may be heterotrophic, given that eukaryotic autotrophy evolved through primary and secondary endosymbiotic events. However, evidence for heterotrophy in the fossil record is scarce. Vase-shaped microfossils and ciliate biomarkers from the Chuar Group are probably the earliest known evidence for heterotrophic eukaryotes.

The best-known heterotrophic eukaryotes are perhaps the animals. There have been many reports of animal fossils from Early Neoproterozoic and Mesoproterozoic successions, but their interpretation has been controversial. *Sinosabellidites huainanensis*, *Pararenicola huaiyuanensis*, and *Protoarenicola baiguashanensis* (Figure 3G), from the Huainan Group and Huaibei Group (*ca*. 740–900 Ma) of northern China, are some of the often-cited Early Neoproterozoic animal fossils. They are carbonaceous compressions of tubes of millimetric diameter and centimetric length with transverse annulations. The transverse annulations superficially resemble animal metameric segmentation. A few specimens bear poorly defined terminal structures that have been interpreted as proboscis-like structures. However, recent study has shown that these carbonaceous compressions are probably benthic tubular algae.

Middle Neoproterozoic

The Middle Neoproterozoic is characterized by multiple global glaciations, and is unofficially labelled as the Cryogenian Period by some Precambrian geologists. On a broad scale, acritarchs and other eukaryotes suffered significant losses of diversity in the Middle Neoproterozoic. The documented diversities of several Middle Neoproterozoic assemblages are extremely low, and such assemblages are typically dominated by *Sphaerocongregus variabilis* (or *Bavlinella faveolata*). This Cryogenian drop in eukaryote diversity may be a true evolutionary pattern that was related to the glaciation events. Despite the loss of diversity, the occurrence of red algae, green algae, photosynthetic stramenopiles, and testate amoebae in Mesoproterozoic and Early Neoproterozoic rocks suggests that some members of these groups must have survived the Middle Neoproterozoic glaciations.

Late Neoproterozoic

Eukaryote diversity rose sharply in the Late Neoproterozoic. Both acritarchs and multicellular algae reached unprecedented levels of complexity and diversity in the Late Neoproterozoic. Some of the multicellular algae are preserved in anatomical detail, allowing them to be placed within the red algae.

One of the most important landmarks in Late Neoproterozoic eukaryote evolution is the emergence of animals and animal biomineralization. Molecular-clock studies suggest that the deepest (protostomes–deuterostomes) divergence within the crown-group bilaterian animals probably occurred in the Mesoproterozoic or Early Neoproterozoic. But, as discussed above, there is no convincing palaeontological evidence to support these molecular-clock estimates. Some have suggested that perhaps the earliest animals were microscopic in size and would not be well preserved in the fossil record.

The Doushantuo Formation and Dengying Formation of South China provide several taphonomic windows onto the Late Neoproterozoic biosphere. Carbonaceous shales, cherts, and phosphorites of the Doushantuo Formation (*ca*. 600–550 Ma) preserve some of the most extraordinary eukaryote fossils in the Neoproterozoic. More than 20 taxa of macroscopic carbonaceous compressions have been reported from the Yangtze Gorges area and elsewhere in South China. Most of these compressions can be unambiguously interpreted as multicellular algae (Figure 4A). Some of them show clear evidence of holdfast anchoring, dichotomous branching, apical meristematic growth, and specialized reproductive structures. A few of these compressions (for example *Calyptrina striata* and *Sinospongia typica*; Figure 4B), however, have been interpreted as sponges or cnidarians, but such interpretations are not unique and an algal interpretation cannot be falsified conclusively. In any case, it is safe to conclude that none of the Doushantuo compressions can be interpreted as macroscopic bilaterians (bilaterally symmetrical animals).

Multicellular algae also occur in the Doushantuo cherts and phosphorites. Cellular features are preserved (Figures 4C–F), so anatomical detail can be deduced from these fossils. Many of these silicified or phosphatized algal fossils show pseudoparenchymatous thallus construction, apical meristematic

growth, thallus differentiation (Figure 4C), and specialized reproductive structures (Figures 4D and 4E). Some of them have been interpreted as stem-group florideophyte red algae or stem-group coralline algae, suggesting the presence of advanced red algae in Late Neoproterozoic oceans.

In addition, the Doushantuo cherts and phosphorites contain an assemblage of large (several hundred micrometres in diameter) acanthomorphs that are morphologically complex and taxonomically diverse (Figure 4G and 4H). This assemblage includes nearly 30 species, some of which are also known to occur in other Late Neoproterozoic successions, for example the Pertatataka Formation of central Australia, the Scotia Group of Svalbard, the lower Krol Group (Krol A) of Lesser Himalaya, and lower Vendian rocks in eastern Siberia. In the Yangtze Gorges area, elements of this acritarch assemblage (for example *Tianzhushania spinosa*) first appear just metres above Cryogenian glacial deposits, suggesting that the eukaryote recovery occurred shortly after the last Cryogenian glaciations.

The Doushantuo diversification of complex acritarchs appears to be ephemeral, however. Available evidence suggests that most of the Doushantuo acritarchs disappeared when Ediacaran animals

began to diversify about 575 Ma ago. The disappearance is unlikely to be a preservational artefact: slightly younger phosphorites in the Dengying Formation contain no Doushantuo-type acritarchs, and basal Cambrian acritarchs are entirely different from those in the Doushantuo Formation. It is possible that the extinction of Doushantuo-type acritarchs is related to yet another small-scale glaciation in the Late Neoproterozoic.

Perhaps the most exciting fossils from the Doushantuo Formation are the submillimetric globular microfossils preserved in phosphorites at Weng'an in Guizhou Province. These globular microfossils have been interpreted as animal blastulae at successive cleavage stages, containing 2^n blastomeres within an envelope of roughly constant size (Figure 5A–D). The geometry of these microfossils is consistent with blastula cell division. It has not been determined, however, to which animal clade(s) these fossil embryos belong. Their chimeric combination of features that individually occur in crown-group sponges, cnidarians, and bilaterians suggests that these embryos may belong to stem groups at the animal, eumetazoan, or bilaterian levels. There are other microfossils in the Weng'an phosphorites that have been interpreted as adult sponges, adult cnidarians (Figure 5E), and putative bilaterian gastrulas. However, none of these are more than a few millimetres in size. Perhaps the earliest animals, at least bilaterian animals, were indeed microscopic.

Macroscopic bilaterian animals probably first evolved in the latest Neoproterozoic Ediacaran time. Among the best-known Ediacaran fossils, those in the Newfoundland assemblage (*ca*. 575–565 Ma) are probably the oldest, those in the White Sea and South Australia assemblages (*ca*. 555 Ma) are younger, and those in the Namibia assemblage (*ca*. 549–543 Ma) are the youngest. There do not appear to be any unambiguous macrobilaterians in the Newfoundland assemblage. The White Sea and South Australia assemblages, on the other hand, include body and trace fossils of macrobilaterians (e.g. *Kimberella quadrata*), as well as classic Ediacaran fossils such as *Dickinsonia* (Figure 5F) whose phylogenetic interpretations are still controversial. The Namibia assemblage and its equivalents (for

example the Dengying Formation in South China) include biomineralizing animals such as *Cloudina* (**Figure 5G**), *Namapoikia*, and *Namacalathus*. These Ediacaran assemblages, therefore, record a succession of evolutionary events leading to the rise of macrobilaterians and animal biomineralization. Most Ediacaran fossils, however, disappeared near the Precambrian–Cambrian boundary, closing the last chapter in Precambrian eukaryote evolution.

Acknowledgments

I would like to thank the National Science Foundation for funding my research on Proterozoic palaeontology. Nicholas J Butterfield, Hans J Hofmann, Hong Hua, Andrew H Knoll, Susannah M Porter, Bruce Runnegar, Leiming Yin, and Xunlai Yuan kindly provided the photographs used in this article.

Prokaryote Fossils

M D Brasier, University of Oxford, Oxford, UK

Introduction

Conditions for the development and survival of life on the young planet Earth are thought to have been extremely harsh. Reconstruction of those conditions requires multidisciplinary and interdisciplinary research (combining astronomy, planetary science, microbial and molecular biology, genetics, geochemistry, petrology, palaeobiology, and geology). These disciplines are united in the emerging field of astrobiology (exobiology), which covers the phenomenon of life within the solar system and beyond. Astrobiology takes a particular interest in modern and ancient prokaryotic ecosystems on Earth and in the prebiotic–biotic transition and its definition.

Meteoritic and lunar research shows that accretion of planet Earth took place around 4550 Ma ago (*see* **Earth Structure and Origins**). This accretion was soon followed by melting of the planetary surface owing to the energy released through gravitational collapse. A cataclysmic collision with a Mars-sized planet is

thought to have produced the Moon within the first 100 Ma or so. The Moon played a major role in setting the equable conditions for life on Earth through its influence in stabilizing our planetary motion about the rotational axis and by providing stable tidal and seasonal oscillations. Earth's surface had cooled and the oceans had probably condensed by about 4000 Ma, as shown by *ca*. 4200 Ma old (hydrous melt) zircons in the oldest rocks of Canada and by putative sediments in the 3800 Ma Akilia and Isua Groups of Greenland. Even so, the study of craters on the Moon and Mars shows that their surfaces were bombarded by large asteroids between 4550 Ma and 3800 Ma. Similar bombardment is likely to have affected the surface of the Earth, although any evidence has been destroyed by the mobility of the planetary surface. These bombardments would have had a devastating effect on any early biosphere (see Figure 1; the so-called 'impact frustration of the origin of life'). For example, the impact of an asteroid more than 350 km across would release enough energy to boil off the oceans, while that of

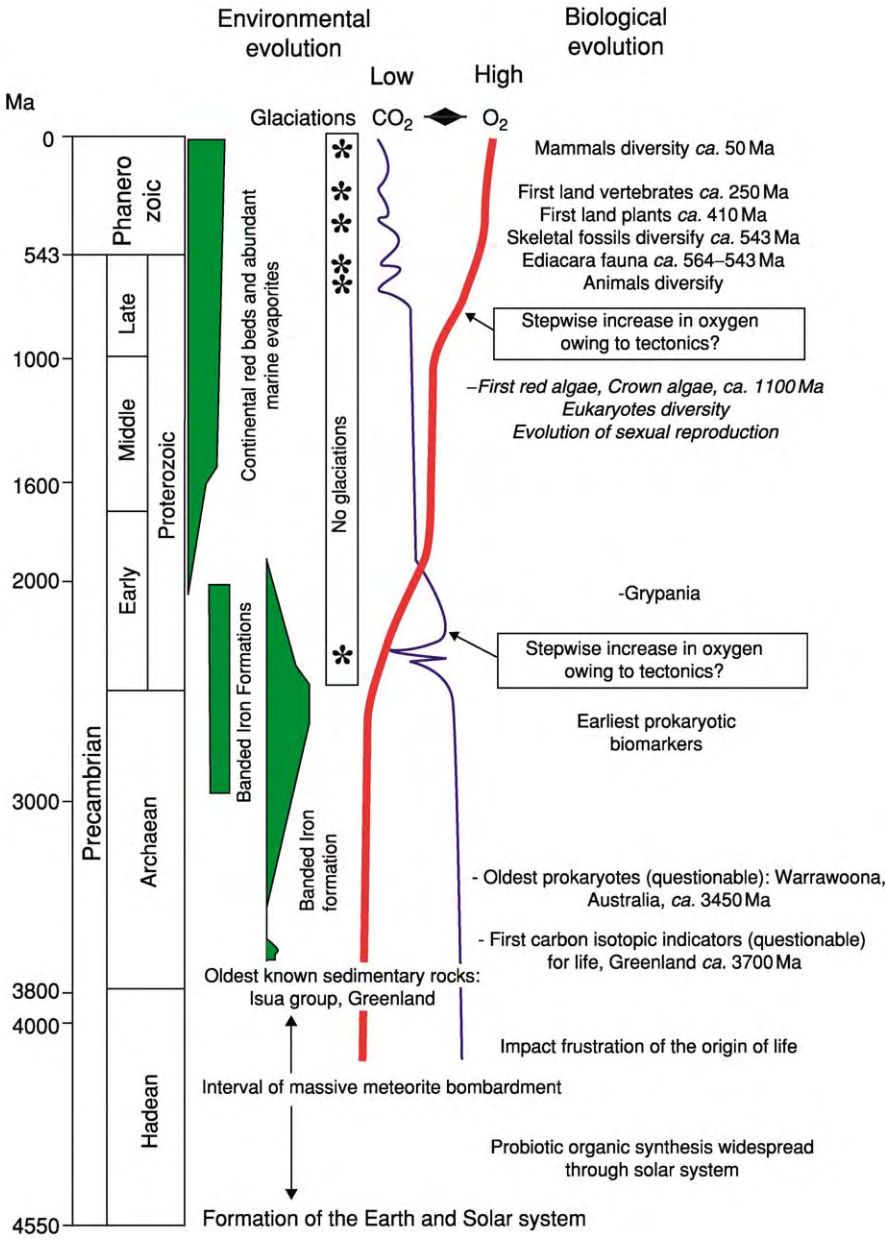

Figure 1 The main succession of events inferred for the evolution of the biosphere alongside geological evidence for changing levels of atmospheric oxygen and carbon dioxide during the Precambrian. The evidence for the first isotopic indicators (more than 3700 Ma) and the oldest prokaryotes (*ca*. 3450 Ma) is currently in dispute.

one about 150 km across could destroy the photic zone. Any life-forms synthesized prior to 3800 Ma could therefore have been repeatedly destroyed by episodic catastrophes. The only forms that could have survived such a holocaust would have been heat-tolerant hyperthermophile bacteria, which today are found living around volcanic and hydrothermal vents or deep in the Earth's crust. Such life-forms arguably originated from amino acid to RNA and DNA synthesis around hot alkaline hydrothermal vents. This is suggested not only by the antiquity of hyperthermophiles, as shown by molecular phylogeny (see below), but also by the ready availability of carbon sources (methane, carbon dioxide, carbon monoxide, aliphatics) and electron donors (metals, hydrogen sulphide, hydrogen) around such vents today, together with a plentiful supply of the phosphorus and transition metals that are needed to synthesize nucleic acids and enzymes. Against this, it has been argued that hydrothermal temperatures are too high to allow the necessary stability of complex organic molecules. But, on the early Earth, such hydrothermal vents were rich in metals (most of the world's metal resources come from the Archaean to Palaeoproterozoic crust) and clay minerals. These metals and clay minerals could arguably have allowed the stabilization of nucleic acids, even at relatively high temperatures. No other site on Earth could supply these essential building blocks in so many forms and so readily.

Asteroid bombardment of the Earth is thought to have declined progressively between about 3800 Ma and 3000 Ma. The hot, thick, and largely oceanic crust of this age can be envisaged as mantled by oceanic waters of moderate depth with a mean temperature of approximately 60°C. This means that aquatic habitats on Earth prior to about 3000 Ma may have been essentially hydrothermal in nature. It was not until about 3000 Ma that the wide shallow continental shelf seas, deep-sea troughs, and land areas began to develop. Crustal sources of free energy may therefore have begun to dwindle after about 3000 Ma, and the emerging biosphere may have been forced to switch to using solar energy, with one group perhaps converting from a heat-seeking catalyst to a light-seeking (photosynthetic) one.

Prokaryotes are considered to be the most primitive organisms on Earth and are assumed to have emerged early in the comparatively hot world of the Archaean. The cells of still-living forms are extremely small, generally less than 1 μm in diameter, and they lack a nucleus (hence the name prokaryote, which is derived from the Greek *pro* = before and *karyos* = nucleus). They may be single or colonial, the latter enclosed within a mucilaginous sheath called a capsule. Some living bacterial cells bear a whip-like thread (flagellum), and a few contain chlorophyll pigments for photosynthesis. Prokaryotes are important today in the formation of microbial sediments (*see* **Biosediments and Biofilms**), such as cyanobacterial mats and stromatolites, iron and manganese ores, carbonate concretions, and sulphide and sulphate minerals. They also yield important information about the early evolution of the cell and the histories of methanogenesis, photosynthesis, and biogeochemical cycles.

Molecular and Biochemical Evidence

Contrasts between the ribosomal RNA sequences of diverse bacteria, protists, fungi, plants, and animals indicate that life on Earth can be divided into three primary domains: the Archaea (or 'Archaebacteria'), which includes the methanogenic and sulphur bacteria; the Bacteria (or 'Eubacteria'), which includes cyanobacteria and other forms with photosynthetic pigments; and the Eucarya (or 'Eukaryota'), which includes all the protists, fungi, plants, and animals (Figure 2). It is notable that all the most deeply rooted branches of the tree of life are occupied by modern hyperthermophilic bacteria, which live at temperatures of 80–110°C and are seldom able to grow below 60°C. This has been taken to suggest that the

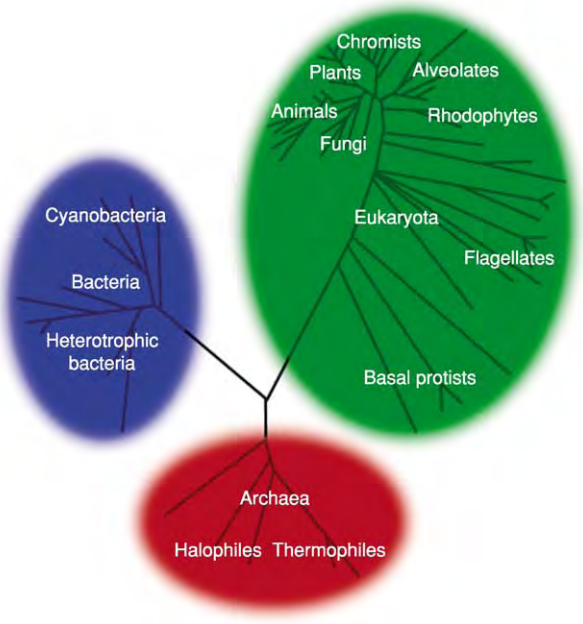

Figure 2 The three branches of the tree of life, in which all the deep seated branches are hyperthermophilic bacteria (shown in bold). Time increases along the branches, but not necessarily in a linear fashion or at the same rate in each branch. Longer branches relate to faster evolution.

last common ancestor of all living organisms was a hyperthermophile, adapted to hot hydrothermal springs or to life deep in the Earth's crust. One explanation for this is that life originated in such conditions. Another explanation is that hyperthermophiles were pre-adapted to survive the catastrophic period of meteorite bombardment between 4500 Ma and 3800 Ma.

Biochemical evidence can be taken to suggest the following evolutionary sequence of autotrophic prokaryotes, each of which used carbon dioxide as their sole source of carbon.

1. Anaerobic chemolithotrophic prokaryotes, which mainly use hydrogen produced from inorganic reactions between rock and water as their main electron source.
2. Anaerobic anoxygenic prokaryotes such as green and purple sulphur bacteria, which use photosynthesis to reduce carbon dioxide to form organic matter, with hydrogen sulphide as the electron source, in the absence of oxygen.
3. Oxygenic cyanobacteria, which use photosynthesis to reduce carbon dioxide to form organic matter, with water as the electron source, releasing oxygen. These must have had an enormous impact on Earth surface processes and the biosphere, and considerable interest has been focused by astrobiologists upon their first appearance in the rock record. At the time of NASA's Viking missions to Mars in 1976, it was such photosynthetic autotrophy that scientists were hoping to find.

Heterotrophic prokaryotes do not synthesize organic matter. Like us, they use preformed organic matter as their source of carbon and can use a range of oxidants to break it down and release the energy bonds. Methanogenic Archaea are among the most primitive heterotrophs alive today, living in highly reducing sediments (such as peat bogs) and releasing methane gas. Sulphate-reducing bacteria use seawater sulphate (SO_4) ions in the absence of oxygen, but require a highly oxidized form of sulphur (SO_4), which may not have been widely available in the early ocean. Aerobic heterotrophic bacteria use freely available atmospheric oxygen and are unlikely to have radiated before the so-called Great Oxygenation Event, 2450–2200 Ma ago, when various indicators of the weakly reducing planetary surface (banded iron formations (*see* **Sedimentary Rocks:** Banded Iron Formations), detrital pyrite, uraninite, and siderite) begin to disappear from the rock record and red beds start to appear. This oxygenation event may relate in part to increasing rates of carbon burial in expanding cratonic basins and subduction zones and in part to the irreversible loss of hydrogen to space from the upper atmosphere. While oxygen producers and consumers could have existed prior to 2450 Ma, they were probably restricted to rather local oases of oxygenation. This inferred evolutionary sequence of methanogenic to sulphate-reducing to aerobic heterotrophic prokaryotes is likely, on the basis of evidence from living bacteria, to have been accompanied by an increasing yield of energy from the same amount of carbonaceous 'food'. Significantly, this evolutionary succession closely resembles the modern distribution of prokaryotic populations within marine muds, with methanogenic Archaea lying deep within the sediment pile, aerobic heterotrophs and photoautotrophs in the upper layers of the sediment, and sulphate reducers in between.

Evidence for the Earliest Biosphere

Biogeochemistry

The fossil evidence for life on Earth gets increasingly scarce as the age of rock units increases. This is because older rocks have suffered more exposure to erosion and have experienced a greater degree of alteration by metamorphism. Hence, the oldest rocks on Earth (approximately 3800–3700 Ma), from Isua and Akilia in Greenland, have been too heavily metamorphosed to yield morphological evidence of life. Possible traces of life must therefore be explored using biogeochemical techniques. Stable isotopes of carbon from Isua and Akilia, for example, are somewhat lighter than usually expected from an inert world (*ca.* −18‰ δ^{13} CPDB cf. Pee Dee Belemnite standard). This has been taken to imply that life was able to self-organize and survive the period of catastrophic meteorite impacts before about 3800 Ma (**Figure 1**). Such a view is now controversial for a variety of reasons. The sedimentary origin of the carbonaceous grains is questionable: fractionation of carbon compounds could also have resulted from abiogenic processes or even from carbonaceous meteoritic debris. The carbon may also be younger than claimed. While light carbon isotopes (*ca.* −40‰ to −25‰ δ^{13} PDB) are commonly encountered in rocks younger than about 3500 Ma, some of these hydrocarbon compounds may also have an abiogenic origin, and precise discriminators, such as C–H ratios, H isotopes, and aliphaticity, are needed to discount this possibility. Even so, most scientists assume that this 25–40‰ difference in carbon isotopes of carbonates and organic matter seen after about 3500 Ma provides key evidence that biological metabolic pathways (i.e. autotrophic fractionation of carbon isotopes) were in place by this time.

A trend towards highly negative carbon isotope ratios about 2800–2200 Ma ago has been explained as the result of a bloom in heterotrophic methanogenic and methanotrophic Archaea at that time, prior to the Great Oxidation Event. Sulphur isotopes can also be used to trace the history of prokaryotic metabolism. In this case, ^{32}S is preferentially taken up by sulphate-reducing bacteria, leaving the water column enriched in the heavier isotope, ^{34}S. Recent studies of the ratio between ^{32}S and ^{34}S in sedimentary pyrite and in supersaturated barite, gypsum, and anhydrite have been used to argue that bacterial sulphate reduction was not in place before about 2450 Ma. Prior to this, sulphur isotope fractionation seems to have been of the abiogenic mass-independent kind, more like that seen in the Martian atmosphere. This lack of bacterial sulphate reduction before about 2450 Ma may be explained by a lack of sufficient atmospheric oxygen to form the sulphate ions and/or by surface water temperatures that were too high in the Archaean to produce a measurable fractionation.

Organic geochemical 'biomarkers' can also be sniffed out in well-preserved rocks, at least as far back as 2700 Ma. Biomarkers called 2-methylhopanes have been reported from rocks of this age in Western Australia and have been taken to indicate the presence of cyanobacteria at that time. This line of uniformitarian reasoning assumes, of course, that such biomarkers were not present in any other prokaryotic group, living or extinct, which is rather difficult to refute. Unfortunately, most rocks older than 2700 Ma appear to be too 'cooked' to preserve complex organic molecules.

Stromatolites

Laminated domical structures known as 'stromatolites' (Figure 3A) have been described from carbonate rocks as old as 3450 Ma in the Pilbara Supergroup of Western Australia (Figure 3C) and in the coeval Swaziland Supergroup of South Africa. Although an origin from the accretion of prokaryotic and even cyanobacterial mats has often been inferred for these early Archaean examples, they do not contain microfossils and they show some features that render their biogenicity rather questionable: an association with, and continuation down into, hydrothermal dyke systems; close association with epigenetic crystal fans (e.g. after aragonite, barite, gypsum) and directly precipitated carbonates; intergradation with ripple-like forms having rotational symmetry (i.e. they look the same upside down); lack of multiple

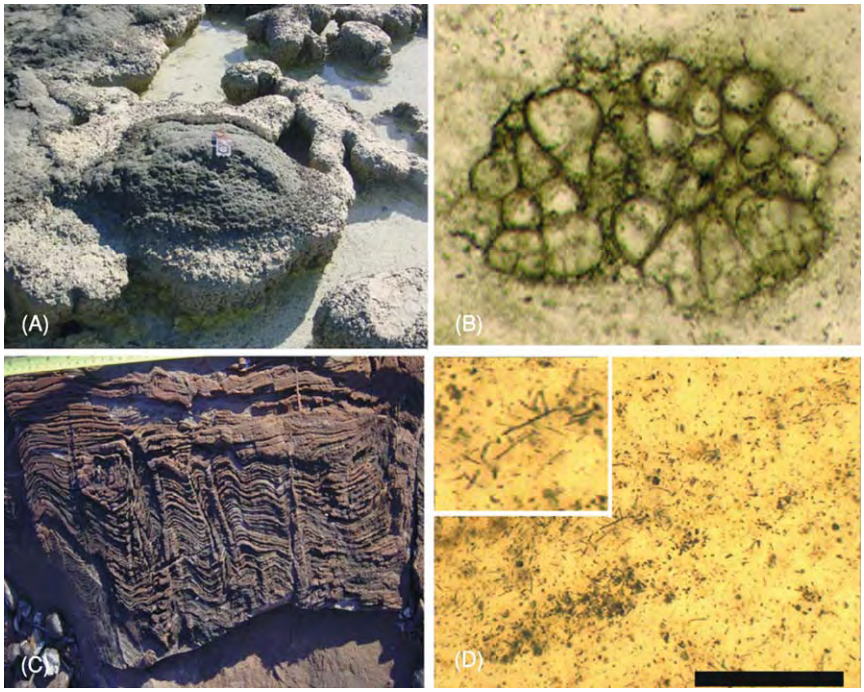

Figure 3 Stromatolites and Precambrian prokaryotes. (A) Living cyanobacterial diatom stromatolites from the hypersaline Shark Bay in Western Australia; compass is *ca.* 6.5 cm wide. (B) The coccoid cyanobacterium *Eoentophysalis* preserved in cherts of the *ca.* 800 Ma old Boorthanna Chert of Australia; scale bar below 100 μm. (C) A 30 cm wide exposure of 3400 Ma old stromatolites from the Strelley Pool Chert of Western Australia; it is unclear whether these are of microbial origin or are an abiogenic crystalline precipitate. (D) The 1900 Ma old filaments of cyanobacterial or iron bacterial origin preserved in the Gunflint Chert of Mink Mountain, Ontario, Canada; scale bar (main picture) 40 μm; scale bar (inset) 100 μm.

fractal dimensions; continuous laminae of barely varying thickness (typical of crystal growth); lack of wrinkle fabrics typical of biofilms; and lack of fenestrae or other signs of biological processing. Such simple stromatolites seem likely to have formed from largely physical processes such as direct chemical precipitation from seawater. It is only after about 3000 Ma that fractally complex stromatolites are found in carbonate platform settings, for which the presence of biofilms seems more plausible, if not always demonstrable. These tend to have wrinkle mat fabrics, discontinuous laminae, and laminar fenestrae (e.g. those from the 2700 Ma old Belingwe Group of Zimbabwe and the Fortescue Group of Western Australia). Microfossils associated with Archaean stromatolites remain questionable, however, until about 2530 Ma and are not really diverse until the 1900 Ma old Gunflint Chert of Canada (**Figure 3D**). Even here, the biogenicity of the associated stromatolites is open to question because they resemble abiogenic sinters.

Silicified Microbiotas

Precambrian oceans appear to have been supersaturated with silica (SiO_2) because it was not being removed from the water column by groups that evolved later, such as the diatoms, radiolaria, and sponges. In environments where early diagenetic silica was able to engulf prokaryotic populations, such as in peritidal hypersaline bacterial-mat settings, prokaryotic sheaths and even cell walls were sometimes (but still very rarely) well preserved in three dimensions. This prevalence of hypersaline settings may have produced an unfortunate bias towards prokaryotic assemblages in the early fossil record. In other words, the inferred dominance of prokaryotic microfossils within Precambrian cherts may be due to their restricted hypersaline setting rather than to evolutionary factors.

Silicified microbiotas are usually studied by means of standard (30 μm) to thick (300 μm) petrographic thin sections, at magnifications of up to about $\times$400. This thin-section technique is paramount because of the way in which it provides for contextual analysis, including three-dimensional morphology, mineralogy, rock fabric, and rock history. Other techniques, such as maceration (digestion in strong acids), etching of rock chips, scanning electron microscopy, and atomic force microscopy, are also used, but these do not provide the requisite information on context and are prone to the inclusion of structures that are later contaminants or 'artefacts' of the preparation process.

A classic example of a silicified Precambrian microbiota is the 1900 Ma old Gunflint Chert, which preserves about 12 taxa of prokaryotes, including forms that superficially resemble coccoid and filamentous cyanobacteria (**Figure 3D** and insert) but may be more closely allied to extant iron bacteria. The putative cyanobacteria *Eoentophysalis* (**Figure 3B**) and *Archaeoellipsoides* are thought to be present in the approximately 2100 Ma old cherts of West Africa and the 2000 Ma old Belcher Group cherts of Canada, respectively. The latter is claimed to preserve the specialist heterocyst cells used by cyanobacteria to help fix nitrogen in an otherwise oxidizing atmosphere. As one moves back into the Archaean, microfossils become both extremely rare and highly questionable, despite the great abundance of carbonaceous cherts and tufa-like carbonates. This may be explained partly by the inference that Archaean cherts were laid down in largely hydrothermal conditions that were often acidic and reducing, and partly by the scarcity of large and resistant cellular materials at that time. Bundles of silicified filaments and tiny calcified holes from stromatolites in the 2530 Ma old carbonates of the Transvaal Supergroup of South Africa may be the casts of coccoid and filamentous cyanobacteria but little of diagnostic significance is preserved. Intriguingly, such encrusted cyanobacterial filaments are rarely seen before about 1000 Ma, and endolithic microborings are not reported prior to 1500 Ma. A single microfossil-like structure from the 2700 Ma old Fortescue Group of Western Australia has been compared with a cyanobacterial filament but its biogenicity and context awaits full documentation.

Skeins of pyritic filaments found within carbonaceous cherts from 3200 Ma old black smokers of the Sulphur Springs Formation in Western Australia may be the remains of anaerobic hyperthermophile bacteria, though the indigenous and biogenic nature of these intriguing structures has yet to be demonstrated beyond question. The oldest cherts containing a supposed diverse prokaryotic microflora (**Figure 4A**) come from the 3450 Ma old Apex Cherts, which are intimately associated with ultrabasic and basaltic lava flows of the Apex Basalt in the Warrawoona Group of Western Australia. At least eleven different kinds of filamentous microfossil have been described from these rocks, some of which have been compared with cyanobacteria (**Figure 4A**). This has been taken to suggest that photosynthesis had begun to release oxygen into the atmosphere by 3450 Ma and that a substantial amount of evolution had taken place by this time. A critical re-examination of the context and fabric of these cherts suggests, however, that all these

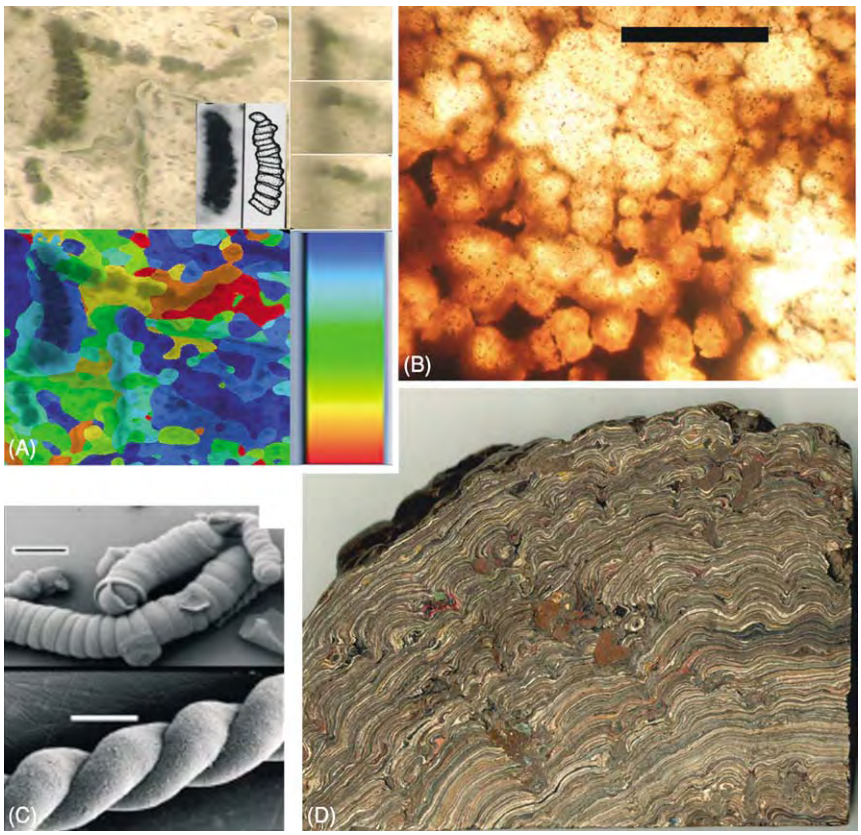

Figure 4 Pseudofossils. (A) Montage of the pseudofossil *Archaeoscillatoriopsis disciformis* holotype from the 3450 Ma old Apex Chert of Western Australia, showing (in black and white) its original interpretation and (in colour) its much more complex morphology when montaged (with topographic map) and its proximity to crystal growths. (B) Spherulites formed by the recrystallization of glassy hydrothermal silica with iron oxide impurities; recrystallization causes the formation of a spectrum of forms that range from abiogenic to microfossil like pseudofossils; scale bar in B 40 μm. structures occur deep within a cross-cutting hydrothermal vein. They comprise a continuous spectrum of arcuate to complexly branched carbonaceous reaction rims, formed around the edges of spherulitic silica botryoids, that appear to have formed during the recrystallization of hydrothermal silica glass to chalcedony and around rhombic crystal margins. Doubt is also cast on other 'microfossils' of about this age from the Warrawoona Group of Australia and from the Barberton mountains of South Africa. Their origin as mineralic pseudofossils or contaminants remains an open question.

Criteria for Biogenicity

The search for the signals left in rocks by very ancient prokaryotes requires a checklist of criteria to help establish biogenicity, not least because prokaryotic cells are so easily mimicked by physical artefacts and so readily introduced by contamination. A previous formula for the recognition of *bona fide* Archean microfossils has been that the putative microfossil structures must be unquestionably biogenic remnants that are indigenous to and syngenetic with the primary deposition of a sedimentary rock, which is itself of known stratigraphic and geographical source and of established Archaean age (i.e. greater than 2500 Ma old).

Until recently, the above criteria have been used to contrast the questionable 'microfossils' in Martian meteorite ALH 84001 with the 3450 Ma old supposedly *bona fide* 'microfossils' from the Apex Chert. It is now necessary to acknowledge, however, that complex structures of organic composition, like those in the Apex Chert, can be assembled very easily (e.g. Figure 4C), including abiogenic artefacts of

isotopically light carbon formed through late-stage remobilization of hydrocarbons with hydrothermal silica. Complexity *per se* is not a valid criterion for the recognition of life. Biological populations may be distinguished from abiogenic ones by the *lack* of a continuous spectrum of morphological variation, limited by the DNA-controlled genetic constraints. This narrow range can be contrasted with complex abiogenic artefacts, which will tend towards a 'symmetry-breaking cascade' of forms, ranging from a few biological look-alikes with rotational symmetry (**Figure 4C**) to highly information-rich forms (**Figures 4A** and **4B**) with poor symmetry.

Research into the earliest biosphere is now served by a marvellous range of new tools, including molecular (RNA and DNA) analysis of living-prokaryote phylogeny, biogeochemical analysis of ancient Earth rocks, and digital-image analysis of putative microfossils. These techniques should not be allowed to prosper, however, at the expense of more traditional techniques such as mapping and thin-section petrography. The latter are also vital for providing a context for early-life studies at a range of scales, from satellite images of greenstone belts, through field mapping, to microfabric mapping of thin sections. Future research will also require a much better understanding of the nature of complexity itself and of the multitudinous ways in which seemingly complex structures can self-organize. (**Figure 4** shows a range of microfossil-like and stromatolite-like objects of inferred non-biological origin.) This better understanding of complexity is needed, not only to understand the ways in which pseudofossils and pseudo-stromatolites can form, but also to comprehend the conditions in which life-forms and their building blocks were able to assemble and develop on the early Earth, and perhaps beyond.

Vendian and Ediacaran

M A S McMenamin, Mount Holyoke College, South Hadley, MA, USA

Introduction

The geological, palaeobiological, and earth systems (i.e., global geochemical) events associated with the Vendian period set the stage for all subsequent Earth history. Unprecedented change took place in the biosphere at this time, and the Vendian witnessed the appearance of the first Ediacarans, the first shelly fossils, and the earliest known animals. The Vendian saw the continuation of breakup of the earliest known giant supercontinent (Rodinia) and, at the end of the period, continuing into the Cambrian, the amalgamation of the supercontinent Gondwana. The Vendian also witnessed the termination of the worst series of glaciations known. The climate change was accompanied by dramatic fluctuations in the records of carbon and strontium isotopes. Linkages between supercontinent breakup and extreme climate change, and between biotic diversification and ecological change (e.g., as driven by metazoan disturbance of the marine substrate), are being actively explored by researchers following diverse avenues of investigation.

The Vendian period and system (called by some authors Lipalian or Ediacaran) spans the interval from 600–543 Ma. It was the final period of Proterozoic time (Neoproterozoic). Some accounts place the beginning of the Vendian as far back as 670–620 Ma, but this would push it into what should be the preceding period (the Sinian, 680–600 Ma). In any case, the Vendian represents the last interval of Precambrian time, and its end marks the most important division in the geological time-scale, the Proterozoic–Cambrian boundary. The importance of this boundary has led to escalating interest amongst researchers, and great advances have recently been made in understanding the Vendian. Many questions remain, however, and amongst them are some of the most contentious issues in contemporary earth science. The primary questions of interest are threefold. First, what caused global climate to warm after the worst glaciation on record? Second, what are the Ediacarans? Third, what events triggered the so-called Cambrian Explosion (*see* **Palaeozoic:** Cambrian) and the appearance of familiar animal types? A host of unsolved secondary questions follow. These include: What was the makeup of supercontinent Rodinia? What was the timing sequence and geometry of its breakup? What were the controls on eustatic sea-level change during the Vendian? Was there a mass extinction at the Proterozoic–Cambrian boundary? If so, what was its cause? What was happening to global geochemistry during this time? The implications of these questions are far reaching, and the discussion that follows is divided into three sections: Geological Events, Palaeobiological Events, and Earth System Events.

Geological Events

It can be said that the prelude to the Vendian world began at 1000 Ma with the amalgamation of the supercontinent Rodinia. The continental collisions that led to the formation of the supercontinent are generally called the Grenville Orogenic Event (*see* **Grenvillian Orogeny**). Named for 1000 Ma rocks that record an ancient episode of mountain building and continental collision in North America, Grenvillian rocks have now been recognized in places as distant as northwest India and Antarctica.

Composed of all the large continents of the Precambrian planet, Rodinia began to split apart beginning at about 750 Ma. Some geologists argue for a failed attempt at breakup at 850 Ma. Rodinia is thus a remarkably long-lived supercontinent, lasting some 250 million years. The rifting event was a drawn out affair that seems to have proceeded in two stages. Stage one began with the opening of the Pacific Ocean, as parts of what now constitute eastern Gondwana (Australia, Antarctica) split apart from what is now the west coast of North America. In stage two, fragments connected to the north-eastern and eastern parts of North America split off and began to collide with the continental blocks already set free by continental drift. The net result of all this continental motion, which was not complete until about the time of the Cambrian boundary, was the reorganization of the continental plate geometry of the planet with the sundering of Rodinia and the amalgamation of Gondwana. Some geologists believe that a short-lived global supercontinent (Pannotia) existed between the times of Rodinia and Gondwana, but evidence for this supercontinent is tenuous at best.

Block faulting and volcanicity associated with tectonic sundering characterize many Vendian stratigraphical sections. Deposition of the Vendian Tindir Group of east-central Alaska was influenced by block faulting in North American basement rocks. The Vendian La Ciénega Formation of northern

Mexico is punctuated by layers of porphyritic basalt erupted from fissures presumably related to tectonic extension.

Palaeomagnetic evidence suggests that the rates of continental motion near the Cambrian boundary were amongst the fastest ever measured. At one point near the boundary, the continents appear to have been moving synchronously, prompting what has been called inertial interchange theory, in which the Earth's crust is thought to have detached from the mantle for a relatively short time.

As the fragments of Rodinia went their separate ways, they set into motion a sequence of events that ultimately resulted in the drowning by seawater of all or most continental margins. As Rodinia split apart, the Rodinia's counterpart superocean, Mirovia, began to vanish beneath the subduction zones along the leading edges of the dispersing continental fragments. This led, overall, to an exchange of old, cold Mirovian seafloor crust for the relatively hot, less dense, and hence more buoyant ocean crust of the newly developing rift basins on the trailing edges of the continents opposite the subduction zones. Seawater was consequently displaced on a massive scale by buoyant, new mid-ocean ridges, and this led to the great marine transgression that began the Palaeozoic era.

The transgression began very slowly, as the early stage of breakup involved only a single (albeit long) continental margin, namely the split between Australia–Antarctica and North America. This gradual rise was then suddenly punctuated by a rapid fall in eustatic sea-level due to the onset of the first of several (Sturtian and Marinoan) Late Proterozoic glaciations. These were the worst glaciations known, leading many to believe that the Earth must have passed through what has been called 'White Earth' or 'Snowball Earth' conditions. The timing of these glaciations is somewhat uncertain, although two groups, an older (Sturtian, including the Rapitan, Chuos, and Stuartian glaciations) and a younger (Marinoan, including the Ice Brook, Ghaub, and Elatina glaciations), appear to each consist of roughly synchronous glacial events.

Compelling evidence exists during both glacial episodes for glaciers on land at sea-level at the equator, and some geologists suggest that the ice cap extended into the equatorial ocean as well. Regardless of the true extent of the ice cap, the glaciation was tremendously severe. The climatic aberration is made all the more curious by the character of the sedimentary layers deposited directly above the glacial deposits. Also, sedimentary (banded) iron formations reappeared during these ice ages after having virtually disappeared from the record for 1.5 Ga. These and other geochemical anomalies are interpreted to suggest almost incredible changes in the oxygen and carbon dioxide cycles of the planet – anoxia under the marine ice cap, leading to banded iron deposition; build-up of sufficient carbon dioxide in a life-depleted Earth to eventually trigger greenhouse conditions and melt the glaciers; and supergreenhouse conditions and supersaturation, leading to massive deposition of cap carbonates under unusual carbonate depositional conditions.

The cap carbonates consist primarily of abiogenically precipitated calcite and dolomite. Carbonate rocks of this nature are usually associated with deposition under very warm climatic conditions. Therefore, the juxtaposition of these sediments directly above deposits of the worst known glaciation is unusual in the extreme. The last Proterozoic cap carbonates were deposited at approximately 600 Ma and define the base of the Vendian system.

With the final melting of the ice, the transgression resumed its flooding of continental shelf areas. The transgression continued essentially unabated until well into the Cambrian. In many stratigraphical sections throughout the world, the base of the Cambrian is marked by a basal unconformity, although this is by no means universal, particularly in regions with a more or less complete Vendian section as well. The Vendian is thus defined in many places by a cap carbonate at its base (a pronounced aid to lithostratigraphical correlation when not associated with an unconformity), but an unconformity at its top (a decided hindrance to correlation efforts). Nevertheless, a combination of radiometric dates, lithostratigraphy, biostratigraphy, palaeomagnetic stratigraphy, and carbon and strontium isotope stratigraphy has rendered preliminary correlations possible between Vendian sections on different continents. Much work remains to be done to refine these correlations.

The Vendian is not characterized by major extraterrestrial impact events, but this may be an artefact of a less well-understood record of mass extinction during the period. The Acraman impact site (570 Ma) of South Australia, associated with a 160 km diameter crater, shock metamorphism, and shattercone development, is comparable in size to the 214 Ma, Manicouagan impact structure of Canada.

Palaeobiological Events

Although eukaryotic organisms are thought to have existed for more than 1000 million years before the beginning of the Vendian, they are rather inconspicuous until the Vendian begins. Thus, the Vendian marks the beginning of the Phanerozoic, the age of

visible life. The reason for the rapid expansion of eukaryotic life at this time is unclear, but some researchers have linked it to the climatic amelioration following the Proterozoic glaciations.

Biogenic stromatolites, known from the oldest rocks bearing microbial fossils, dramatically changed texture during the Vendian. The concentric lamination that characterized more ancient stromatolites gave way to a clotted, thrombolitic texture. This transition from stromatolite to thrombolite has been attributed to the burrowing and lamination-disturbing activities of early animals.

Biological inferences regarding the origin of metazoa, based on molecular clock data, indicate that metazoa appeared by at least 1000 Ma, but these inferences are beset by controversy. The date of origin of the animal kingdom is controversial as well, and the rock record before the Vendian does not provide many unambiguous clues to metazoan origins.

One thing is clear, however; by the Middle to Late Vendian, animals were present, as indicated by their trace fossils (*see* **Trace Fossils**). These trace or ichnofossils show evidence of peristaltic burrowing and displacement of sediment by burrowing activity, indicating that, by the end of the Vendian, animals with hydrostatic skeletons (coelomic spaces) were well established in the marine biosphere.

A difficulty with the study of Vendian animals is the fact that, apart from some phosphatized embryos that cannot be identified confidently to phylum, and some fossil sponges with preserved spicules, actual body fossils of these animals are rare. A comb-like structure from Russia, called *Redkinia,* may represent the flexible, filter-feeding mouthpart of a Vendian animal. However, apart from this, there are very few Vendian animal body fossils, particularly body fossils of the burrowing tracemakers.

The Cloudinidae consists of Vendian shelly fossils. The cone-in-cone tubular shells of genera such as *Cloudina, Sinotubulites* (**Figure 1**), and *Wyattia* are presumed to have been formed by worm-like animals. Cloudinids are occasionally associated with a bizarre, weakly calcified, stalked, goblet-shaped organism called *Namacalathus*. The biological affinities of cloudinids and namacalathids are not well understood, but they do seem quite unlike the more familiar skeletonized animals of the Early Cambrian. An algal affinity for the two has been suggested and cannot be ruled out. Large pores in the calyx of *Namacalathus* were probably filled with soft tissue in life; the pores might have served to admit light into the organism to sustain photosymbionts.

Ediacarans are the most puzzling part of the Vendian biota. These bizarre creatures grew to enormous sizes by Vendian standards, with some of the frondose forms reaching 2 m or more in length. The Ediacaran body is non-skeletal and seems to have been formed of a tough integument, in some cases partitioned into modules of similar shape. Unlike most other soft-bodied creatures, Ediacarans were capable of being preserved in sandstones. Ediacarans appear to be multicellular, but even this inference has been subjected to dispute. The concept of metacellularity (i.e., a body composed of uni- or polycellular partitions called metacells) has been applied to Ediacarans with some success.

Many palaeontologists have assigned these forms to conventional animal phyla, such as the Cnidaria,

Figure 1 *Sinotubulites cienegensis.* An early shelly fossil, this cloudinid is from the La Ciénega Formation of Sonora, Mexico. Holotype specimen. Length of largest tube, 12 mm.

Echinodermata, or Annelida, but the arguments supporting these assignments have not convinced everyone. Sceptics point out that not a single uniquely animalian trait has been identified on any of the thousands of Ediacaran fossils collected so far. A consensus for at least some of the fossils may be emerging, however, with recent new evidence showing trilobitoid arthropod features in *Spriggina,* and with the association of *Kimberella* with grazing traces.

In addition to the difficulties with systematic placement, there is the thorny problem of Ediacaran preservation. None of the Ediacaran fossils have skeletons, with the possible exception of the cloudinids and the namacalathids (whose relationship to the other Ediacarans is not known). Their cuticle also appears to have been relatively soft and flexible. Many of the Ediacaran fossils are preserved in relatively coarse sandy sediment, not ordinarily considered to be a good substrate for the preservation of non-skeletal organic remains. Thus, the preservation of Ediacarans must be explained either by unusual properties of the cuticle itself, or by anactualistic processes on the Vendian seafloor that could account for the preservation of soft tissue in sandstone. The latter possibility has evoked what is called the 'death mask' hypothesis, namely the idea that microbial mats in some way hardened the surface of dead Ediacarans, allowing them to be preserved as fossils. Unfortunately, the death mask theory is invoked by its supporters to explain all aspects of Ediacaran taphonomy – for example, the death mask mats supposedly formed beneath layers of storm sand and both above and below living Ediacarans, three highly uncertain propositions.

A key bedding plane surface from Newfoundland provides a new perspective on the death mask controversy (**Figure 2**). This bedding surface was smothered by a volcanic ash fall, entombing specimens of an unnamed spindle-shaped Ediacaran and a stalked form called *Charniodiscus*. The *Charniodiscus* was superimposed over the spindle form, and yet the morphology of the spindle creature shows clearly through the cuticle of the *Charniodiscus*. Thus, the death mask hypothesis is falsified, as there was no space for a post-mortem microbial mat to form between the *Charniodiscus* and the spindle. If the death mask hypothesis were correct, only the overlying *Charniodiscus* morphology should be preserved, but this is clearly not the case in this example.

Consequently, we are left with the idea that Ediacarans bore an unusually resilient cuticle. There is much going for this concept, as a link between Ediacarans and a problematic group known as conulariids (first suggested in 1987) has been dramatically confirmed by the discovery of the probable conulariid *Vendoconularia triradiata* in Vendian strata of the Ust'-Pinega Formation of the Onega River region, Russia. Conulariids appear to be a group of Ediacarans that survived well into the Palaeozoic. As with the Ediacarans themselves, most attempts at classifying

Figure 2 Cast of specimen of *Charniodiscus* superimposed over a spindle shaped form from the Mistaken Point assemblage in Newfoundland. Fibreglass cast (Pratt Museum, Amherst College). Width of view, approximately 11 cm.

conulariids have tried to assign them to the Cnidaria, and have met with failure. Part of the problem seems to be that conulariids display, as do other Ediacarans, both triradial and fourfold radial symmetry. This translates in metacellular terms to the unipolar iteration of six, eight, twelve, or sixteen founding metacells. The phosphatic nature of the (also somewhat flexible) conulariid cuticle may provide an important clue to the nature of the Ediacaran cuticle.

The most difficult Ediacaran problem is that of body geometry. Attempts to classify Ediacarans as animals have been hindered by their unusual constitution, which can show combinations of triradial symmetry and glide symmetry (as in the genus *Pteridinium*; Figure 3); these have proven to be impossible to fit into a conventional metazoan body plan model. Some researchers have tried to break the impasse by arguing that Ediacarans are colonial communities of individual animals. This explanation is not adequate to the task either, as each Ediacaran seems to be a well-integrated individual holobiont rather than a loose collection of individuals in a colony. Furthermore, there is no evidence for the loss of morphological features in specialized individuals, as is the case in the highly integrated colonies of modern hydrozoans.

The concept of metacellularity may help to solve this morphological problem. Some Ediacarans are apparently modular partition creatures, and the individual units or partitions, referred to as metacells, are either uni- or polycellular pods that may be flattened, stretched, inflated, or repeated (to form an iterated chain of metacells) as required. Metacellular creatures of this style are known amongst the modern biota (e.g., characean pondweeds, such as *Nitella*, can have individual cells measuring up to 15 cm in length), but no other type of organism has explored the potential of metacellularity as thoroughly as have the Ediacarans. The concept of metacellularity seems to apply best to the Ediacarans of the Mistaken Point biota in Newfoundland, the morphologies of which (spindle forms, branch forms, pectinate forms) are strange even by Ediacaran standards.

The metacellularity concept does not solve the problem of whether Ediacarans are animals; for example, hexactinellid (glass) sponges can undergo a coenocytic or syncytial (plasmodial) stage that is quite uncharacteristic for animals. Metacellularity is unknown in living animals and, for this reason, a number of palaeontologists prefer to place at least some of the Ediacarans into their own Kingdom, the Vendobionta. These Ediacarans could conceivably bear a closer relationship to several protoctist groups (such as the xenophyophores) than they do to animals. A common ancestry with the protoctist group that gave rise to the animals is still plausible, though, and may even be likely. Even Ediacarans that would seem to have a more animalian character, such

Figure 3 *Pteridinium simplex*. Cast of specimen from the Nama Group, Namibia. The fossil is viewed from its underside; the undersides of two vanes are visible, and the basal part of the third vane is visible between them as a stitch like chain of tube ends. Scale bar in centimetres.

Table 1 Ediacaran body forms, classified by metacellular grade

Original number of metacells	*Founding metacell(s) only, no iteration*	*Unipolar iteration of metacells*	*Bipolar iteration of metacells*
One	*Cyclomedusa, Evandavia, Parvancorina (?)*	*Charniodiscus, Charnia*	Spindle form of Newfoundland
Two	*Gehlingia*	*Dickinsonia, Phyllozoon*	*Windermeria, Ernietta*
Three	*Tribrachidium, Anfesta, Albumares*	*Swartpuntia*	*Pteridinium simplex*
Four	*Conomedusites*	*Spriggina (?), Marywadea (?)*	*Pteridinium carolinaensis*
Five	*Arkarua*	*Rangea (?)*	Unknown

Figure 4 *Evandavia aureola*. This hiemalorid Ediacaran occurs in the Clemente Formation, Sonora, Mexico. It is perhaps the oldest known (approximately 600 Ma) specimen of a complex life form. Scale bar in centimetres.

as *Yorgia waggoneri* from the White Sea region in Russia, show strange asymmetries in the 'head' region that challenge the animal interpretation.

Many Ediacarans may be placed in the metacellular grouping (Table 1). These forms manifest both a smooth central metacell surface and a surface formed of radial (and often bifurcating) tubes. *Evandavia aureola* is a non-iterated discoidal form from Sonora, Mexico, with a single metacell and radial tubes in its outer ring (Figure 4). Figures 5 and 6 show *Parvancorina minchami* from Australia, displaying a single trifold metacell with numerous branches coming from each branch of the initial metacell. *Parvancorina* serves as the subunit counterpart to *Tribrachidium* and *Gehlingia*, with the 'thumb structures' in the bilaterally symmetric *Gehlingia* and in the triradiate *Tribrachidium* homologous to the main medial branch in *Parvancorina* (Figure 7). Similar metacellular rearrangements may be observed in another Ediacaran clade, which includes the Newfoundland spindle-shaped form (Figure 8) and a 2 m long Newfoundland frond ('*Charnia*' *wardii*) shaped like an extremely elongate primary feather of a bird's wing. An interesting variation on the discoid body theme is a Chinese fossil from the Xingmincun Formation, southern Liaoning Province, consisting of a single, elongate metacell helically coiled into a flat disc. These specimens reach up to 4 cm in diameter.

Earth System Events

Eukaryotic phytoplankton are known from strata approaching 2 Ga in age, but, by the Vendian, these organisms began to resemble the modern phytoplankton at least in terms of diversity of tests, skeletons, and sheaths. Siliceous chrysophyte algae are known from Vendian strata of the Tindir Group, Alaska, and genera such as *Chilodictyon* and *Characodictyon* share a superficially diatom-like aspect.

Figure 5 *Parvancorina minchami.* A cast of a specimen from the Pound Supergroup of South Australia. Greatest dimension of specimen, 10 mm.

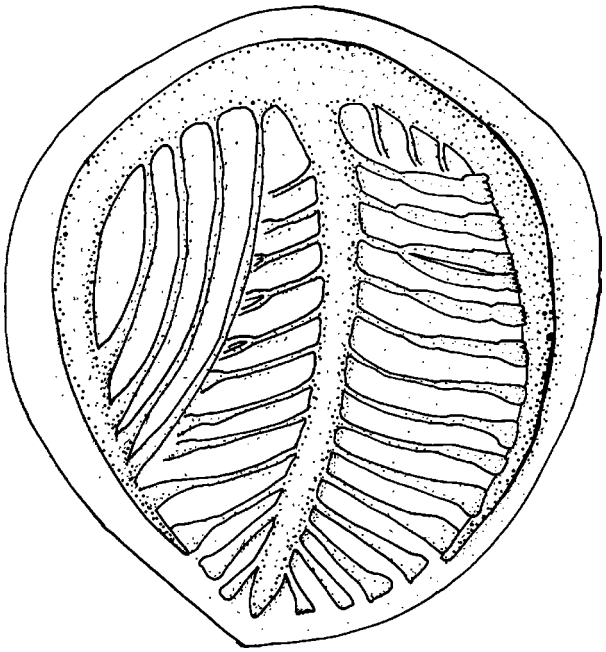

Figure 6 *Parvancorina minchami.* This Ediacaran poses difficulties for the arthropodan interpretation of this genus. Greatest dimension of specimen, approximately 10 mm.

In contrast, however, the Vendian seafloor had a distinctly primitive character. Microbial mats still blanketed the seafloor, as they had been doing since the Archaean, and stromatolites remained abundant even as burrowing began to alter their internal texture to the thrombolitic state. A wide variety of unusual sedimentary structures (with names such as *Arumberia*, *Kinneya*, and 'elephant-skin' texture) are known from fine clastic rocks of the Vendian. Lozenge-shaped structures (**Figure 9**) are often found on Vendian bedding surfaces; whether or not such structures might have use as a basis for interbasinal correlations is unknown. These primary sedimentary structures are puzzling, leading sedimentologists to invoke anactualist sedimentary processes to explain them. It seems quite reasonable to do so, as microbial mat carpeting of the seafloor would certainly influence the nature of marine sedimentation. Preston Cloud once called stromatolites 'organo-sedimentary structures', and the shelf, slope, and rise sediments of the Proterozoic may be thought of as a gigantic, connected, organo-sedimentary structure. Judging from the diversity of bedding plane texture types, never before or since have microbes had such a direct and intimate association with the basic processes of clastic sedimentation. Ediacarans evidently adhered to the surface of these mats or (in the case of forms with holdfasts and possibly in the case of *Pteridinium*) lived beneath them.

Metazoan burrowers apparently began their excavations beneath this mat surface, and evidence suggests that the earliest ichnofossil makers were submat burrowers. A good example is the Vendian trace fossil, *Vermiforma,* from the Carolina Slate Belt. This enigmatic and relatively large trace fossil, associated with other types of submat burrowers, consists of ten specimens that all follow the same rather tortuous track. As the traces are separated from one another by some distance, all underneath the mat, it is hard to

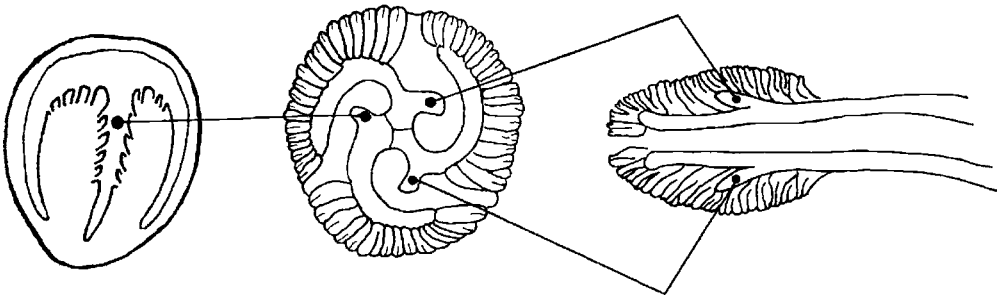

Figure 7 Ediacaran homology. Homologous structures ('thumb structures') linking the Ediacaran genera *Parvancorina* (left: length, 1 cm), *Gehlingia* (right: length, 8 cm), and *Tribrachidium* (centre: diameter, 1 cm). In spite of the vast differences in body symmetry type, the three genera are seen to be closely related.

Figure 8 Spindle shaped form from the Mistaken Point assemblage in Newfoundland. Fibreglass cast (Pratt Museum, Amherst College). Scale bar in centimetres.

imagine how and why the track paths were coordinated in shape. Arguments that *Vermiforma* is a pseudofossil are called into question by the presence of other types of trace fossils on the same bedding plane surface.

Throughout its duration the Vendian is marked by steadily increasing levels of bioturbation. The top of the Vendian system is currently defined by the appearance of the three-dimensional trace fossil *Trichophycus pedum*. The maker of this trace was able to excavate vertically as well as horizontally, and its activities (along with those of other vertical burrowers, such as the makers of *Skolithos*) tended to homogenize seafloor sediments. It would also presumably have punctured and shredded any microbial mats in the immediate vicinity.

It is thought that, towards the end of the period, the seafloor mat seal began to break down due to the intensity of metazoan burrowing activity. Such uncapping of the seafloor had dramatic consequences, both for the carbon budget of the planet (e.g., buried carbon was put immediately back into circulation) and for marine nutrient levels (e.g., sediment grains in suspension make wonderful substrates for nutritious bacterial growth). At about the same time, there was a tremendous flux of mineral nutrients to the oceans resulting from the fact that the Vendian saw a rare tectonic coincidence in Earth's history: the simultaneous occurrence of both divergent tectonics (final breakup of Rodinia) and convergent tectonics (formation of Gondwana, in an event known as the Pan-African Orogeny (*see* **Africa:** Pan-African Orogeny)), on a massive scale. As suggested by marine strontium isotopes of the Vendian, huge amounts of siliciclastic debris were shed from rift valley margins into the Vendian ocean. This would have been added to the volcaniclastic sediments derived from weathering of rift-associated basalts. The enhanced pool of igneous rock debris contributed mightily to an oceanic fertilization event that has been implicated in the emergence of skeletonized animals and the Cambrian explosion.

Figure 9 Lozenge shaped structures from the Clemente Formation, Sonora, Mexico, found in association with *Evandavia aureola* and other Ediacarans. Such structures are known from Ediacaran bearing strata on other continents. Scale bar in centimetres.

It appears that a massive palaeoecological reorganization of the marine biosphere took place at the end of the Vendian. With the exception of some very Late Vendian evidence for predatory activity in Sonora, Mexico, no evidence for large predators has been recognized in Vendian strata. In contrast, the Early Cambrian exhibits evidence for a great intensity of macropredation, involving forms such as the 2 m long predatory animal *Anomalocaris*. The Vendian biosphere has thus been referred to as a uniquely peaceful Garden of Ediacara, where large creatures, many with flattened bodies, partook of sunlight (via photosymbiosis), hydrogen sulphide (via chemosymbiosis), or osmotrophy (direct absorption of dissolved nutrients in seawater) on a mat-covered seafloor surface free of large predators. However, it was too good to last, and animals in the role of burrowers from below and predators from above triggered a rapid end to the Garden and the end of the Vendian.

The question of whether or not there was a mass extinction at the end of the Vendian is unresolved at present. A number of Ediacarans appear to have survived the Cambrian boundary, occurring with Cambrian fossils in Australia, Ireland, and elsewhere. Studies based on borehole data from the oil-producing strata in Oman have recently shown that cloudinids vanish from the record without a trace, and that this disappearance is not associated with any discernible lithological change. Thus, the disappearance of cloudinids from Oman cannot be attributed to environmental or facies change. Their loss has thus been interpreted as a major extinction event. Whether or not this localized loss of cloudinids represents a mass extinction, or an extinction event at all, is not known. Cloudinid-like fossils have been reported from the Cambrian Torneträsk Formation in northern Sweden.

Secular variations in secular isotopes in the Vendian are rather difficult to interpret, but, after a slight decrease from $-3‰$ $\delta^{13}C$ to $-5‰$ $\delta^{13}C$ after the Marinoan glaciation (Canadian and Namibian sections), the $\delta^{13}C$ values during the Vendian appear to undergo a fairly steady rise to a value of over $+3‰$ right before the Cambrian boundary (Dvortsy section, Aldan River, Siberia). The Vendian–Cambrian boundary itself is marked by a sudden $+3‰$ to $-1.4‰$ drop in $\delta^{13}C$ over a very short stratigraphical interval, as measured at the Dvortsy section.

This excursion has been linked to a variety of factors, including some sort of global environmental perturbation that also triggered the extinction of the cloudinids and many of the Ediacarans. Another way to look at it, though, is that the boundary excursion represents that moment in geological time when marine burrowing intensity crossed a threshold. At this critical point, the microbial mat seal on the seafloor may have been breached, resulting in previously immobile sediments (and their associated organic matter) becoming mobilized and injecting huge amounts of biogenic carbon into the water column. Owing to biogenic isotopic fractionation, this detrital organic matter was significantly depleted

in the heavy isotope of carbon and, as it went into circulation in marine water, caused the precipitous drop or boundary excursion in the $\delta^{13}C$ value.

It therefore seems reasonable to interpret the Vendian carbon isotope curve as a record of gradually increasing biotic productivity, with sequestering of much of the organic matter within and below the seafloor microbial mats, followed by a relatively sudden release of part of this organic matter deposited at the end of the Vendian as a result of increased burrowing intensity. Other factors, such as destabilization of gas hydrates in seafloor sediments, may also have been involved in these isotopic excursions.

A number of other phenomena can perhaps be traced to what has been called the Cambrian Substrate Revolution. The Vendian and Cambrian both saw an increase in the proportion of calcified filamentous microbes (such as *Girvanella*), which were perhaps less palatable to mat grazers than filamentous cyanobacteria and unprotected algae. With all the new sediment and organic matter in suspension, filter feeding probably became more possible throughout the water column, leading to the evolution of the first tiered filter feeders in the Cambrian. The only Vendian organisms that were likely to engage in suspension feeding were the cloudinids, which lived close to the sediment–water interface.

Finally, assuming that we are interpreting the secular carbon isotopic curve correctly, it is entirely possible that oxygen levels increased in the Vendian due to the sequestration of organic matter. Whether or not increasing oxygen levels influenced metazoan evolution is not known, although it seems fair to say that early burrowing animals would not have required high levels of oxygen. The earliest animal habitat appears to have been the submicrobial mat environment, where oxygen levels would probably have been rather low considering the relative abundance beneath the mats of hydrogen sulphide and other reduced compounds.

Glossary

abiogenically A term applied to rocks formed by processes not directly influenced by living organisms.

anactualistic processes Processes that occurred at one time in the Earth's past, but which are no longer operational today.

cloudinid A late Vendian calcareous shelly fossil consisting of closely nested, thin-walled tubes or cones. Thought to represent one of the earliest examples of a shelly animal fossil. Includes the genera *Cloudina* and *Sinotubulites*.

coelomic spaces The compartments that house the rigid, fluid-filled body cavity present in many animals. The coelom serves as a hydrostatic skeleton.

conulariid Any member of an enigmatic group of Vendian/Cambrian to Triassic shelly organisms. They formed conical, often pyramidal, tapering cones with transverse ribbing, composed of calcium phosphate.

Ediacaran Any member of a group of marine, megascopic fossils with a metacellular growth pattern. Found primarily in strata deposited before the Cambrian period. Assigned to extinct Kingdom Vendobionta.

frondose forms Ediacarans with a leaf, palm, or frond body form.

Garden of Ediacara A palaeoecological theory that holds that the marine ecosystems of the Vendian were largely free of megascopic predators and thus allowed organisms such as Ediacarans to survive unmolested using photosymbiotic, chemoautotrophic, and osmotrophic life styles.

holobiont A single integrated organism, as opposed to a colonial organism.

hydrostatic skeleton A fluid-filled internal organ or support structure within an animal's body that can be kept rigid or made limp by control of internal water pressure.

metacell A single or isolated modular unit of a metacellular organism; usually consists of a single enlarged cell.

metacellularity Term applied to organisms that are either multicellular (such as animals and plants) or consist of clusters or metacells (such as Ediacarans and certain types of aquatic algae).

Mirovia The Precambrian superocean that surrounded Rodinia.

molecular clock Any gene or gene sequence used by biologists in an attempt to determine the evolutionary time of divergence from a common ancestor between two or more groups of organisms belonging to different species.

osmotrophy A feeding strategy utilizing osmosis or direct absorption of nutrients.

peristaltic burrowing A burrowing strategy in metazoans that consists of rhythmic muscular contractions along the length of the body.

Rodinia A supercontinent consisting of all or nearly all of the continents. Consolidated one billion years ago (in an event referred to in North America as the Grenville Orogeny), this supercontinent broke up into smaller continents by the process of plate tectonics and continental drift before the Cambrian.

Sinian The Precambrian geological period immediately preceding the Vendian period.

Snowball Earth An extreme phase of glaciation in which glaciers reached tropical latitudes.

thrombolitic texture A texture in sedimentary rocks characterized by disrupted bedding lamination and a clotted fabric. Stromatolites develop this texture when influenced by burrowing metazoa.

Vendian The latest Precambrian geological period, immediately preceding the Cambrian period. Synonymous with Lipalian or Ediacaran.

Vendobionta The extinct kingdom to which Ediacarans are assigned.

PSEUDOFOSSILS

D M Martill, University of Portsmouth, Portsmouth, UK

Introduction

This entry discusses those objects that appear to be fossilized organic remains – often called pseudofossils – but which in reality are natural structures that merely resemble real fossils. Such structures occur commonly in sedimentary rocks and can easily deceive inexperienced, or even experienced, geologists and palaeontologists.

There are many types of pseudofossil, and they often occur associated with real fossils. They may be formed by both physicochemical and biochemical processes, some of which may be the same processes that are responsible for generating real fossils (*see* **Diagenesis, Overview**). Pseudofossils are highly variable in form, and the resemblance of a pseudofossil to a real fossil can be quite remarkable. To some degree an object's categorization as a pseudofossil is a reflection of the experience of the discoverer, and, as such, there is no strict definition of what is or is not a pseudofossil. Those with little or no experience of genuine fossils can easily believe that rocks and pebbles with striped or mottled patterning or unusual shapes might be genuine fossils; indeed, some pseudofossils are real fossils. Some calcareous algae can assume growth forms that resemble miniature versions of macro plant remains. A famous example of this is the so-called Landscape Marble from the Upper Triassic of the Bristol District of England. Here, intermixed arborescent and laminated growths of calcareous algae resemble scenes of forested hills (**Figure 1**).

Objects that are commonly confused with genuine fossils include both three-dimensional objects that represent some form of *in situ* mineral growth – called concretions or nodules – and largely two-dimensional entities occurring on rock surfaces that assume patterns resembling organic remains. In the latter category are the banded mineral growths called Liesegang bands (**Figure 2A**), dendritic mineral growths (**Figure 2B**), and various types of fracture surface (**Figures 3** and **4**).

Liesegang Banding

Liesegang banding (**Figure 2A**) is the result of the diffusion of soluble chemicals through micropores in a rock in differing concentrations and/or oxidation states and their precipitation to produce colourful (often orange, red, and brown) and variable banded patterns. Trace fossils (*see* **Trace Fossils**), such as filled burrows, can be prone to such diffusion and may resemble segmented worms and arthropods. In fact, such a structure would be both a genuine trace fossil (the burrow) and a pseudofossil (the imagined worm).

Liesegang banding occurs very commonly in chert nodules in the Cretaceous chalk formations of Europe. It also occurs commonly in many rocks where iron and manganese in a reduced state are weathering from the fresh rock to form oxides, such as goethite ($Fe_2O_3.H_2O$) and pyrolusite (MnO_2). Liesegang rings may penetrate the rock or may be restricted to surfaces such as bedding planes, joints, and microfracture planes.

Dendrites

Dendrites are arborescent patterns produced by the fractal growth of minerals as they precipitate from solutions that migrate through fractures in rocks. Commonly they occur as black traces of manganese dioxide (the mineral pyrolusite) or orange-brown precipitates of hydrated iron oxides such as goethite, although other mineral types may also occur. Such structures are commonly mistaken for the remains of soft foliage such as ferns and liverworts. Particularly beautiful examples occur in the Jurassic Solnhofen Limestone (**Figure 2B**) of Bavaria, Germany, and are often sold as ornaments.

Fracture Surfaces

The fractured surfaces of rocks may exhibit patterns that can be confused with organic remains. Very fine-grained and glassy rocks may split with conchoidal fracture – a series of concentric ripples emanating from the initial point of fracture (**Figure 3A**). Indeed, the very name suggests that the fracture resembles a shell. It is common for flint to fracture in this way, and such conchoidal fractures in flint may resemble the bivalve *Inoceramus* (**Figure 3B**), which is a genuine fossil that often occurs in Cretaceous flints.

Some fracture surfaces may exhibit feather-like traces, while others may show regular banding resulting from the intersection of cleavages or bedding planes with the fracture surfaces.

Figure 1 A real fossil resembling another. A cut surface through the Late Triassic 'Landscape Marble': both the laminated and the arborescent patterns were formed by calcium carbonate precipitation influenced by benthic photosynthetic microbes (probably blue green bacteria). Such structures are known as stromatolites. In former times, small village scenes were painted onto these slabs to create picturesque landscapes.

Figure 2 Superficial pseudofossils on bedding planes of the Late Jurassic Solnhofen Limestone Formation from Bavaria, Germany: (A) Liesegang banding as a series of iron oxide (goethite) diffusion fronts, and (B) dendritic patterns in pyrolusite and goethite. Photographs by Robert Loveridge.

In an unusual example (Figure 4), a piece of highly compacted fossil wood has numerous parallel and orthogonal evenly spaced cracks that have divided the wood into a series of small cubes. Such a blocky fracture pattern is common in fossil woods and can be seen in most bituminous coals. In the specimen shown in Figure 4, each small coaly cube generated a conchoidal fracture when the rock was split to reveal the fossil wood (the split propagated through the fossil wood rather than around it). As a consequence, each cube has a near-spherical surface with concentric ripples. This circular structure resembles the leaf-scar pattern seen on many stems of fossil plants, but the structures are an artefact of splitting.

Cone-In-Cone Structures

Cone-in-cone structures are the result of an unusual growth of minerals in which fibrous crystals assume a cone-like growth form (Figure 5A). They are frequently mistaken for fossils, particularly fossil corals, because the outer surface appears as a series of concentric rings or raised discs (Figure 5B). Cone-in-cone structures are usually composed of fibrous calcite crystals, which nucleate on the surfaces of limestone bands, shell beds, or even large fossils and grow orthogonal to that surface into fine-grained strata, such as clays and shales.

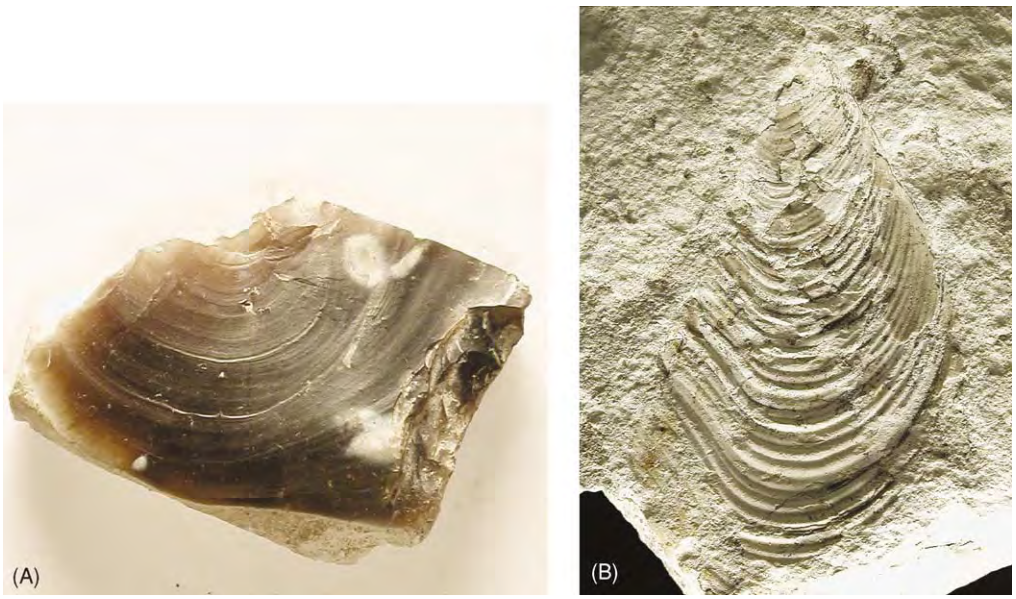

Figure 3 (A) Conchoidal fracture in flint. (B) The bivalve *Inoceramus*. *Inoceramus* occurs commonly in flint, and so conchoidal fractures may be easily confused with this bivalve. Photographs by Robert Loveridge.

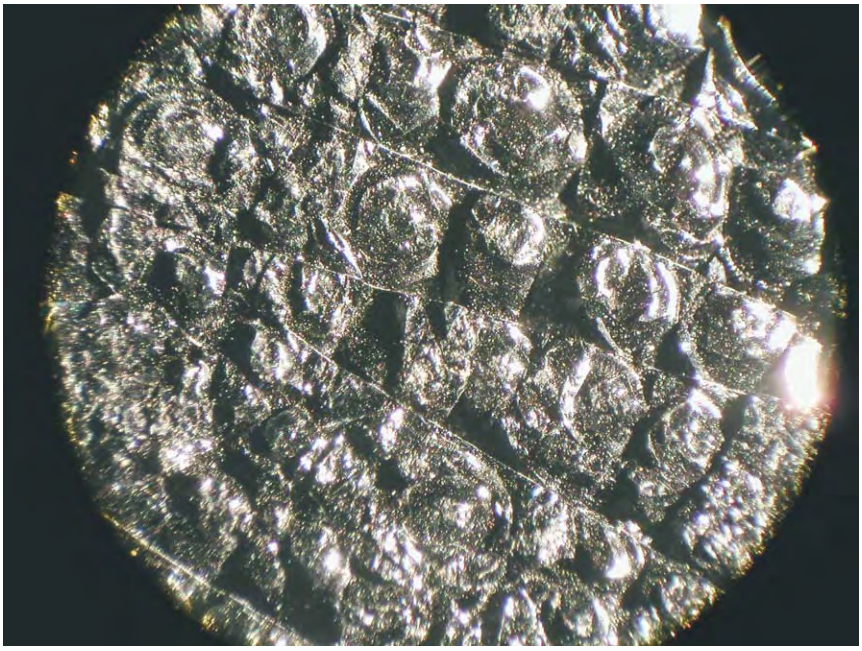

Figure 4 Conchoidal fractures in small cuboid segments of a fossil tree stem from the Lower Jurassic Posidonia Shale Formation of Dottenhausen, Germany. The conchoidal fractures resemble leaf scars but are a consequence of fracturing of the hard amorphous coal like material. Photograph by Robert Loveridge.

Nodules and Concretions

Many of the common diagenetic minerals (those minerals that form in sediment and cement that sediment into rock) form nodular growths that can easily be mistaken for organic remains. Such mineral growths may assume bizarre shapes, influenced by the rate and direction of diffusion of solutes through the sediment and fluctuations in pH and eH. They may contain genuine fossils, and in some cases the external shape of the nodule assumes the shape of the enclosed fossil as it grows around it. The external appearance of nodules and concretions can be

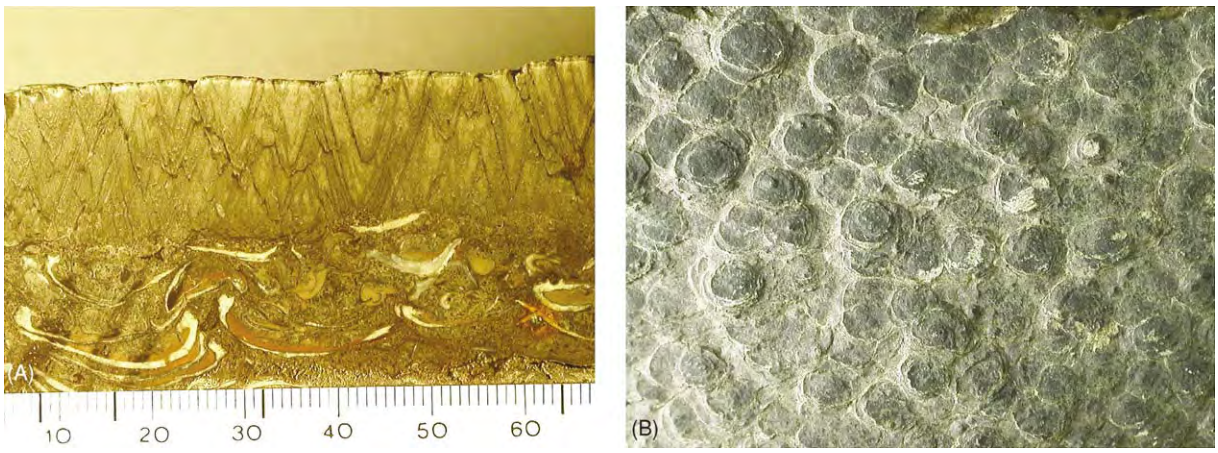

Figure 5 Cone in cone structures: (A) a cut section of a cone in cone that has grown on the surface of a shell bed, and (B) surface view each cone appears as a circle or disc that can easily be mistaken for a fossil coral at first glance. Photographs by Robert Loveridge.

Figure 6 Nodules and concretions. (A) A spherical concretion of mudstone can easily be mistaken for a fossil egg. (B) The concretion in **Figure 6A** is split in half to reveal internal septarian cracking. Such cracks are often mistaken for fossils. Photographs by Robert Loveridge.

highly irregular, and they frequently assume shapes resembling isolated bones or even whole animals when there is no fossil enclosed. Highly spherical concretions (**Figure 6A**) are often mistaken for fossil eggs. Internally, concretions may have radial cracks or a honeycomb network of crystal-lined cracks (**Figure 6B**). Such concretions are called septarian concretions, and they are frequently mistaken for fossils.

Common mineral species that occur as concretions and nodules include the iron sulphide minerals pyrite and marcasite (nodules of the latter are often mistaken for meteorites), silica in the form of chert and flint, and calcite where it cements clay. Nodules sometimes grow in bands or strings, and, en-masse, they can resemble rows of vertebrae or ribs of large skeletons. A nodule of ironstone found within the rib cage of a dinosaur was mistakenly thought to be a fossil heart by a team of Canadian palaeontologists.

Very recently, experiments in which crystals of barite have been grown in gels under laboratory conditions have produced morphologies and sizes that are remarkably similar to structures found in Precambrian rocks that have previously been interpreted as fossil bacteria. The laboratory-grown crystals also resemble structures found in Martian-derived meteorites that were interpreted as evidence of extraterrestrial life. It looks as though these ancient and extraterrestrial microfossils might also prove to be pseudofossils.

PYROCLASTICS

R J Brown, University of Bristol, Bristol, UK
E S Calder, Open University, Milton Keynes, UK

Introduction

Pyroclasts are formed by the explosive fragmentation of magma (molten rock) during volcanic eruptions (*see* **Volcanoes**). They are carried away from the vent by buoyant eruption plumes, extensive umbrella clouds, or by destructive ground-hugging pyroclastic density currents. The largest explosive eruptions can produce pyroclastic deposits many 1000's km^3 in volume, which can be emplaced on a regional scale in a matter of hours. The study of the physical characteristics of pyroclasts and pyroclastic deposits can reveal much about the dynamic processes involved during explosive eruptions and in pyroclast dispersal and deposition. Recognizing, observing, and understanding pyroclastic deposits are vital first steps in assessing and mitigating volcanic hazard (*see* **Engineering Geology:** Natural and Anthropogenic Geohazards). This chapter summarizes the physical characteristics of the principal types of pyroclastic deposits and presents an introduction to their generation and emplacement mechanisms.

Generation of Pyroclastic Material

Explosive fragmentation of magma during volcanic eruptions can occur by two main mechanisms. The first involves the rapid exsolution of dissolved magmatic gases during rapid decompression events (magmatic eruptions), and the second results from the interaction of hot magma with external water sources (phreatomagmatic eruptions). Pyroclastic material can also be generated by rapid decompression and by autobrecciation processes during lava dome collapses.

Magma comprises three separate materials or phases: a viscous silicate melt (of varying composition), variable amounts of crystals (phenocrysts), and gas (volatiles) such as H_2O, CO_2, S, F, and Cl. There is a general positive correlation between the silica content of a magma and the degree of explosivity (Table 1). However, it is the quantity and behaviour of the gas phases that are critically important in determining the eruption style, because it is the rapid expansion of gas during decompression that drives explosive volcanic eruptions. Magma is stored at depth in magma chambers, under high temperatures and pressures. Magmatic eruptions are preceded by an increase in pressure and volume in the magma chamber. This is often attributed to the arrival of new magma into the chamber. The upper parts of many magma chambers are thought to contain a small volume fraction of gas bubbles (vesicles) due to supersaturation with volatiles, and seismic disturbance of these pre-existing bubbles can also lead to increases in magma chamber pressure (Figure 1). Crystallization, which enriches the melt in volatiles, can also act as a trigger. Once a critical point is reached, mechanical failure of the magma chamber roof occurs, allowing magma to rise, decompress, and exsolve gas in a runaway process (vesiculation) that can rapidly drive magma up the conduit at speeds of 200–400 m/s. Vesicle growth is controlled by the volatile content and by the physical properties of the magma (diffusivity rate, density, viscosity, and surface tension). The diffusivity rate is particularly important, and controls the rate at which gas bubbles escape from the magma: where escape is fast (in hot basic lavas), eruptions tend to be effusive or weakly explosive, but where escape is inhibited by high viscosities and low diffusivity rates (in intermediate and rhyolitic magmas), the exsolution of gas can explosively, and very violently, disrupt the magma. The expansion and coalescence of these bubbles forms a magma foam with radically different physical properties to that of the parent magma. During ascent, this rising vesiculated magma is fragmented into discrete particles and transforms into a gas-particle mixture, which accelerates up the conduit and is discharged into the atmosphere (Figure 1).

Phreatomagmatic fragmentation is driven by the volumetric expansion of external water after it has been rapidly heated by contact with magma. This mechanism is not restricted by magma type or vent type and it encompasses a spectrum of eruption styles

Table 1 Summary characteristics for the major types of explosive volcanic eruptions

Eruption type and examples	*C*	*H (km)*	*V (km^3)*	*D (km^2)*	*Common eruption processes*	*Pyroclast types*	*Duration*	*Deposits*
Magmatic								
Hawaiian Kilauea, Mauna Loa, Hawaii	Ba	$\ll$1	$\ll$1	<1	Sustained fire fountains; spatter fed lava flows; lava lakes; weak ash plumes	Scoria, ash, spatter, bombs, Pelee's hair and tears, reticulite	Days to years	Clastogenic lava; scoria cones; spatter cones; spatter ramparts; localized sheet like ashfall deposits

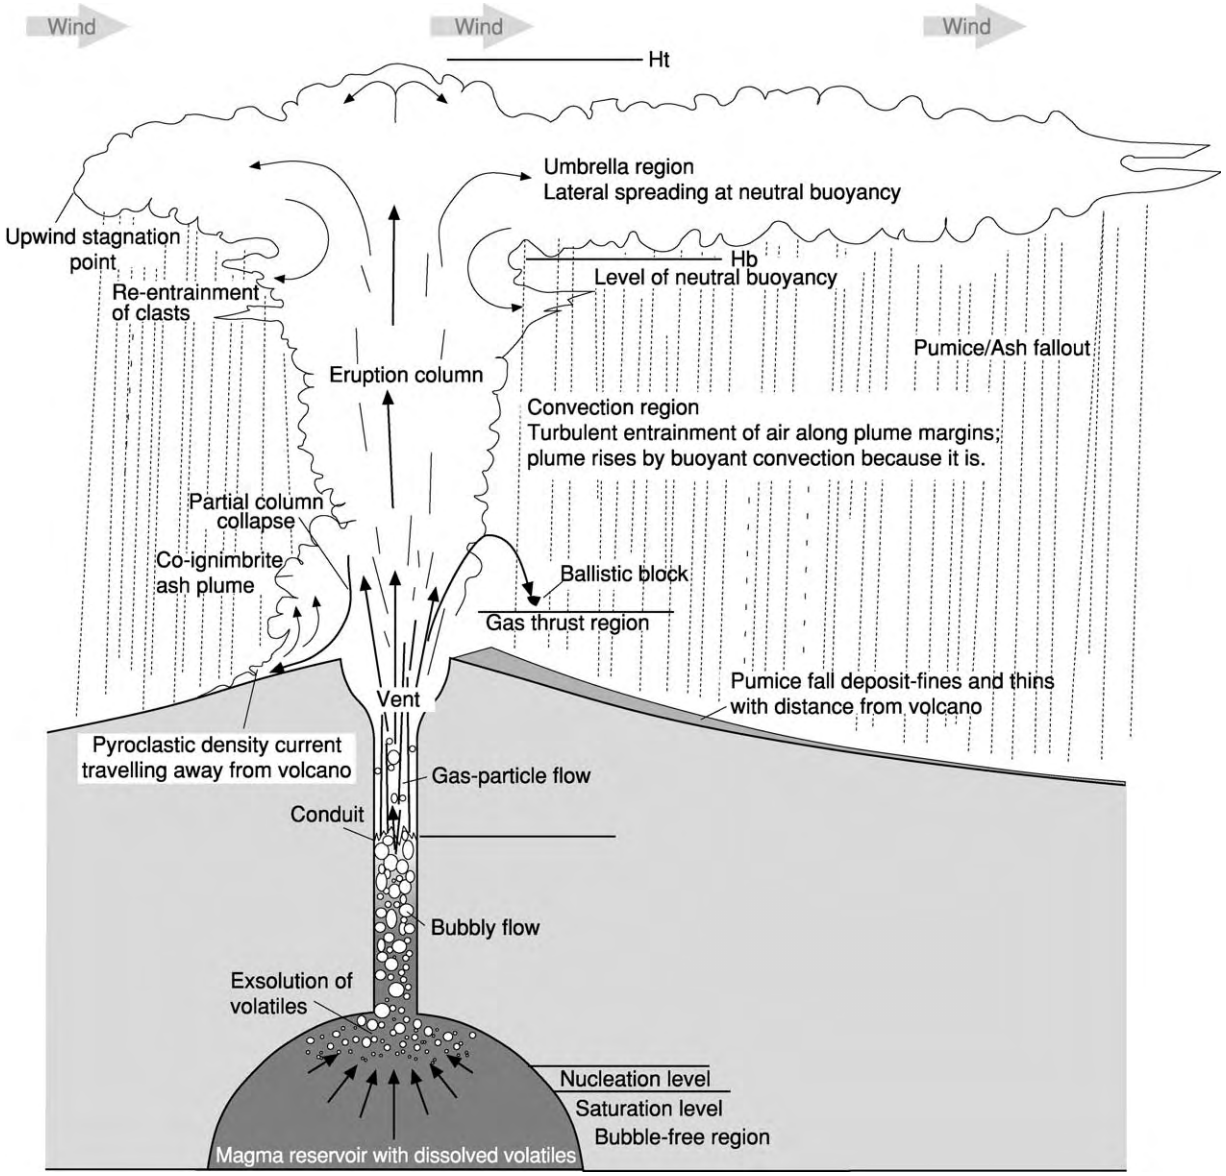

Figure 1 Cartoon illustrating the processes involved during an explosive eruption (in this case a Plinian eruption). Major processes in the magma chamber, conduit, and eruption plume are indicated.

from the shoreline fragmentation of lava (*see* **Lava**) entering the sea, to large volume phreatoplinian eruptions (Table 1). During a phreatomagmatic eruption, thermal energy is converted into mechanical energy (including seismic and acoustic energy) and kinetic energy (fragment motion). Fragmentation is controlled by the mixing ratio between water and magma, and by the magma viscosity, temperature/pressure, and the water/magma contact mode. As the eruption efficiency increases, more mechanical energy is released and fragmentation increases, resulting in a finer grain size and a greater distribution of pyroclasts.

The two fragmentation mechanisms are not mutually exclusive. Exsolving magmatic volatiles may contribute to expansion and fragmentation during phreatomagmatic eruptions, while phreatomagmatic phases are common during sustained magmatic Plinian and less extreme types of eruptions.

Eruption Plumes

Volcanic plumes are generated when explosive eruptions discharge a mixture of pyroclasts and gas into the atmosphere (Figure 2). These may either form buoyant convective plumes, which rise to great

Figure 2 Small Strombolian fire fountain feeding a weak ash plume (Etna, South Italy, 2003). (Photo courtesy of Tom Pfeiffer www.decadevolcano.com)

heights in the atmosphere (<50 km) or they may collapse to form fountains (column collapse), which can generate flows of hot particles and gas that move laterally away from the volcano (pyroclastic density currents; Figure 3). Eruption plumes are termed 'maintained plumes' if the duration of discharge is sustained relative to the ascent time of the plume (e.g., Plinian eruptions) and 'instantaneous plumes' or 'thermals' if the discharge is short-lived relative to ascent time (e.g., Vulcanian explosions). The basic tripartite structure of these plumes is shown in Figure 1. In the gas thrust region the mixture of gas solids and liquid is expelled vertically from the vent as a jet with speeds up to a few hundred metres per second and a bulk density greater than that of the surrounding atmosphere. Air is mixed into the column, heated by the pyroclasts and expands, resulting in a decrease in the mixture density. If sufficient air is entrained and heated, the bulk density of the jet decreases below that of the surrounding atmosphere and the jet becomes buoyant, rising as a convective column. The plume continues to rise until it reaches a level of neutral buoyancy (Figure 1, 'Ht and Hb') at which it spreads laterally in an umbrella cloud. If however, sufficient air is not entrained, the jet decelerates until its velocity becomes zero and since the bulk density is greater than the surrounding atmosphere, the mixture begins to fall back to the Earth's surface.

Eruption Styles

Important measures of an explosive volcanic eruption are the magnitude (volume of erupted dense rock equivalent magma, in km^3), intensity (mass-flux), dispersal (areal extent of fall deposits, km^2), and driving mechanisms (magmatic or phreatomagmatic). These parameters are used to classify explosive eruptions; the characteristics of the major types are summarized in Table 1. Volcanic eruptions are extremely dynamic natural phenomena and many sustained eruptions undergo significant changes or fluctuations in eruption style through time, for example, changing from Surtseyan phreatomagmatism to Strombolian fire-fountaining. Likewise, the opening stages of Plinian eruptions can be phreatomagmatic or Vulcanian in style. Thus, the deposit of one eruptive sequence may comprise layers of contrasting pyroclasts that were formed by differing fragmentation mechanisms.

Pyroclast Types and Deposits

During explosive volcanic eruptions, magma can be transformed into pyroclasts (also called tephra) of widely varying physical properties, that range in size from submillimetric ash up to boulder size. Pyroclasts are classified according to their origin. Juvenile pyroclasts are derived from the erupting magma, and include pumice, scoria, volcanic glass, ash, crystals, and bombs (see Table 2 for descriptions). In magmatic eruptions, juvenile volcanic ash (vitric ash) comprises fine-grained cuspate, platy, or Y-shaped vesicle-wall shards. Vitric shards generated during phreatomagmatic eruptions can have blocky, fusiform, moss-like, platy, and spherical or drop-like shapes, reflecting the many different ways in which water and magma can explosively interact. Cognate pyroclasts are derived from the deposits of earlier eruptions at the same volcano, while accidental pyroclasts are those derived from the subvolcanic basement during the eruption or picked up by a pyroclastic density current during transport. Pyroclastic deposits typically comprise a mixture of juvenile, cognate, and accidental components. Due to the large differences in the physical properties of these components, and the sorting and segregation processes operating during pyroclast

Table 2 Characteristics of the main types of pyroclastic material

Pyroclast	*Description*	*Associated eruption styles*
Ash	Fine grained (<2 mm diameter); whole or broken crystals, accidental lithic clasts or glass (vitric) shards; vitric shards can be cuspate, platy (broken vesicle walls), blocky (unvesiculated glass), or pumiceous	All
Pumice	Highly vesiculated volcanic glass; (density <1.0 g cm^3 floats on water); fibrous or spherical/subspherical vesicles	Silicic explosive eruptions (particularly Plinian)
Scoria	Poorly vesiculated volcanic glass (density <1.0 g cm^3 sinks in water; spheroidal vesicles; vesicularities 70 85%	All explosive eruptions; particularly Strombolian, Vulcanian
Bomb	Fluidal clot of magma that partially cools during flight; types include spindle, cow pat, breadcrust, and cauliflower bombs	Hawaiian, Strombolian, Vulcanian
Spatter	Irregular fluidal clots of magma that can coalesce (weld) on impact	Hawaiian, Strombolian
Pelee's hair/ tears	Hair: long thin strands of glass Tears: irregular droplets with fluidal shapes (e.g., tear drop, ovoid and spheroid)	Hawaiian, Strombolian
Reticulite	Polygonal, lattice like networks of very fine glass rods; very highly vesicular (95 99%)	Hawaiian
Accretionary lapilli	Comprise an ash core surrounded by one or more concentric laminae of usually finer grained ash; also ash pellets, which lack concentric rims; Armoured or cored lapilli comprise a pumice or lithic lapilli core surrounded by a concentric rim of ash	All explosive eruptions that generate abundant fine ash; particularly phreatomagmatic (Surtseyan and Phreatoplinian); Magmatic eruptions during humid atmospheric conditions

Table 3 Particle size parameters for pyroclastic material

phi	*Mm*	*Class*
<3	<0.12	Very fine ash
3 1	0.12 0.5	Fine ash
1 to 0	0.5 1	Medium ash
0 to 1	1 2	Coarse ash
1 to 3	2 8	Fine lapilli
3 to 5	8 32	Medium lapilli
5 to 6	32 64	Coarse lapilli
> 6	>64	Blocks and bombs

dispersal, the lateral and vertical distributions of these components may vary significantly within a deposit.

The grainsize terminology for pyroclastic material is given in Table 3. The term ash, when used to describe a pyroclastic deposit, refers to a unit comprised dominantly of ash-grade particles. When such a deposit is indurated or lithified, it is commonly called tuff. Deposits comprising ash and lapilli-grade particles are referred to as lapilli-tuffs, and deposits containing an abundance of blocks are called pyroclastic breccias. Pyroclastic successions can be best studied by utilizing a lithofacies-based approach. Lithofacies are commonly defined on a two-tier system of sedimentary structure and grainsize, although many classification schemes have been proposed and there is perhaps a strong case to be made for the standardization of pyroclastic lithofacies.

Pyroclastic Fall Deposits

Pyroclastic material carried up in eruption plumes eventually rains out from umbrella clouds to form pyroclastic fall deposits. These are classified according to a spectrum of increasing dispersal and fragmentation (Hawaiian, Strombolian to Plinian, Figure 4), but can also be distinguished on broad lithological grounds; scoria-fall deposits, pumice-fall deposits, or ash-fall deposits. Pyroclastic fall deposits are commonly well sorted and they maintain an even thickness over local topography (mantle bedding). Small eruptions (e.g., Hawaiian and Surtseyan) tend to produce weak, low-level plumes that form steep-sided, high aspect ratio fall deposits (cones), whereas Plinian eruptions produce high level (<50 km) columns that deposit extensive low aspect ratios (sheets).

An important concept in the formation of these deposits is that of terminal fall velocity, which depends on particle size and density and determines at what distance downwind from the source individual particles will begin to settle out. Large pyroclasts are often explosively ejected on ballistic trajectories (ballistic clasts) and are unaffected by the wind. The

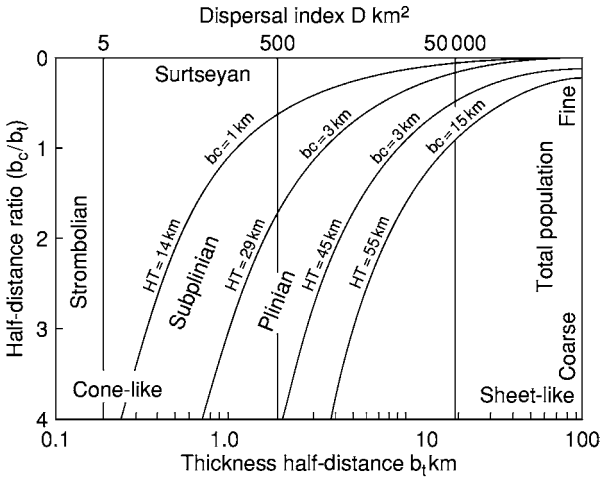

Figure 4 Classification scheme for fall deposits. The half distance ratio represents the total grainsize population and the thickness half distance represents the dispersal. The figure is contoured for clast half distance b_c and for total column height in km H_T. (From Pyle (1989).)

Figure 5 Parallel bedded Plinian pumice fall deposits (Bandas del Sur Group, Tenerife, Canary Islands) overlying palaeosol (level with man's chest). Thin ash layers are visible in the middle of the deposit. White unit at top of photo is an ignimbrite. (Photo: M. Branney.)

thickness and grainsize of fall deposits decays approximately exponentially away from source and the rate of this thinning or fining is conventionally described by the 'half-distance', a measure of the distance over which the thickness or grainsize of the deposit halves. Quantification of fall deposits relies on the accurate mapping of the distribution and on detailed granulometric analysis. Isopach (contours of equal thickness) and isopleth (contours of equal grain-size) maps can be constructed and used to determine erupted volumes and investigate eruption dynamics. Isopachs and isopleths are commonly elongated downwind due to wind shear, although varying wind velocities and directions at different levels in the atmosphere, or changes in wind direction through time, can complicate dispersal patterns during sustained fallout.

Fall deposits are sensitive indicators of eruption dynamics. Barring interference from local atmospheric phenomena, quasi-steady eruption conditions should produce texturally homogenous, massive fall deposits. Such conditions are rare in nature and many fall deposits exhibit features indicative of eruption unsteadiness, for example, bedding (Figure 5), stratification, vertical grainsize variation (grading), and/or compositional variations (e.g., in abundance of accidental lithic lapilli). Such features are usually better developed in proximal deposits, becoming less well defined toward distal regions due to increased transport time. Table 4 summarizes some common features of fall deposits and their possible interpretations.

Pyroclastic Density Currents and Their Deposits

During an explosive volcanic eruption, pyroclasts can be carried laterally away from the vent as pyroclastic density currents (PDCs). These are ground hugging (i.e., they are denser than air) particulate gravity currents comprised of gas, ash, lapilli, and blocks. Pyroclastic density current is a general term given to a wide variety of phenomena generated by a number of very different mechanisms, for example, the collapse of an eruption plume, sustained boil-over fountain eruptions and directed lateral blasts (Figure 6). They can travel at high velocities (30–200 ms), can have high temperatures (>550°C), and can reach over 100 km from their source. PDCs tend to be controlled by the topography over which they flow, often being preferentially channelled down valleys but they can also surmount topographic obstacles more than 1.5 km high and travel many kilometres across open sea.

The nomenclature relating to the types of pyroclastic density currents and their respective deposits is notoriously complex. Pyroclastic density current deposits can be subdivided and classified in a number of different ways. Obvious distinctions can be made based on composition, deposit volumes, and dominant lithofacies, or on generic interpretations such as whether they resulted from either short-lived transient currents (e.g., during phreatomagmatic eruptions) or from sustained currents (during Plinian eruptions).

The term 'ignimbrite' is generally used to describe an ash and pumice-rich deposit generated during a Plinian-type eruption. Ignimbrites are some of the most impressive deposits on the planet: vast landscape burying sheets, emplaced over a few hours that can be several hundred metres thick and cover huge areas (>45 000 km^2). Ignimbrite range from small volume

Table 4 Major features of pyroclastic fall deposits and possible interpretations

Fall deposit characteristic		*Interpretation*
Geometry		
High aspect ratio cone		Fallout from a low (<2 km) eruption column; restricted dispersal
Low aspect ratio sheet		Fallout from a high eruption column (>2 >45 km); widespread dispersal
Circular isopachs/ isopleths		Fallout during no wind conditions; fallout from a powerful eruption column undeformed by wind
Elongate Isopachs/ isopleths		Strong distortion of eruption column by wind (elongation in downwind direction)
Changing isopach/ isopleth distribution with height		Variable wind directions at different heights; changing wind directions with time
Secondary thickening of fall deposit		Downwind aggregation of ash and premature fallout of large aggregates with greater settling velocities
Structure		
Grading	Inverse	Fallout from a growing eruption column (waxing eruption intensity); gravitational (downslope) remobilization of deposits (e.g., Strombolian deposits)
	Normal	Fallout from a waning eruption column (waning eruption intensity)
	Bedding	Fallout during unsteady eruption column dynamics (fluctuating eruption intensity)
Cross stratification, lenses		Reworking of falling or deposited clasts due to surface winds, PDCs or gravitational remobilization (rolling down steep slopes)
Erosion surfaces (unconformities)		Removal of deposit due to mass wasting (landslides), PDCs, surface processes (alluvial/slope erosion)
Impact sags		Deformation by ballistic clasts
Compositional changes		
Chemical zoning of juvenile pyroclasts		Changes in the chemical composition of the erupted magma with time eruption from a zoned magma chamber
Layers rich in accidental clasts		Explosive fragmentation of vent walls following blocking, collapse or increase in erosive power
Vertical changes in accidental clast composition		Vertical or lateral (from fissure vents) shift in locus of vent erosion
Layers rich in dense juvenile clasts (e.g., obsidian)		Explosive clearance of a cognate volcanic plug
Intercalated thin ash beds		Short lived phreatomagmatic explosions which generate abundant fine ash; settling of fine ash from atmosphere during pauses in fallout activity
Pink ash coatings on pumice lapilli		Thermal alteration (oxidation) of pyroclasts
Accretionary lapilli; ash pellets; armoured lapilli		Moisture driven aggregation of ash common during phreatomagmatic activity and during humid atmospheric conditions; electrostatic attraction of fine ash particles
Texture characteristics		
Poor sorting (presence of an ash matrix)		Partial phreatomagmatic activity (hybrid eruption); coeval deposition of fallout and fine ash from a dilute ash rich PDC or a co ignimbrite ash cloud
Rounded pumice clasts		Emplacement by lateral currents (PDC); reworking by alluvial processes
Welding		Proximal high temperature agglutination of hot (fluidal) pyroclasts; contact fusing of pyroclasts by an overlying welded ignimbrite

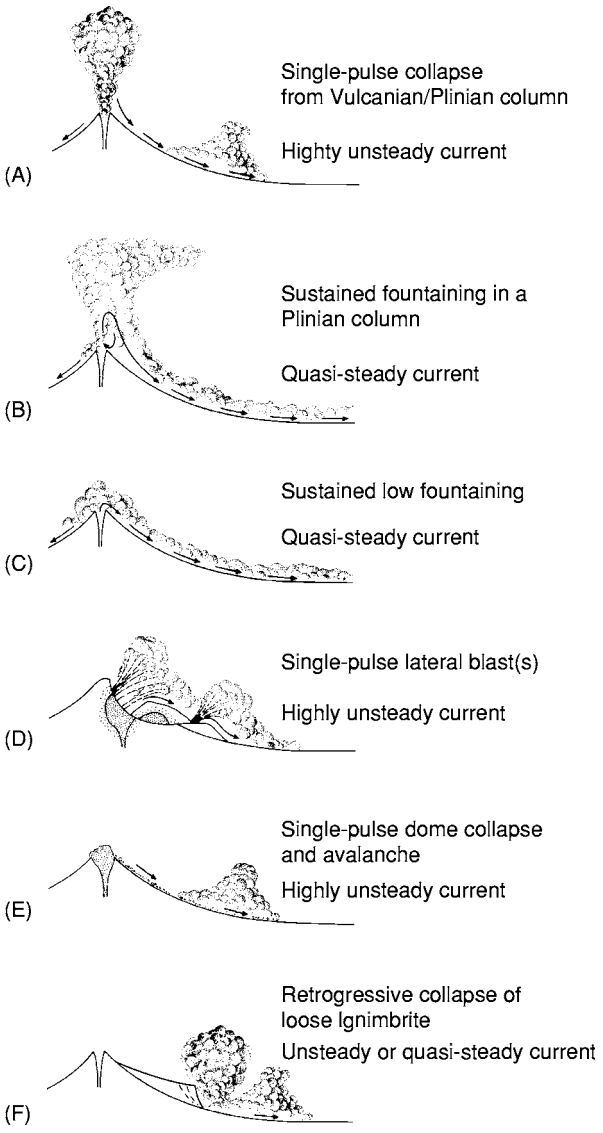

Figure 6 The origins of pyroclastic density currents. Most large volume ignimbrites are derived from B and C. Type D refers to transient pyroclastic density currents generated by lateral blasts or small scale phreatomagmatic activity (Surtseyan or Taalian eruptions). Type E commonly produces block and ash flows. (From Branney and Kokelaar (2002).)

ribbon-like deposits confined to valleys to extensive sheets distributed radially around the vent or across mountain ranges. Plinian eruptions are usually sustained for hours to days, and PDCs may be generated for all or part of that time, or intermittently. Ignimbrites exhibit a breath-taking diversity in their physical characteristics (e.g., geometry, bedding, sorting, grainsize, clast grading, geometry). Many are massive (Figure 7) and exhibit internal coarse-tail grading patterns the size grading shown by the coarsest particles in the deposit, but bedded, stratified, and cross-stratified lithofacies also occur. Detailed lithofacies

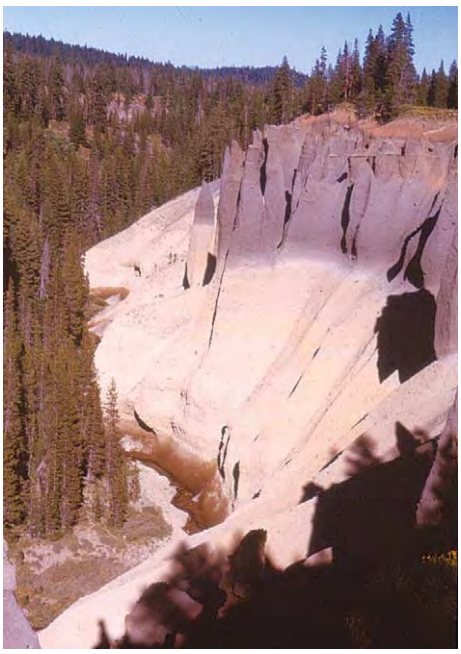

Figure 7 Compositionally zoned ignimbrite (Mount Mazama ignimbrite, Crater Lake, Oregon). (Photo: M. Branney.)

analyses, similar in approach to those applied to sedimentary deposits, have proved most successful in dealing with the complexity of ignimbrites and in elucidating important information about emplacement mechanisms. Moderate volume ignimbrites (1–10's km^3) often have complicated lateral, longitudinal, and vertical lithofacies transitions (ignimbrite architecture). Ignimbrites often show evidence for crystal enrichment relative to the juvenile pumice clasts, indicating significant loss of ash during transport (a process termed elutriation). This elutriated ash forms co-ignimbrite plumes, which rise vertically from moving flows and can later deposit extensive ash deposits.

Progressive evacuation of a chemically zoned magma chamber results in vertical chemical zoning of juvenile pyroclasts in an ignimbrite (Figure 7). Typically, juvenile pyroclasts become more basic with height (e.g., rhyolite to andesite; the inverse of vertical zoning in the magma chamber). Early phases of the eruption tap acidic magma (e.g., rhyolite) at the top of the chamber, while lower and more basic levels (e.g., andesite) are tapped during later phases. High temperature emplacement can lead to the agglutination of hot pyroclasts on deposition (welding). Pumice lapilli can flatten and deform to produce bedding-parallel *fiamme*, and columnar joints, similar to those developed in lavas, can develop. In extreme cases, the aggrading ignimbrite can start to flow as a dense viscous liquid and can end up looking superficially like lava.

Small volume ($<<1\,km^3$) well stratified pyroclastic density current deposits ('surge deposits') are typical products of monogenetic phreatomagmatic eruptions (e.g., Taal, Philippines) and directed lateral blasts (e.g., Mount St Helens, 1980). The pyroclastic density currents are typically transient single-surge types that travel out horizontally from source and rapidly wane. Each deposit can exhibit a wide range of sedimentary structures, and they characteristically show a proximal to distal lithofacies transition from massive coarse-grained lithofacies near source, stratified and cross-stratified deposits (with spectacular dune bedforms, Figure 8) further out, and planar-bedded deposits in more distal areas. Fine-grained ash fall deposits extend out from the distal limit of the sheet. Vertical lithofacies sequences often match the proximal–distal lithofacies transitions, reflecting deposition during strongly waning flow. Phreatomagmatic eruptions are characterized by numerous closely timed explosions, and during the course of the eruption, the deposits build up gently tapering cones with radii of several kilometres (called tuff rings or tuff cones). Due to the presence of external water, evidence for cool emplacement ($<100°C$) may be common in phreatomagmatic deposits, for example, abundant accretionary lapilli, vesicles in ash beds, rain-splash micro bedding, and the plastering of ash layers against objects.

Also included under the general term pyroclastic density currents, are hot avalanches of dense lava blocks and ash (block and ash flows) generated when portions of growing lava domes collapse due to gravitational instability. These events are short-lived and occur in discrete pulses. A classification has developed for these small volume pyroclastic flows depending on their generation mechanism. The term 'nuée ardent', favoured in some of the older literature, has also been applied in a rather general sense to most of these flow types. The generation of small pyroclastic flows by dome-collapse has been observed on numerous occasions (Montagne Pelée 1902; Fuego 1974; Mt Unzen 1990–1995; Merapi Volcano, and Soufrière Hills Volcano, Montserrat 1996–1998). These flows have been observed to move as far as a few kilometres from the vent at speeds of up to 60 ms. Due to the style of eruption, pyroclastic flows produced by gravitational collapse of lava domes occur repeatedly over significant time periods, typically, a few months to several years. This has enabled significant progress to be made in understanding the behaviour of these flow types in comparison to those of large volume ignimbrite eruptions. The deposits of these flows (block and ash flow deposits) vary from dense lava blocks and ash to dense semi-vesicular pumice and ash with only minor accidental components. Collapse volumes and local topography determine whether deposits are valley confined or sheet-like in nature. Small volume ($<0.5 \times 10^6\,m^3$) deposits tend to form well-defined lobate deposits with well-defined flow fronts and levees (Figure 9), while more extensive block and ash flow sheets tend to form deposits which thin laterally and have tapering margins.

Figure 8 Cross stratified pyroclastic density current deposit emplaced during a small volume phreatomagmatic eruption. Note spectacular dune bedforms interbedded with thicker mas sive deposits (Caldera del Rei tuff ring, Tenerife, Canary Islands). Current direction from right to left. (Photo: M. Branney.)

Pyroclastic Density Current Transport and Deposition

The literature on pyroclastic density currents has been dominated by discussions on alternative concepts of transport and emplacement mechanisms. The physical nature of these flows and the mechanisms of sediment transport and deposition are still not fully understood. Conceptual models have been developed, ranging from dense concentrated suspensions dominated by particle interactions and fluidisation effects to very dilute

Figure 9 Well developed lobes in block and ash flow deposits (Soufriere Hills Volcano, Montserrat). Small stripped trees for scale in left upper middle of photo. (Photo: E. Calder.)

turbulent suspensions. In high particle concentration models, pyroclastic flows are considered as avalanche-like granular flows analogous to debris flows and rock avalanches. Variants of models involving high particle concentration granular flows emphasize non-Newtonian rheology, fluidisation effects, and hindered settling. Conceptual models have also been proposed that to varying degrees bridge the gap between the two rheological extremes. These latter models, which perhaps best describe the dynamics of PDCs generated during larger ignimbrite forming eruptions, propose separate low-concentration flows and higher-concentration depositional systems (flow-boundary processes). The historical development and evolving ideas surrounding this still somewhat controversial topic are covered in detail in several textbooks and major reviews (see **Further Reading** section at end of this article).

Pyroclastic density currents transport components of widely differing grainsizes and hydrodynamic properties (low density pumice, ash, and dense lithic clasts). During transport, these pyroclasts may be supported by a number of different mechanisms (fluid turbulence, saltation, rolling and sliding along an interface, and clast collisions) and adjacent clasts in a deposit may have different transport and particle support histories. Several field investigations support the idea that ignimbrites can be rapidly aggraded increment-by-increment from the bases of pyroclastic density currents (a process termed 'progressive aggradation', Figure 10A). Vertical chemical zoning of juvenile pyroclasts, gradual changes with height in an ignimbrite in grain fabric orientation, and lateral transitions from massive to stratified lithofacies, provide good evidence for incremental deposition. Deposition accompanies transport and the thickness of a deposit reflects the durations and rates of deposition, with basal parts deposited earlier than upper parts. Each particle carried in the current must pass through a lower flow boundary zone before it can be deposited (Figure 10).

The massive, poorly sorted nature of many pyroclastic density current deposits (Figure 7) indicates deposition from high particle concentration flows or flow boundary zones in which particles are supported by collisions (in granular flows, Figure 10D) and the upward flux of dusty gas produced as larger particles are hindered in settling, Figure 10E). Hindered settling results in partial fluidisation (sedimentation fluidisation) and greatly increases a current's mobility. Stratification and cross-stratification result from traction sedimentation involving fully dilute flow boundaries in which particle interactions have little role in particle support or segregation or in current rheology (Figure 10C). Small particles are supported by the turbulence in the surrounding dusty gas (air and suspended ash), whereas larger particles move by saltation along the base (as a bedload). Fully dilute conditions in the flow boundary zone result in more efficient segregation mechanisms and the deposition of relatively well-sorted stratified and cross-stratified deposits ('surge deposits', Figure 8). Small volume phreatomagmatic eruptions tend to produce currents initially of these characteristics, but which lose energy rapidly as they travel away from the vent. This results in higher rates of suspended load fallout, increasing particle concentrations and the deposition of more massive deposits with distance from source. Flow-boundary conditions in between the two end members outlined above (for example, in terms of particle concentration) will result in deposits that are gradational in character (diffuse stratified and bedded ignimbrites).

Inferences made from the deposits about the structure (e.g., particle concentration, density stratification) within the moving pyroclastic density currents have to be made with caution. However, the ability of some flows to travel large distances across water and scale mountains up to 1500 m high, >45 km from source, indicates that the greater thickness of these currents were dilute, low particle suspensions. Fluid turbulence is likely to be the dominant particle support mechanism in the upper parts of the currents. Additional evidence on the vertical structure of PDCs can be gleaned from ignimbrites that were emplaced over rugged topography. Parts deposited over high ground tend to be thinner and stratified or bedded, while contemporaneous deposits in depressions and valleys are more typically thick and massive (Figure 11). Such evidence suggests that conditions in the flow-boundary zone (e.g., in terms of current velocity, turbulence, and particle concentration) of the PDC varied significantly across topography and that aggradation rates were significantly higher in the valleys. What remains unclear for most pyroclastic density currents, however, is the partitioning of material between a higher concentration lower flow boundary zone and an overlying dilute and turbulent zone, noting that the vertical structure and the vertical density gradients are likely to vary considerably, both between and within PDCs, due to current non-uniformity and unsteadiness (see below).

Detailed lithofacies analyses of ignimbrite sheets provide important information on spatial variations (non-uniformity) and temporal variations (unsteadiness) in PDC flow-boundary conditions, induced by changes in eruption dynamics and by interactions between the flow and the substrate topography. Many large volume ignimbrite sheets were emplaced over minutes to hours during the sustained collapse or

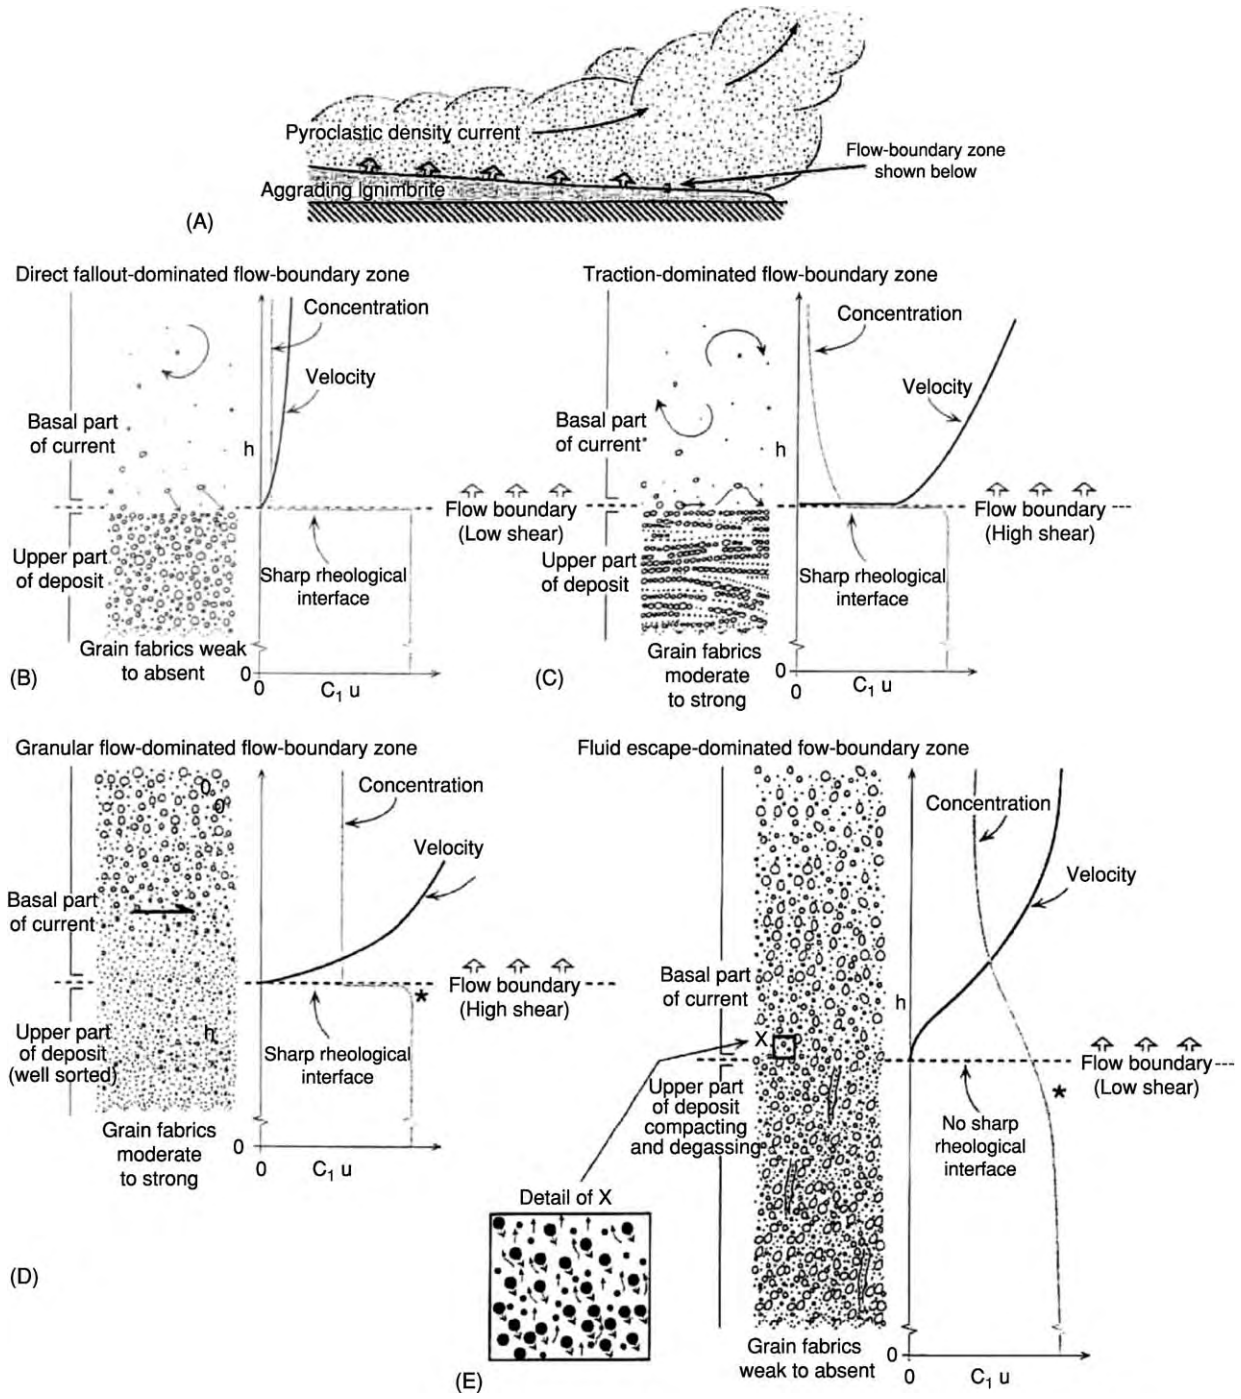

Figure 10 Four hypothetical types of pyroclastic density current flow boundary zones during steady conditions. (A) Scale and location of flow boundary zone emphasizing that depicted zones only include the basal part of the current and the uppermost part of the current. Most currents have flow boundaries intergradational between these types. (From Branney and Kokelaar (2002).)

fountaining of an eruption column. Sustained events are complex and can exhibit waxing and waning phases, pauses, and marked changes in eruption style. This can result in multiple flow-units and complex vertical lithofacies transitions and grading patterns. As the flows travel and deposit material, they substantially modify the substrate (e.g., by filling valleys, or by eroding loose material), and this, in turn, can affect sedimentation and flow boundary conditions up and downstream in subsequent parts of the current. Passage over uneven topography, changes in slope angle, and topographic blocking

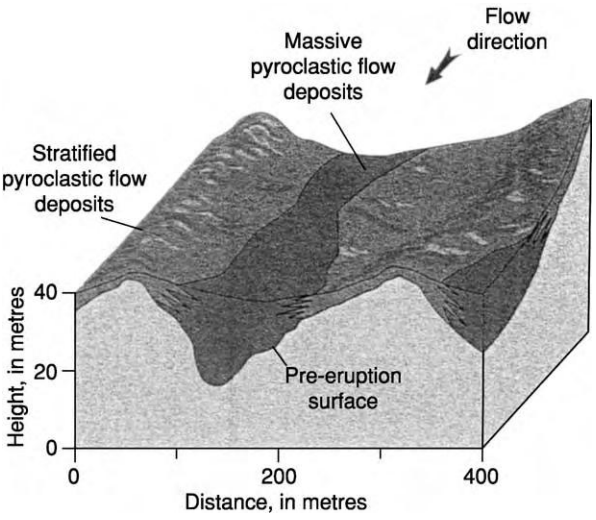

Figure 11 Lateral transitions from stratified ignimbrite (topographic highs) to massive ignimbrite (valleys) in the ignimbrite emplaced during the climactic 1991 eruption of Mount Pinatubo. (From Scott *et al.* in Newhall and Punongbayan (1996).)

(by mountain ranges), can all induce spatial changes in flow boundary conditions within a PDC and thus the deposit.

The dynamics of the small volume, end-member flows, such as those formed by fountain collapse during short-lived Vulcanian explosions and lava dome collapse are perhaps less controversial. Particle support mechanisms invoked for these small, relatively dense flows are commonly considered to be dominated by granular flow mechanisms (Figure 10D), where partial fluidisation may also play a role. The ash and gas components are considered important in friction reduction. Granular flow behaviour is controlled by a combination of the viscosity of the interstitial fluid and grain-to-grain interactions. In these dense small volume pyroclastic flows momentum is largely believed to be managed through grain-to-grain contacts. Low shear rate grain flows move as plug flows and become arrested en masse; high shear rate grain flows are smeared out during deposition as friction consumes momentum most strongly at the base while higher portions continue to move. Observations suggest separate mobile systems in which granular underflows or 'dense basal avalanches' occur beneath overriding turbulent ash clouds. The different properties of the two parts allow flow separation to occur, and the overlying ash cloud can move independently as a dilute pyroclastic density current.

QUARRYING

A W Hatheway, Rolla, MO and Big Arm, MT, USA

Introduction

Quarries are resource extraction sites for removal of stone. The quarried stone is used as all manner of building materials, mainly as crushed-rock aggregate for concrete, road metal (crushed stone for road surfacing), asphaltic concrete pavement, and building construction stone. The stone is removed from 'pits' as cobbles, gravel, sand, and clay soil. Quarried stone is separated from outcrops along vertical working faces termed 'highwalls'. Highwalls are cut into a hillside of bedrock underlain at locations that have been selected to have little or no unconsolidated overburden (weathered rock, or 'soil'). Many quarries are developed as multisided rectangular excavations, and when the highwall exceeds a few tens of metres in height, the next level of extraction is 'benched' inward, leaving a stepped highwall, useful for control of inflowing groundwater. Where the host rock is not massive and may have some jointing dipping into the depression, bench heights are reduced to a general minimal height of 5–8 m. Stone removed from the quarry is hauled up a vehicle ramp for further processing at the company plant. Most stone is mechanically processed (broken and sized) to produce a size-graded product meeting engineering specifications of the buyer. When a quarry site is closed, environmental authorities typically require procedures to be followed as specified in a final closure plan; waste stone (spoil) is incorporated into the plan. Many urban-area quarries are closed out as disposal sites filled with environmentally inert construction and demolition wastes, mainly broken concrete and asphaltic concrete (Figure 1).

Creation of a geological quarry site model is essential for locating and proving quarry sites, in designing economical means for removing rock, and in devising environmentally sensitive ways for operation and closure. A number of geological factors and social/environmental considerations control the way in which quarries are located and operated:

- Stratigraphy and origin/mode of emplacement.
- Geomorphic setting.
- Postdepositional alteration of the host rock units and their rock fabric.
- Presence and orientation of discontinuities and potential layers of unacceptably altered weak rock.
- Nature and position of groundwater and management of its inflow, and ability to manage such water in terms of quarry operation and of mitigation of adverse impact on groundwater that is a neighbourhood resource.
- Ability to manage precipitation.
- Ability to manage rock extraction in such a way as to avoid instability of the highwalls, particularly in terms of quarry worker safety.
- Ability to manage waste rock (which typically amounts to about 5% of the extraction).
- Ability to operate in such a manner as to avoid danger to citizens and nearby residents, and to not degrade the environment.
- Development of a government-approved closure plan so that the closed quarry does not constitute a danger to the environment or to public health and safety.

Figure 1 Quarry operated for construction aggregate, road metal, and granular fill, in dolerite (diabase) and high grade crystalline metamorphic country rock of Prince George's County, Maryland, USA; the vertical face is approximately 15 m high. The pit has reached the lateral limits of the deposit of usable rock and also has come to the maximum viable depth for maintenance of the pit, removal of groundwater seepage, and precipitation runoff. The site was being considered for conversion to a long term secondary use compatible with environmental protection requirements. Photograph by the author.

Engineering Geology in Design and Operation of Quarries

Quarry development and operation has become a recognized field of practice requiring engineering geologists. As with many industries, quarry technology entered the machine age post-World War II, when excavation equipment became universally available to the family enterprises that owned most quarrying operations. Small operations are now rapidly disappearing and multinational companies control most of the stone that is mined today. In some instances, this equates to huge scales of magnitude (the 'superquarry'). Such are the economies of scale and the relatively low cost of bulk ocean transport that stone is imported over considerable distances, especially from quarries located close to coastal shipping.

Geological Factors Affecting Quarried Stone

Building stone is the traditional building material of mankind and still remains a critical construction material today, primarily as the aggregate, or bulking agent, for Portland cement and asphaltic concrete. Both cement and asphalt have been known to humans for several thousand years, yet their modern counterparts and their uses stem strictly from the industrial age.

Desirable Physical Properties of Quarried Stone

Quarried stone must have certain physical properties to serve as an effective building material. It must have strength, mainly compressional, to resist the load forces applied in engineered works; it must be durable and resistant to surface wear, especially when the use is for pavement; and it must be resistant to dynamic and chemical attacks, particularly from marine (saline) waters when the use is for port, harbor, and seacoast protective structures. Mined stone for building purposes must also be resistant to 'weathering' due to chemical attack by water and incident urban rainfall and must have consistency, be of uniform quality, and contain no deleterious minerals (e.g., pyrite, which causes staining of facing stone, and chert nodules, which cause eruptive pitting in concrete).

Desirable Mass Characteristics of Quarried Stone

Recovery cost for quarried stone is governed by several invariant cost factors inherent in the quarry site geology. The nature, pervasiveness, and orientation of discontinuities control the ease of extraction and the resultant stability of highwalls and benches. Stored tectonic stress may be a cost factor related to uneven responses to blasting patterns and explosive loading, due to release (relaxation) in strain-displacement relief ('pop-ups') of floor rock. The compressive strength of the quarry product, independent of geological structure, serves as a measure of the explosive force that will be needed (and thus the cost of explosives) to break the rock to requisite handling size.

Other Characteristics of Quarried Stone

Every stone quarry starts with an outcrop of durable stone or an excavated pit made in the overburden of surficial soils, often glacially deposited, so as to expose an artificial outcrop (working face) of stone. Once exposed, the stone must be subjected to efforts to dislodge it from the rock deposit. In most cases, the rock deposits selected for quarrying are cut by natural geological structural and depositional discontinuities such as bedding planes, foliation planes, and joints. Figure 2 depicts a rock face in which the supporting rock mass has three dominant joint 'sets', each representing a distinct array of joints, all of which will control the overall character and planar outline of a quarry developed in the rock mass.

Rock masses are virtually without strength in tension, and thus mechanical efforts to remove rock from a working face employ excavation machines to pull ('rip') discontinuity-bounded rock blocks from the quarry face (Table 1). Where the rock cannot be ripped, it is pulled from the working face by the judicial (planned) use of explosives set in geometrically arrayed and nominally vertical, drilled 'shot holes'. Discontinuities have value to the final product of the quarry only when the rock is destined to be recovered and sold as dimension stone, building stone, ornamental stone, or rip-rap. Rip-rap, used in shore protection works, is of great value when its quarry blocks are without further discontinuities, because the pieces can resist the constant pounding and surging action of ocean waves.

Many quarries also contain crystalline igneous and metamorphic rocks and the harder varieties of igneous and volcanic intrusive rocks. The many types of geological formations worldwide and their importance in quarrying operations are shown in Table 2.

Types of Rock Quarries

Quarries are established on the simple theme of locating and supplying a needed stone product at a competitive price in the free-enterprise system. There are some interesting relationships of quarry rock type and location worldwide (Table 2). Stone is intrinsically nearly valueless, and when obtained on a royalty

Figure 2 Rock highwall in rhyolite near Munsan, Republic of Korea, exhibiting three prominent joint sets of consequence to development of the site as a quarry. Such features should be taken into direct consideration in quarry dimensioning and in specification of the bearings of bounding highwalls; the horizon tal width of the exposed joint faces is about 5 m, left to right. Photograph by the author.

basis nets the landowner literally pennies per tonne. Thus the primary quarry costs are essentially those related to extraction machinery/explosives costs, labour costs, and haul costs (for transportation from quarry to buyer).

Planning Considerations

Planning, regulatory involvement, and engineered design are required to develop a new stone quarry. The overall effort (Table 3) is aimed at minimizing both the cost of production and the operational and postoperational impacts on the local environment. Proposed quarries, and even expansion of existing quarries, must go through a typical sequence of feasibility studies, engineered design reviews, permit applications, operational environmental compliance reviews, and eventual closure and postclosure land-use reviews in accordance with conditions established prior to initiation of operations.

Engineering Geological Inputs

In addition to the geological tasks that are required to open a quarry and begin quarry operations, engineering geologists are necessary to the continued operation of quarrying. A stone quarry is a dynamic venture in which previously unidentified geological situations develop on a regular basis. There is an ongoing need to identify, classify, describe, record, and update all quarry site data in a three-dimensional geological model. Regular auditing of product and spoil utilizes digitized geological data and geostatistical analyses of the potential reserves (and thus the ongoing viability of the operation). These measurements and computations generally are compiled on 30-cm contour intervals at lateral scales of 1:1000. Geologists are the ideal staff members for the entire spectrum of detection, evaluation, interpretation, recording, and notification responsibilities necessary to proper management of the site. Geologists are also the most logical choice to serve as quarry managers, officers, and corporate directors.

Environmental Aspects

The most prevalent environmental issues in quarry operations are related to nuisances experienced by or perceived by a site's 'neighbours' (Table 4). Typical concerns are the noise emitted by the crushing, washing, and sizing operations and the noise and traffic caused by stockpile movement and loading and departure of haul vehicles. Though these concerns are not geological in origin, monitoring the disruptive operations often is best handled by geologists because of their skills in observation, location, mapping, and recording. An important aspect of environmental compliance is blast vibration; monitoring utilizes portable seismometers, in order to meet permit obligations and to provide defence against claims for structural damage allegedly caused by transitory ground motions from production blasts.

Careers in the Quarrying Industry

Technical and professional geological aspects of stone quarrying are fascinating and offer a distinct challenge to the geologist interested in the day-to-day practical application of their scientific knowledge. Quarries live and die on optimization of costs of producing buyer-acceptable products, and in doing

Table 1 Geological characteristics relevant to stone quarrying

Characteristic	*Importance*	*Geological considerations*
Discontinuities	Provide natural rock break surfaces	Normally occur in predictable 'sets' of three dimensional orientation in space; usually two sets represent each historical tectonic deformation phase of the region around the quarry
Uniaxial compressive strength	An engineering property that basically relates to the ability of explosives to break the rock deposit at the quarry face, in the absence of appropriate discontinuities	Individual explosive arrays, employed at 'shots', serve to lift, displace, and move the drilled and loaded face mass of rock outward, into the quarry, in a pile on the quarry floor, for subsequent working and removal
Structural domains	Rock masses with a geological history of tectonic, intrusive, or geochemical alteration have a characteristic three dimensional variance in the orientation of discontinuities	Each 'domain' has definable geological contacts, within which the body of rock has predictable three dimensional attitudes of its discontinuities; these control the whole activity of 'pulling' rock at the quarry face
Fault blocks	Quarries operated in tectonically damaged or seismically active terrain often show block displacement of masses of quarry rock, incorporating 10^5 or 10^6 m^3 of stone in the fault bounded deposit selected for mining	Requires geological mapping and projection of geological structure, especially if the quality of fault displaced portions of the quarry mass have different engineering properties or characteristics
Perched water	Water of all sorts is a hindrance to quarry operation	Will drain in hours and days and can generally be engineered so as not to reoccur; where encountered in the quarry face, must be channeled to a floor sump and pumped free of the quarry
Groundwater	Rock masses generally contain some groundwater and this will 'bleed' into the quarry over its operational life	Place the quarry at the highest elevation of the groundwater shed and thereby limit the movement of groundwater towards the quarry, which will otherwise perform as an undesirable master sump
Dykes, sills, and other igneous intrusives	Undesirable in all respects; these features follow pre existing faults and shear zones and may foreshadow later discovery of fault block displacement of the quarry deposit; intrusions generally are associated with some degree of lithological damage from ancient geochemical alteration	Engineering geological exploration and ongoing operational mapping should be guided so as to detect and avoid these conditions, which represent a high probability of the presence of undesirable rock properties and/or characteristics detrimental to the value of the stone produced at the quarry

so in compliance with environmental controls. There is little room for error or mistake, because stone must be handled effectively the absolute minimal number of times and supplied on demand to the client. The industry is highly competitive in terms of price and reliability of product and delivery. Solution of potential and actual geological problems associated with production and environmental compliance is a high-value return based on employment of competent professional geological staff in quarry operations. Undergraduate geologists giving consideration towards career employment in the stone industry may thus be duly rewarded. In fact, any geologist experiencing family demands towards a reduction in travel and time away from home may well want to exploit the opportunities in the stone industry. Technical expertise, when blended with managerial capacities, tends to be appreciated by the new-breed of large-industry quarry operators.

Underpinnings in geology required for success in the technical aspects of quarrying include the ability to make field geological maps and to operate at mapping scales of less than 1:1000; sound knowledge of igneous, metamorphic, sedimentary, and volcanic petrology; skill at petrographic analysis; a fundamental knowledge of hydrogeology; an interest in environmental protection and the supporting regulatory, permitting, and compliance issues; and an understanding of the national standards governing stone quality as a material of construction.

Seeking and Gaining Stone Industry Employment

There are two pathways towards professional-grade employment in the geological engineering field related to quarrying; both routes ideally require an informed and caring university faculty. A direct approach to the industry can often be effected through faculty

Table 2 Regional generalizations

Location	*Generalization*	*Geological considerations*
Singapore	Bukit Timah Granite and Gombak Norite quarried in the central third of the island for all hard stone use	All pit and quarry space previously dedicated for follow up use as potable water storage in accordance with the Master Plan of the Republic
San Francisco peninsula, San Francisco, California, USA	All bedrock essentially weathered and/or altered ultrabasic subduction rock	Market requires long distance rail haul of suitable stone for aggregate
Los Angeles basin, Los Angeles, California, USA	Aggregate production mainly from coarse Pleistocene alluvial deposits; shortages made up from nearshore deposits of similar nature	Few quarries; mainly pits and these mainly converted to flood control storage in recognition of the endemic cloudburst nature of rainfall in the region; some utilized as infiltration sites for treated wastewater effluent as 'water factories'
Missoula, Montana, USA	Coarse postglacial displaced outwash deposits of the Clark Fork of the Columbia River	Crystalline igneous and metamorphic rock
Most of Nebraska, USA	Coarse Plio Pleistocene gravels of then rising Rocky Mountains	Crystalline igneous and metamorphic rock contaminated with noticeable content of vertebrate faunal bones
Lower Mississippi River valley, USA	Huge open pit quarries occupy the west bank of the Mississippi River, Missouri, below St. Louis; delivered by barge	Crushed Palaeozoic marine limestone of high carbonate content
Chicagoland: greater Chicago, Illinois, USA	Large, multisided quarries set below surrounding land surface	Palaeozoic dolomite; delivered by truck and rail
Greater Kansas City, Kansas, USA	Underground room and pillar limestone mines in dense, high strength Mississippian aged limestone	Modern mines engineered for long term stability and conversion to high value underground storage space
New York City/ Newark, New Jersey, USA	Triassic diabase (dolerite) quarries in New Jersey, with barge transport to New York City	High value for quarry end use as disposal sites for inert construction and demolition waste

and professional society contacts; the secondary pathway is to take quality control employment with transportation or environmental agencies and become involved, respectively, in the review of specification quality of quarried stone products or in the environmental permitting and compliance oversight of producing quarries.

Literature Support for the Quarry Geologist

Quarry geologists should act quickly to assemble a reference library of relevant published materials (*see* **Building Stone**). Though much of the literature is relatively old and therefore available primarily from dealers of used and rare books, older works are easily searchable on the Internet. Worldwide, the current standard literature staples are the outstanding books on aggregates compiled by the Engineering Working Group of The Geological Society, London (*see* **Aggregates**). Subscriptions to trade journals are also essential, as are library trips to recover helpful geologically oriented articles from the historical literature archives. Though stone recovery methods have improved vastly since the end of Word War II, the underlying scientific principles are timeless.

Quarry Restoration

With the advent of environmental awareness in the 1970s, quarries in First World nations generally became subject to closure requirements as an integral part of environmental and/or land-use permit regulations. These requirements are well in place both in the European Union, particularly in the United Kingdom, and in Canada and the United States. In most cases, the requirements have in common the following parameters:

- Mandatory termination of extraction activities at pre-established bounds, both lateral and vertical.
- Filing of a closure plan and a postclosure plan with a regulatory agency, including appropriate engineering details of the concept by which the site is to be made safe for residents of the surrounding area and by which precipitation and groundwater inflow are to be managed in an environmentally acceptable fashion, to include safeguarding against dumping of waste at the closed facility.
- Placement of closure and postclosure funds in an escrow account, with amounts and payments tied to quantity of rock extracted.

Table 3 Typical sequence of events

Event	*Action agency*	*Geological considerations*
Market feasibility study	Proposed operator	Nature, value, and cost to produce the end product(s)
Feasibility of prospective quarry	Proposed operator and financial partners	Estimated unit cost of product(s); cost to develop plant, as amortized over estimated quantity of stone reserves; estimated cost to close the site at termination of productive life; nature and value of end use of site
Development of topographic contour map	Consultant to proposed operator	Basis for planning of property geological exploration plan
Conceptual design of proposed quarry	Proposed operator, with assistance of consultants or corporate engineering staff	Location and bounds of the bedrock deposit; identification of potential geological constraints to operation and closure; management of groundwater and production spoil
Phase I geological exploration	Consultant to proposed owner or corporate engineering staff	Prove the existence of minimal reserve of suitable bedrock for production of stone product(s)
Tentative facility operational concept	Proposed operator, operator staff, or consultants to proposed operator	Identifies stages or phases of site development and product treatment; staging, groundwater, and surface water control features; and management of production spoil
Environmental impact report	By consultants to proposed quarry operator	Geological map of soil, bedrock, and groundwater conditions; hydrologic and hydrogeologic impact; control of dust, fugitive emissions, spoil, and runoff
Environmental impact statement	By state, county, or provincial public environmental agency	Identifies all physical and social environmental impacts and proposes appropriate mitigative measures; identifies and quantitifies risks to public health and welfare
Land use zoning application	Proposed owner	Identifies geological constraints related to nature land use, as such impact provisions of land use specified in the General Plan of the governmental administrative body; shows that proposed quarry is an acceptable land use in consequence of facility operational concept
Permit application	By proposed operator to the public agency holding regulatory control	Mainly equivalent to that of the environmental impact report
Operation, compliance, expansion, and/or closure	Proposed owner, staff, and consultants	All above noted geological considerations

Table 4 Major sources of environmental impact of quarrying

Impact	*Relevance*	*Geological considerations*
Alteration of groundwater regime	Quarries, as cuts and depressions, interrupt groundwater flow and create artificial flow gradients and discharge points/areas	Most of these 'interruptions' create, in fact, a 'shadow' of impact on the position and flow path of groundwater
Fugitive dust	Extraction of stone creates breakage and some comminution (size reduction), resulting in small particles subject to wind movement	Method of extraction, method of breakage, and method of size treatment for market product
Fugitive sediment	Results from dust caught up in the path of runoff	Reduction of amounts of dust and other small particles produced; methods of entrapment and sequestering from release to the environment
Loss of ground support to adjacent activities and structures	Slope instability could be induced here in the highwall, with the potential to ravel or migrate backward into adjacent land and buildings	Generally mitigated geologically by lateral buffer ground separating the highwall from adjacent activities and attention to the effects of adverse geological structure in the highwall rock (such as dips into the quarry)
Collateral damage from flying rock and ground motion of production blasting	Physical guidelines are well established for control[a]	Control related to empirical relationships of burden, ratio of explosive charge to mass of rock to be shot, and pattern and time delay of charges

[a]See guidelines of the United States Bureau of Mines, for example.

- An agreement on the postclosure land use for the property, including both the pit and highwall areas, the property roads, drainage, and the buffer zone surrounding the quarry.

In the twenty-first century, quarries have taken on a new postclosure value for several reasons, not the least of which includes the potential for new developable space following quarry backfilling with construction and demolition debris. Conversion to reservoir use for water supply storage, conversion to high-value residential use of the quarry rim when pit quarries are converted to recreational areas, and conversion to sanitary landfill use (if and where groundwater conditions and appropriate engineered design features can preclude environmental degradation) also are potentially valuable applications of former quarry sites. Conversion to some form of conservation use, often in agreement with local or regional public agencies, is another positive outcome for defunct stone mining operations.

REGIONAL METAMORPHISM

A Feenstra, GeoForschungsZentrum Potsdam, Potsdam, Germany
G Franz, Technische Universität Berlin, Berlin, Germany

Introduction

Regional metamorphic rocks form from other rocks (protoliths) by changes in mineralogy and texture in response to changing physical conditions (temperature, lithostatic pressure, and, in most cases, shear stress). These changes are essentially solid-state reactions, but very often a fluid phase is present, either participating in the reaction or as a reaction medium. Many regional metamorphic rocks have a chemical composition that is very similar to that of their sedimentary or igneous precursors, with the exception of removal or addition of volatiles (mainly H_2O and CO_2). This type of behaviour is termed 'isochemical metamorphism'. Metamorphism may also take place as a result of a change in chemical environment; this may occur by transport of elements between chemically contrasting rock types (e.g., formation of calc-silicate minerals at a quartzite–marble contact) or by circulation of fluids that dissolve some substances and precipitate others. This process of significant chemical change during metamorphism is known as 'allochemical metamorphism' or 'metasomatism', and rocks formed in this manner are metasomatic rocks. Metasomatism is, however, mostly of local significance, and the total volume of metasomatic rocks in regional metamorphic terranes is rather minor. The distinction between metasomatism and isochemical metamorphism is also a matter of scale. On the scale of individual grains, mass transport takes place during all phase transformations; on the scale of a thin section, it is probably the rule for regional metamorphism; on the scale of a hand (-sized) specimen, it can be observed frequently; and on a larger scale, it is the exception.

Regional metamorphism is nearly always accompanied by deformation and folding, which happens at converging plate boundaries and leads to orogenic belts. Therefore, regional metamorphic terranes follow the contacts between ancient lithospheric plates (suture zones), typically have an elongated shape that is parallel to the mountain belt, and cover areas of several 1000 to 10 000 km^2. Two basic types of regional (orogenic) metamorphism may be distinguished. The collision type relates to the collision of essentially continental plates and mainly produces metamorphic rocks at medium pressures and medium to high temperatures, often associated with partially molten (migmatites) and magmatic rocks. High- and ultra-high-pressure terranes ($P \approx 1.5$ GPa up to >3 GPa) from the deep roots of the collision zone can be preserved within the medium pressure (<1 GPa) belts. A variety of sediments from the continental margin and shelf (clay–shale, quartzofeldspathic rocks, limestone, marl), their metamorphosed equivalents, and acid magmatic rocks constitute the protolithic material of the collision type, whereas rock types of oceanic affinity are volumetrically unimportant. Typical examples include Mesozoic–Cenozoic metamorphic terranes in the Alps and Himalaya, Palaeozoic terranes in the Caledonides of Scotland and Scandinavia, as well as many Palaeozoic–Precambrian terranes in the shield areas of the continents.

The subduction type of regional metamorphism is associated with subduction of an oceanic plate underneath a continent and results in rocks formed at high pressure and relatively low temperatures (blueschist, eclogite). Basic igneous rocks (basalt, gabbro, volcanogenic rocks) together with clay-bearing clastic sediments are the dominant protolithic materials. Continental rocks may be included locally in the subduction-type terranes as well. Well-documented examples are found in the circum-Pacific region (Japan, California, New Caledonia, New Zealand), the Alps, and the eastern Mediterranean (Cycladic islands, Greece; south-western Turkey). In the case of a terminating oceanic plate, the oceanic subduction may be followed by a continent–continent collision, such that the two types may overlap each other in time.

Regional Metamorphic Processes

Large-scale geotectonic processes move rocks along particular paths in pressure–temperature–time (P–T–t) space. During movement along this path, the rocks re-equilibrate, and when chemical equilibrium is attained (when the reaction kinetics is fast enough), the mineral assemblage and the compositions of the individual minerals will react continuously by adapting to the new physical conditions. In addition to the mineralogy, the fabric of the rocks also changes, because regional metamorphism is a dynamic process typically accompanied by an anisotropic pressure field. Minerals with an elongated or platy habit will commonly align to the confining stress field. Mineral grains will also increase in size with increasing temperature, reducing the surface free energy (typically observed, for example, in metacarbonate rocks and quartzites). This process is termed 'static recrystallization'. Deformation in the anisotropic pressure field, however, reduces the grain size by various processes, depending on temperature and confining pressure; this is called 'dynamic recrystallization'.

Particularly at low-level metamorphic conditions, when deformation of the rock is non-penetrative, and in fluid-deficient rocks, equilibrium is often incomplete and minerals initially present in the protolith, and minerals formed during early metamorphic stages, may locally survive metastably. Such metastable persistence of minerals (e.g., as relict inclusions in newly formed minerals or as compositional zoning in minerals from core to rim) is fortunate for the petrologist in the way that it records the early geological history (the prograde path) of rocks. Petrological studies of metamorphic rocks traditionally aim to estimate the peak metamorphic conditions (pressure, temperature, and composition of coexisting fluid phase) that a rock has experienced, based on the assumption that the mineral assemblage essentially documents this peak equilibrium assemblage. Equilibrium among the minerals is commonly verified by textural evidence, i.e., that all minerals of the peak assemblage should be in mutual contact. Chemical evidence for equilibrium can be obtained from comparison of the composition of coexisting minerals in different bulk compositions; no crossing tie lines should be present and the tie lines (e.g., of garnet–biotite) should follow a systematic pattern. During the cooling and exhumation (the retrograde path), this peak metamorphic assemblage experiences only minor changes, because these processes are commonly associated with fluid-free conditions and minor deformation. A retrograde reaction, i.e., the formation of lower grade, mostly hydrous minerals from higher grade ones, thus typically occurs on a local scale. Examples include the replacement of garnet or biotite by chlorite or the replacement of plagioclase by calc-silicates such as (clino)zoisite, prehnite, or pumpellyite. Many occurrences of retrograde hydrous and carbonate phases are spatially connected with late (brittle) deformation, implying that deformation may facilitate local fluid introduction and thus formation of retrograde minerals.

In virtually all regional metamorphic terranes, mineral reactions are associated with deformation. Therefore, it is often possible to determine relative time relationships between growth of minerals and major deformation events characterized by development of a distinct foliation, folding, or shearing. Growth of a mineral can be specified as pre-, syn-, or post-tectonic with regard to specific deformation events. Relationships between mineral growth and deformation may be complex, however, because multiple or long-lasting deformation and mineral growth are the rule rather than the exception during orogenic cycles. Studies of regional metamorphic rocks conveniently separate the rocks' evolution into the three categories of prograde, peak, and retrograde stages using petrological and structural criteria. The researcher should be aware, however, that this is a simplified picture and the P–T–t paths of metamorphic rocks are in general quite complicated.

Regional Metamorphic Zones and Facies

It was recognized very early that metamorphic rocks can be classified according to different 'intensities' of metamorphism, or metamorphic grades. The concept of gradation is not applicable to the other families of sedimentary or magmatic rocks; a magmatic rock cannot be 'more magmatic' than another one, whereas a metamorphic rock can be metamorphosed more intensely. This concept also emphasizes that the processing of a sediment through diagenesis, then forming a metamorphic rock, is transitional, and it therefore is impossible to mark an unequivocal beginning of metamorphism (*see* **Diagenesis, Overview**).

The concept of metamorphic index minerals typical of metamorphic grade was first introduced by George Barrow in the south-east Highlands of Scotland in the late nineteenth and early twentieth centuries. Studying a sequence of metamorphosed clay-rich sediments, Barrow related the systematic change in mineralogy in these metapelitic rocks to changing metamorphic conditions. Barrow recognized chlorite, biotite, garnet, staurolite, kyanite, and sillimanite zones as representing increasing metamorphic grades

that are characterized by index minerals not present at lower grades. 'Mineral-appearance' isograds were mapped by drawing lines between locations where each index mineral first appeared. It later became common practice to replace these classic mineral isograds by 'reaction' isograds related to a particular metamorphic reaction and to use the equilibrium assemblage of that reaction as a zone boundary. The reaction isograd is defined by assemblages of reactant(s) on one side, of product(s) on the other side, and, if present, the equilibrium assemblage on the isograd line (surface).

It should be emphasized that in metamorphic petrology, an isograd is not exactly a line (surface) of constant temperature (and pressure). Various aspects of metamorphic reactions should be considered. (1) In cases in which minerals with variable chemical compositions (solid solutions) participate in the isograd reaction, the position of the isograd in pressure–temperature (P–T) space may depend on mineral compositions (and the bulk chemical composition of the rock). (2) The P–T position of reactions producing or consuming volatiles (H_2O, CO_2) may also depend strongly on the composition of the metamorphic fluid. The reaction kinetics may vary on a local or regional scale in metamorphic terranes, especially at the lower metamorphic grades. These aspects imply that mapped reaction isograds will only approximately reflect lines (surfaces) under identical peak temperature (and pressure) conditions.

Following the pioneering studies of Goldschmidt in southern Norway, in 1920, Pentii Eskola developed the concept of metamorphic facies. Studying mafic metamorphic rocks (mostly basaltic protoliths) in southern Finland, he recognized that "in any rock or metamorphic formation which has arrived at a chemical equilibrium through metamorphism at constant temperature and pressure conditions, the mineral composition is controlled only by the chemical composition". This concept has now been validated worldwide in innumerable regional field studies demonstrating that many rock compositions develop mineral assemblages typical of the physical conditions of formation. For a certain bulk composition, the mineral assemblages formed at these different metamorphic grades are then related by mineral reactions. Experimental determinations of the relative stabilities of metamorphic minerals and assemblages, followed by thermodynamic calculation of such phase equilibria, have allowed an approximate quantification of the pressure and temperature conditions of each metamorphic facies.

The metamorphic facies diagram shown in Figure 1 differs in some details from that proposed by Eskola, who named his metamorphic facies after

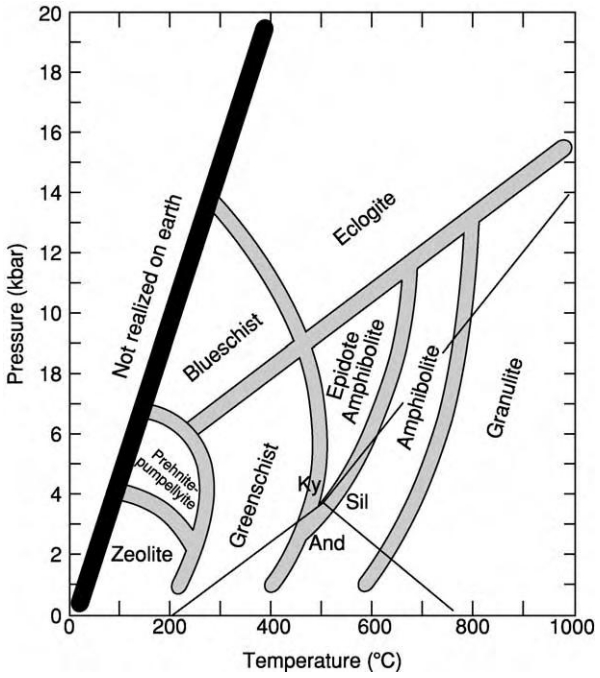

Figure 1 Pressure temperature diagram, showing principal metamorphic facies; approximate boundaries are represented by thick grey lines. Thin black lines designate the stability fields of the three Al_2SiO_5 polymorphs (And, andalusite; Ky, kyanite; Sil, sillimanite). Reproduced with permission from Spear FS (1993) *Metamorphic Phase Equilibria and Pressure Temperature Time Paths*. Washington, DC: Mineralogical Society of America.

metamorphosed mafic rocks. Nowadays, differences in facies classification exist mainly in the transition from greenschist facies to amphibolite facies at higher pressure; some authors prefer, and others do not, to introduce an epidote–amphibolite facies (Figure 1). In addition, the classification of the facies below the greenschist facies is summarized by several authors as 'subgreenschist facies'. In any case, the borders between different facies are not sharp, and the classification should be used in a broad sense. It is schematic, but there is consensus on the temperature and pressure limits for each facies. The boundaries between the facies represent the P–T conditions at which key minerals or mineral assemblages appear or disappear.

Extensive petrological studies were carried out in metamorphic terranes around the world during the twentieth century. These studies revealed that distinct metamorphic facies series (high, medium, and low pressure and very low grade) correlating with specific geotectonic settings could broadly be distinguished.

Facies of High Pressure

High-pressure rocks of the blueschist and/or eclogite facies were metamorphosed at a low geothermal gradient, i.e., small increase in temperature with

depth (Figure 1). They are typically formed during subduction of a cold oceanic plate underneath a continent. Mafic protoliths best document such high-pressure conditions by their diagnostic mineral assemblages in blueschist (sodic amphibole bearing; the term 'blueschist' derives from the blue sodic amphibole, glaucophane) and eclogite (dominated by garnet + omphacitic clinopyroxene). Metapelitic rock compositions may develop diagnostic minerals or assemblages such as carpholite, phengite, jadeite + quartz, and talc + kyanite.

Facies of Medium Pressure

Most metamorphic terranes, especially in the internal parts of continents, are composed of greenschist, amphibolite, and granulite facies rocks, including migmatites at the high metamorphic grades. Such a facies series is related to a geothermal gradient of 20–35°C km $^{-1}$, typical of the Barrovian-type metamorphism as defined by Barrow in south-east Scotland. A well-documented example of a Barrovian-type metamorphic zoning is exposed on the island of Naxos, Greece (see later). As already discussed, medium-pressure regional metamorphic zones are best developed in Al-rich metapelitic rocks, which may contain either kyanite or sillimanite, or both Al-silicates. The formation of staurolite and the breakdown of chloritoid are generally considered to reflect the greenschist–amphibolite facies transition in pelitic rocks. In mafic rocks, the greenschist–amphibolite facies transition is designated by the appearance of hornblende and Ca-rich plagioclase and the disappearance of actinolite and Na-rich plagioclase. In metapelites, the amphibolite–granulite transition is considered by some workers to be indicated by the assemblage K-feldspar + Al-silicate forming at the expense of muscovite + quartz. Other workers consider the formation of orthopyroxene to be typical of granulite facies conditions, although this occurs at significantly higher temperatures (100–150°C higher) than does formation of K-feldspar + Al-silicate. In mafic rocks, the presence of orthopyroxene, which forms at the expense of hornblende and/or biotite, is considered indicative of granulite facies conditions. The role of water activity, however, complicates characterization of the amphibolite–granulite facies transition. If rocks are water saturated, they will, with a eutectic or eutectoid chemical composition near to granite, partially melt at P–T conditions in the muscovite + quartz stability field. When water activity is low, pervasive partial (dry) melting will occur at much higher temperatures and hydrous minerals (muscovite, biotite, and amphibole) may decompose to anhydrous ones by local dehydration melting.

Facies of Low Pressure

Low-pressure facies are in many cases typical for contact metamorphism (*see* **Thermal Metamorphism**), but especially in cordilleran-type mountain belts this contact metamorphism can be of regional extent due to long-lasting intrusive activity over a large area, producing a transition to regional metamorphism (Buchan-type in Scotland, Abukuma-type in Japan). It also may follow the medium-pressure facies. Metapelites are characterized by andalusite and cordierite.

Facies of (Very) Low Grade

Facies of very low grade are present in the transition zones of an orogenic mountain belt to the sedimentary foreland (e.g., Swiss Alps), but are often missing in regional metamorphic terranes, where the metamorphic rocks are overthrusted onto the foreland. They are typically best developed in regions with burial or hydrothermal metamorphism (e.g., New Zealand, Central Andes).

The Barrovian-Type Metamorphic Complex of Naxos

The island of Naxos is part of the Attic–Cycladic Metamorphic Complex that stretches from mainland Greece to south-western Turkey. Isoclinally folded sequences of metasediments (pelitic and psammitic schists and gneisses, quartzites, and calcitic and dolomitic marbles) and metavolcanics (amphibolites and mafic schists) are the dominant lithologies on Naxos (Figure 2). Ultramafic rocks occur in a few stratigraphic horizons and as isolated lenses. Metacarbonate units are widespread and contain in certain stratigraphic horizons diaspore and/or corundum-bearing lenses (up to ≈8 m thick; Figure 2), for which protoliths are bauxite formed in a karst soil. These metabauxite occurrences offer a unique opportunity to investigate the prograde metamorphism of a rock composition with excess Al.

The metamorphic pattern of Naxos was shaped during a late Alpine medium-pressure event that culminated 15–20 Ma; it consists of concentric zones of decreasing metamorphic grade, outward from a high-grade migmatitic core (Figure 2; Table 1). In the western part of Naxos, a ≈13-My-old granodiorite intruded the metamorphic complex and induced andalusite–sillimanite-type contact metamorphism in about a 1-km-wide zone. In this same region of Naxos, a post-intrusive upper unit, comprising Tertiary sediments and ophiolite-suite rocks, tectonically overlies the metamorphic complex and granodiorite. Petrological and geochronological studies indicate that relict

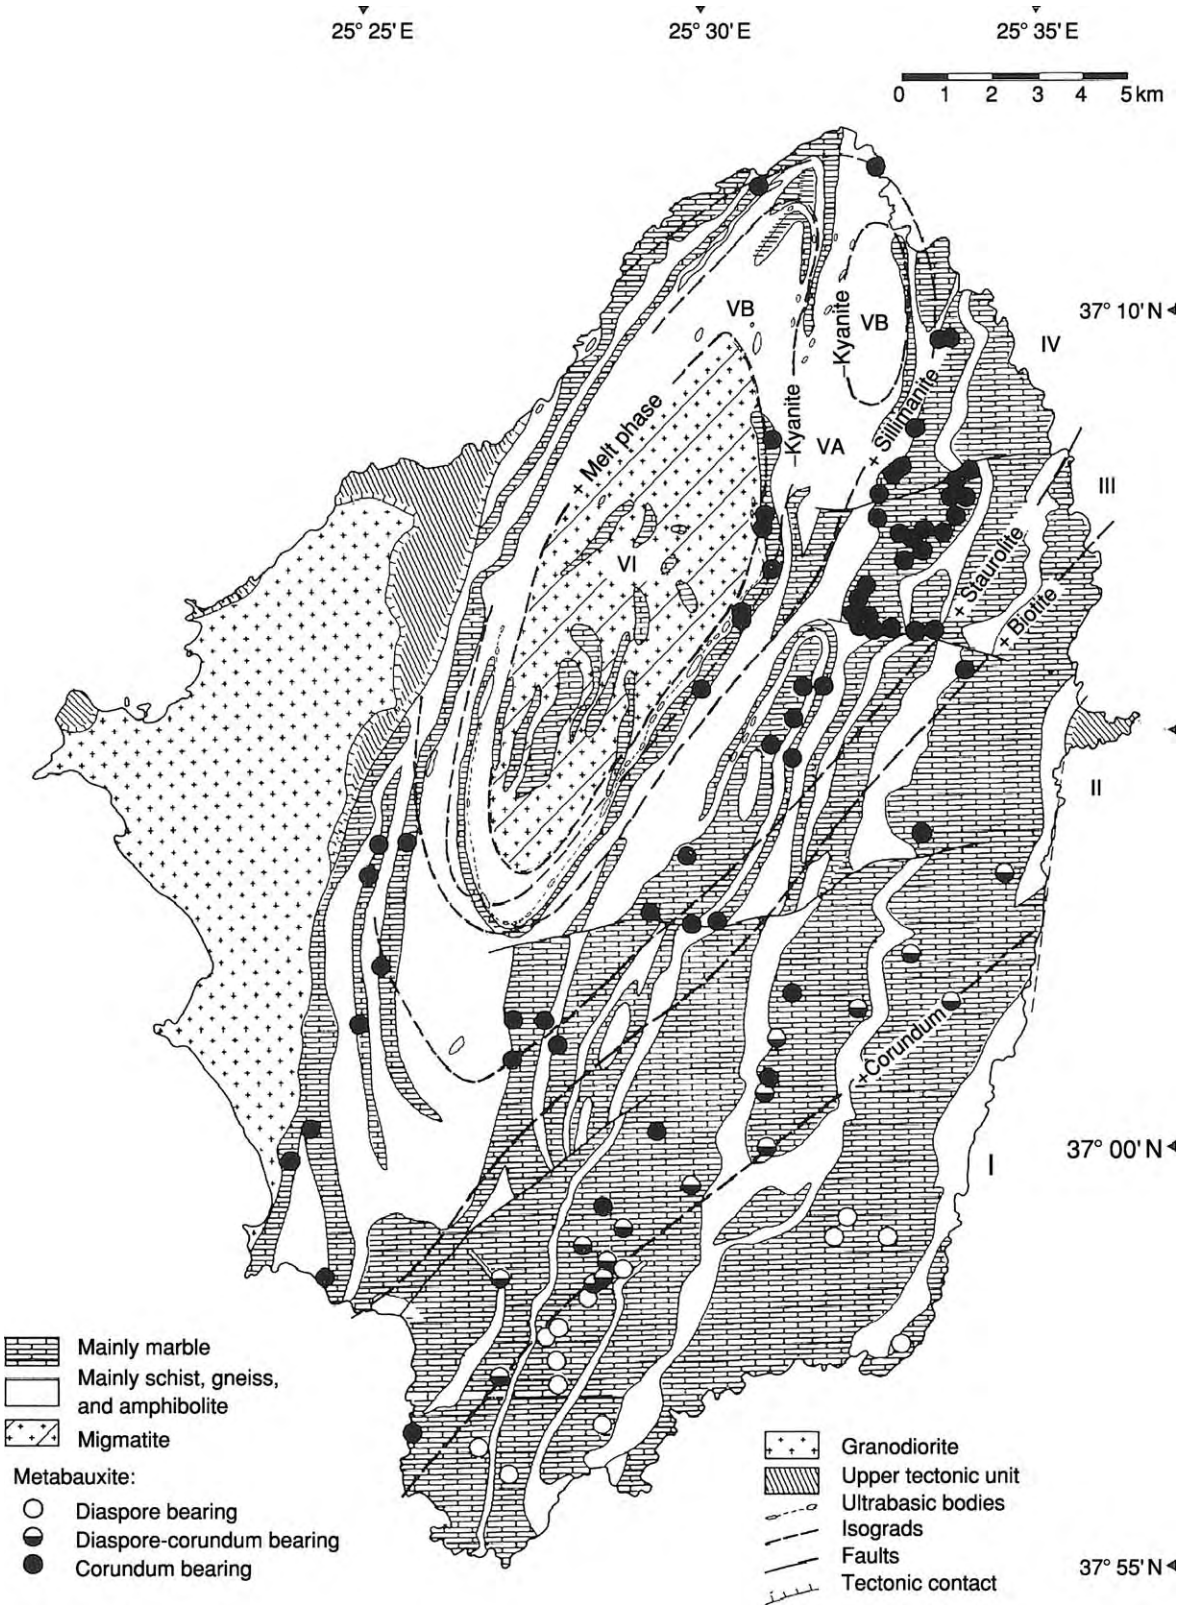

Figure 2 Geological metamorphic map of Naxos (Cycladic Islands, Greece), showing main lithologies, isograds, and metamorphic zones (I VI). The following isograds were mapped with increasing grade: corundum in (metabauxites); biotite in (metapelites); Fe rich staurolite in (metabauxites and metapelites); sillimanite in (metapelites); kyanite out (metapelites); melt phase in (metapelites). (Adapted from Feenstra A (1985).)

mineral assemblages of an early Alpine high-pressure/low-temperature metamorphism (about 45 Ma) locally occur in south-eastern Naxos (zones I–II) and that part of the migmatite core (zone VI) is of pre-Alpine origin (from ≈300 Ma).

Temperatures during the Barrovian-type metamorphism are estimated to have ranged from ≈700°C in the migmatite dome to ≈400°C in south-eastern Naxos at pressures of 0.5–0.7 GPa. Six isograds mapped in metapelitic and metabauxitic rocks divide the metamorphic complex into seven Barrovian-type metamorphic zones (Figure 2; Table 1). The first three zones (I–III) belong to the greenschist facies: their subdivision is based on the first occurrence of corundum, by the reaction diaspore = corundum + H_2O (in metabauxites), and of biotite, by the reaction chlorite + muscovite = biotite + H_2O (in metapelites). In mafic rocks, biotite already occurs locally in zone II, whereas the first biotite in bauxitic rocks appears in zone IV.

The presence of staurolite, both in pelitic and bauxitic rocks, indicates the beginning of amphibolite facies conditions. Staurolite formation is related to complex breakdown reactions of chloritoid and approximately coincides with the disappearance of chloritoid. Zones IV, VA, and VB belong to the amphibolite facies; whether zone VI, the beginning of which is defined by partial melting of metapelites, is amphibolite or granulite facies is a matter of debate. The subdivision of the amphibolite facies zones of Naxos is based on the appearance of sillimanite and the disappearance of kyanite in metapelitic rocks. The Naxos rocks clearly illustrate that bulk composition controls the formation of particular minerals or assemblages. In common with other Barrovian terranes, the first kyanite in metapelitic rocks is found in staurolite-grade zone IV, whereas kyanite in bauxitic rocks is already formed in zone I by the reaction pyrophyllite + diaspore = kyanite + H_2O (Table 1).

The upper amphibolite or granulite facies zone VI contains areas where partial melting of SiO_2-rich rocks was intensive (melt phase has a granitic composition) and areas showing little evidence of melting. Variations in the degree of migmatization may relate to local variations in water activity and rock composition. The typical mineral assemblage in metapelitic composition is K-feldspar + sillimanite + biotite. Muscovite often occurs, but textural evidence suggests it is mostly of retrograde origin. Mafic rocks are devoid of orthopyroxene but the presence of sapphirine + spinel + corundum at a few localities in zone VI argues for granulite facies grade conditions.

REMOTE SENSING

Contents

Active Sensors

G Wadge, University of Reading, Reading, UK

Introduction

The amount of solar radiation reflected from rocks at longer wavelengths (>1 mm) is very small. To properly exploit this microwave part of the electromagnetic spectrum for remote sensing, artificial sources of radiation are used. These artificial, or 'active' techniques allow measurements to be made at night as well as during the day. The longer wavelength of microwave radiation compared to that in the optical part of the spectrum also makes clouds transparent, allowing microwave radiation to 'see' the ground surface in all weathers, day and night.

In radar (Radio Detection and Ranging) remote sensing, a series of timed pulses of microwave energy are transmitted through the air, strike targets (e.g., the ground) and are reflected back to the radar which receives the returned signals. There are parallels between radar and seismic exploration techniques. The principle of 'ranging' is common to all active sensors in remote sensing described here. Because the energy source is under the control of the instrument designer, the frequency and wavelength of the radiation is chosen with a very narrow range so that it can be recognized more easily on reflection and its arrival timed accurately. Knowing the two-way (to the ground and back to the sensor) travel time (t) and the speed of travel through the medium (c), the distance or range (R) to the ground is given by:

$$R = ct/2 \qquad [1]$$

After briefly reviewing the three allied 'active' techniques of radar, lidar, and sonar, attention is focused on radar and the basic principles behind its use and interpretation. There are three main application areas relevant to geology: structural and geomorphological mapping, exploitation of the ability to measure fine surface roughness, and the measurement of surface motions including those associated with earthquakes (*see* **Tectonics:** Earthquakes) and volcanoes (*see* **Volcanoes**).

Radars, Lidars and Sonars

Radars send pulses of microwave radiation (wavelength usually 3–30 cm) from antennas through the atmosphere to the ground, in our case, and receive the return signal. Lidars do the same but with optical wavelength light (800–1000 nm) from lasers. Lidars do not work through cloud, as radars do. Sonars are the oceanographic equivalent to radars that send pulses of energy (1–15 cm wavelength) through the water column to strike the seabed. Figure 1 shows the typical sensing arrangement of the three techniques. Radars have made the most impact on geology.

Lidars have been relatively little used in geological applications to date but the technology is newer. Usually flown from low flying aircraft, they are used as a simple track or swath altimeter with a small footprint. With their high vertical (~10 cm) and horizontal (~1–2 m) resolutions, detailed digital elevation models (DEMs) can be created. They will become increasingly useful to studies requiring detailed geometric knowledge of the terrain, such as process-based simulations.

Sonars have a much longer history of sea-floor mapping. The sensors are towed behind a ship at various levels above the seabed. Absolute positioning is a more involved process than for space-borne sensors. The range information received by the sonar is used to form bathymetric maps with accuracies of a few tens of metres in some cases. As with radar, the magnitude information is a function of the geometrical relationship of the sensor, and the seabed and the surface roughness. Particularly valuable results have been achieved at spreading ridges, accretionary prisms, and in mapping the apron of gravity collapse deposits around oceanic islands.

Radar Techniques

Altimetry

Radar altimeters are the simplest form of radar. They are usually simple ranging devices recording the distance from the radar to the ground, pointing vertically downwards from a satellite. Their footprint on the Earth's surface is large (kilometre scale) and as a result their profiling measurements are only easily interpretable on surfaces that are relatively flat at this length scale (e.g., oceans and ice sheets). Their importance to geology has been that they have provided a measure of the shape of the geoid in the ocean basins that reflects the dynamic processes of plate tectonics (*see* **Europe:** Mediterranean Tectonics): subduction and spreading ridges.

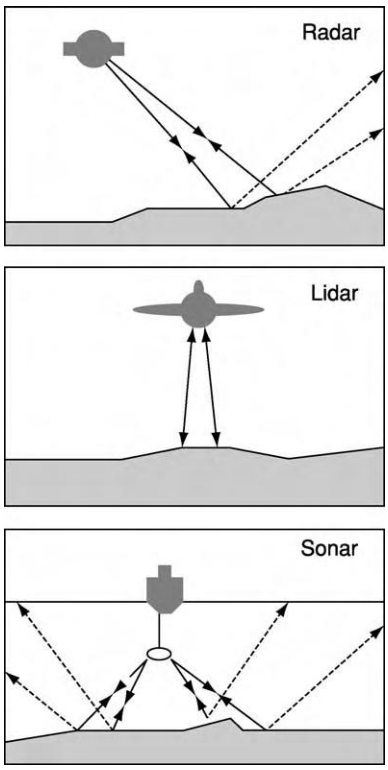

Figure 1 Schematic of the typical operating geometries of a spaceborne SAR, an airborne lidar and a multi swath sonar.

Doppler Radar

In an active remote sensing device, the engineer can control the rate of pulsing of signals transmitted to the surface and the range of frequencies of radiation transmitted and received. This means that the measurements can remain 'coherent' from one measurement time to another, provided that the external conditions remain the same. Such a coherent radar signal has three measurable quantities: timing, magnitude, and phase. Any relative movement between the radar antenna and the reflecting surface from one pulse to another can be detected as a change in the frequency of return of these pulses – a Doppler shift. The size of this shift allows the relative motion to be calculated. Doppler radars of this type have been designed to measure the dynamics of volcanic ash columns. Lower frequencies of radar signal are more sensitive to larger fragments. Using multiple frequency bands in the same instrument, it is possible to measure the relative motions of different particle size fractions. Because many ash eruption columns are usually obscured by fine turbulent cloud, Doppler radars offer the only practicable way of seeing through this and measuring the internal dynamics of the column.

Imaging Radar

The majority of Earth science applications of radar employ imaging techniques. Table 1 summarizes the characteristics of the main space-borne radar imaging systems to date and those planned in the next decade. In addition there are a number of airborne systems and ground-based systems. Future development of more compact systems and the exploitation

[a]Proposed InSAR mission dedicated to ground motion measurement.

of the millimetre wave part of the spectrum will add considerably to these capabilities.

The motion of a plane or a satellite relative to the Earth's surface can be used to build up a 2D image of the radiation returning from its reflections, or backscatter. Such imaging radars are usually pointed to one side of the platform (**Figure 1**). This removes the ambiguity of signals returning from equal distances to the left and right of a downward pointing instrument. Most imaging radars are Synthetic Aperture Radars (SARs). In these instruments, the Doppler frequency information from radar returns received ahead of the moving radar (positive shift) relative to those behind (negative shift), are used to 'synthesize' electronically a larger antenna size. This is needed to improve the resolving power of the radar in the along-track or azimuth direction. The details of radar image formation and processing are complicated, but the resulting images essentially contain data on both the magnitude or amplitude and the phase (ϕ) of the returned signal reflected from the ground. Three main factors control these quantities in a radar image: the wavelength of the radar, the slope, orientation and roughness of the reflecting surface, and the dielectric properties of the surface.

The radar image amplitude is generally greater if the surface slope is close to perpendicular to the radar line-of-sight (LOS), which is often several tens of degrees from the vertical. It is also greater if the surface is 'rough' and if it is 'wet' (water content is the main determinant of dielectric behaviour). Within the instantaneous field of view of the radar there may be several individual surfaces or edges (e.g., rock facets) that return much stronger signals than intervening areas. Because the radiation is coherent, these strong signals may reinforce or destroy each other, depending on their relative positions. Depending on the arbitrary location of these strong reflectors on the surface then one radar pixel may have a high amplitude whilst its neighbour, comprising very similar surface material, has a low amplitude. This gives radar amplitude images their 'speckle' character. It also means that, in general, a meaningful measure cannot be retrieved of the surface properties from a single pixel of an amplitude image (unlike a passively acquired optical image). Instead a spatially averaged measure of backscatter amplitude is needed. A similar conclusion applies to the phase information measured. The cumulative sum of phase values from an individual pixel gives a cyclic angular measure ($0 < \phi < 2\pi$) that has no intrinsic significance. However, these values are not noise and the radar should retrieve exactly the same values on re-measurement. These phase data are used by taking temporal differences of phase in the technique of radar interferometry.

Radar Applications

Structural/Geomorphological Mapping

The ability to image large contiguous areas through cloud from airborne radars was first demonstrated in the 1960s. It enabled the first hundred kilometre scale reconnaissance structural mapping of cloud covered areas in the humid tropics. Slopes nearly perpendicular to the radar LOS appear bright in amplitude images and slopes away from this appear dark. This light and shade effect is the same as that seen in optical imagery. However, radar amplitude images suffer from distorting effects that complicate qualitative interpretation. Radar-facing slopes are foreshortened, whilst those facing away are extended. At very steep slopes in alpine-type terrane the foreshortening becomes 'layover' when the tops of peaks appear to overhang their valleys. Most of these distortions can be corrected quantitatively if a DEM is available. Suitably detailed surveys of several areas, particularly young fold and thrust belts in cloudy regions, have proven genuine exploration aids. The sensitivity of a radar amplitude image to a fault-controlled topography or any other geomorphological features is always a function of the angular relationship between the radar LOS and the feature on the surface. Features parallel to the LOS are hard to see. Airborne surveys can be designed with this in mind. The erosional morphology of different lithological terrains is also well expressed in radar amplitude imagery, permitting lithological discrimination (**Figure 2**). This is, of course, scale dependent, particularly where there is tree cover obscuring ground features less than about 100 m in size. With the increasing availability of high resolution DEMs for much of the globe then the value of imaging SAR at this reconnaissance scale is being superceded.

The most remarkable radar mapping survey yet undertaken was that performed by NASA's Magellan mission to Venus (*see* **Solar System:** Venus) from 1990 to 1992. Radar had to be used to penetrate the thick Venusian atmosphere. In addition to the huge scope of the global mapping undertaken, a lot of the geomorphological features seen had no obvious terrestrial analogues and hence stretched the interpretational skills of the Magellan science team.

Roughness Mapping

Radar backscatter is sensitive to the roughness of surfaces at length scales much less than the wavelength of the radar. For example, the C-band (wavelength = 5.8 cm) radar of the ERS/ENVISAT satellites are sensitive to surface roughness at the scale of millimetres. Thus, any changes in roughness in space or time that are relevant to geology can be utilized.

Figure 2 Radar amplitude image of part of north central Jamaica viewed by the SEASAT L band radar in 1978. The radar illumination is from the left (west south west) of the image at an incidence angle of about 20 degrees from vertical. Most of the scene is covered by ''dimpled'' pattern typical of tropical karst topography of Cenozoic limestones, except for the bottom left corner which is an inlier of Cretaceous volcanic and volcaniclas tic rocks. In the northernmost central part of the image a straight normal fault scarp downthrows the limestones to the north. This is cut by one of two, subparallel curving fault scarps. The east ernmost one shows the clear pattern of a scissor fault. To the south the fault shows a west facing escarpment that is bright in the image and futher north this changes to an east facing escarpment in shadow. The image measures about 36 × 24 km.

Satellite radar imagery can be used for offshore oil basin reconnaissance using this technique. Oil seeping from depth forms a film on the sea surface that dampens the backscatter roughness relative to surrounding areas. These areas of surface oil appear darker in amplitude images. Hydrocarbon-rich basins often have a variety of discrete oil seeps that help define the basin extent and character. These seeps can be detected by radar roughness mapping. Shorter wavelength radars (e.g., X-band, 3 cm) give a stronger roughness contrast than longer wavelength radars. The ambient sea-state also plays a role: contrast is enhanced by moderate wave formation and by viewing from perpendicular to the wave motion. In order to distinguish between natural seeps and ship pollution it is necessary to build up a time series of observations that establish the semi-permanent nature of seep locations.

Of course, most rock surfaces do not change their roughness over periods relevant to remote sensing. One environment that does, however, is arid playas. Here the evaporation of groundwater leads to the surface formation of evaporite minerals, particularly gypsum and halite. During the summer months, when evaporation is highest and rainfall negligible, the growth of these minerals, specifically halite, can produce a surface that becomes increasingly rough. The C-band radar of ERS is sensitive to this seasonal roughening of the surface of arid playas such that, using a time series of ERS radar amplitude images at 35-day intervals, it is possible to monitor quantitatively the evaporation rate from the backscatter values using models of roughening. Confidence in this approach only comes when the region is very flat and extensive, so that slope effects can be discounted.

Radar is very effective generally in deserts (*see* **Sedimentary Environments:** Deserts), because it can penetrate dry, unconsolidated materials. Where sheets of windblown metres-thick dry sand cover eroded surfaces in the Sahara, it is possible to image these buried surfaces and their subtle differences in roughness beneath their cover, even from space. This is best done with the long wavelength (24 cm) L-band radar which can penetrate several metres into the extremely dry sand by a process known as volume scattering. On reaching a buried rock surface, the radar signal it is reflected back through the sand. Shallow former river channels, eroded in wetter periods, form smoother reflectors relative to their surrounding eroded interfluves, revealing patterns totally hidden beneath their aeolian cover.

Ground Motion Measurement

The phase information from imaging radar can be used to measure the relative spatial motion of the ground surface between two separate images. This technique uses the principle of interferometric synthetic aperture radar (InSAR) and has made a major impact on the Earth sciences in the past ten years, since its practical value was first demonstrated using data from the ERS satellites. It relies on the ability to measure the change in phase at each pixel between two images. If the surface of part of the image moves towards or away from the radar LOS more than in another part of the image, then a phase gradient is measurable (Figure 3). Without independent control on motion, the technique known as differential InSAR only gives relative, within scene, motion-detection. The motion sensitivity is proportional to $4\pi/\lambda$, where λ is the wavelength. Typically for InSAR, using ERS data, LOS accuracies of about 1 cm can be achieved. After each 2π of phase change the phase wraps around and the interferogram image displays a fringe of interference. To retrieve a monotonic motion signal the

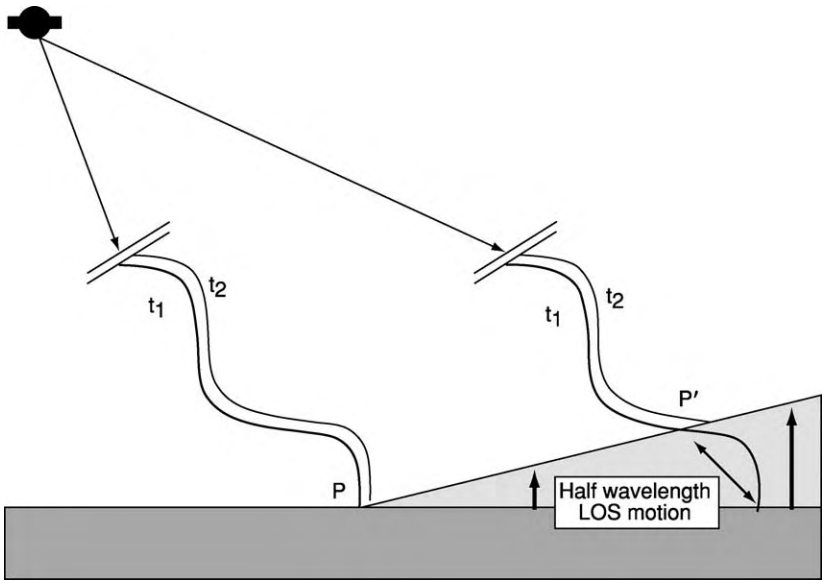

Figure 3 Schematic of the principle of differential InSAR. A radar images the earth's surface at time t_1 as represented by the thick cyclic lines reflecting from the surface at two places. After an interval the radar images the scene again, at time t_2, from the same orbit. During this time the ground surface has moved differentially as shown by the lighter shaded triangle such that there is now a difference in path length along the LOS of the radar of one half a wavelength of the radar between positions P and P′ on the ground. This corresponds to a gradient of 2π in phase, or one fringe in the interferogram made from the difference in phase of the two radar images.

phase fringing must be 'unwrapped' using automated algorithms.

InSAR has opened up a new form of space geodesy at the same time that GPS measurements of surface motion have become commonplace. The two techniques are largely complementary, InSAR has a dense spatial, but sparse temporal sampling, opposite to that of continuous GPS. InSAR also has the potential to work anywhere, without the need for ground instrumentation. However, there are a number of complicating factors that inhibit InSAR's practical usefulness at present. The technique requires the surface scatterers to remain unchanged between the two images of the interferogram. Vegetation change is a major inhibitor here at X- and C-band. Variable water vapour distribution in the troposphere produces unwanted path effects. Also, remarkably, none of the current space-borne radars were designed with InSAR in mind and so a lot of the radar parameters are not optimised for InSAR. Potentially, InSAR has a role to play in any Earth process that involves the motion of the Earth's surface at length scales of 100 m to 1000 km and at strain rates of 10^{-5}–$10^{-7}\,\mathrm{yr}^{-1}$. The Earth science fields that have made most use of it are the study of earthquakes and tectonics, volcanology, and the study of shallow subsidence processes.

Earthquakes and Tectonics

Seismology has dominated the study of earthquakes. In recent years, however, the ability to measure the surface ground motion field associated with fault rupture by InSAR has brought a new dimension to the study of shallow earthquakes. By inverting the co-seismic motion field of InSAR with numerical models of the fault plane motion in a 3D space, knowledge of the earthquake fault mechanism can be improved. Specifically, InSAR can greatly improve knowledge of exactly where the fault plane rupture was and estimates of its dip, whilst seismology is better at resolving the moment released. Immediately following a large earthquake the ground surface can move more slowly over the following months. This can be measured by InSAR to help constrain the physical processes potentially involved: afterslip on the fault plane, poroelastic pressure changes or viscoelastic relaxation in the lower crust/mantle. The other component of the earthquake cycle, the interseismic strain, can also be detected by InSAR, for example, on the San Andreas and North Anatolian Faults. This requires pushing the technique to its limits of sensitivity in measuring very slow strain buildup over several years across widths of about 100 km.

Not all Earth strain involves seismicity and sudden displacements. InSAR is starting to reveal a wealth of surface strain events in the continental plate boundary zones that whilst linked to fault systems, do not themselves display significant seismicity. Aseismic displacement events triggered by nearby seismic events has been measured and shallow folding deformation may be revealed in low competence

rocks. This raises the exciting prospect of being able to relate the current day surface deformation to neotectonic processes and geomorphological features of the past few hundred to thousands of years.

Volcanoes

Earthquakes and volcanoes can share a similar cycle of surface straining associated with the repeated charging of their systems by external forcing (plate motion and magma buoyancy) (*see* **Volcanoes**). In the volcanic case, dilational strain during charging of the magma reservoir is released suddenly, perhaps with shallower planar rupture deformation (dyking and surface fissuring). InSAR is having an impact on our knowledge of the volcano cycle as it has for earthquakes. In the volcano case, we also have the possibility of using the volume of erupted magma during an eruption to constrain the magma loss event in the reservoir. However, the complementarity of InSAR and seismicity in defining the source mechanism of earthquakes is not available in volcanoes. Because of this and the inherently more complex three-dimensional shape of pressured magma reservoirs, progress in refining their location and dynamics has been slower.

Many volcanoes are susceptible to gravitational instability and in particular to spreading under their own load if there is a suitable weak basal layer. This has been measured by InSAR. A complex mixture of spreading forces, local fault accommodation of these, regional tectonic movements, and pressurizing magma reservoirs mean that the INSAR-measured deformation at many volcanoes may reflect a much more complex system than hitherto realized (Figure 4).

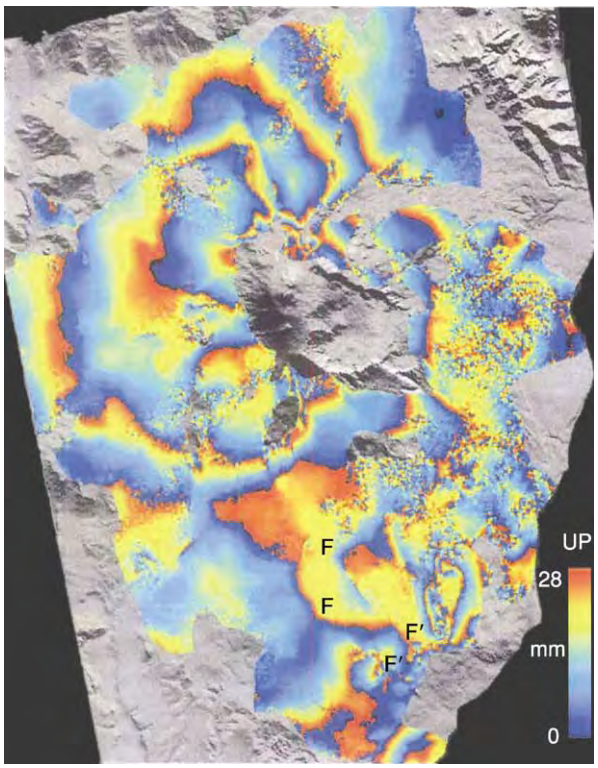

Figure 4 A differential radar interferogram of the Etna volcano in Sicily created using two ERS SAR images from 1995 and 2000. Each colour cycle from blue to red represents one fringe of relative motion of 28 mm. The parts of the scene where the phase data are too noisy are replaced by a shaded relief image of the topography. The displacement pattern of the ground surface shows apparent LOS uplift of >10 cm of the summit region of the volcano relative to the flanks. Also indicated by the F F′ symbols is evidence of relative movement along two faults on the southern flanks. The image is about 40 km wide. The ERS data were supplied by the European Space Agency.

Subsidence

There are a number of natural and anthropogenic or human-induced mechanisms that can produce shallow and hence local subsidence of the Earth's surface: for example, soluble rock dissolution, landslides, mining, groundwater/oil extraction, and tunnelling. InSAR has been shown to be valuable in monitoring all of these. Because of their small spatial extent, it is easier to calibrate the absolute motion.

Local subsidence events are of considerable concern in urban environments and a variant of the InSAR technique has been developed to take particular advantage of this. Buildings and roofs of a variety of shapes and orientations serendipitously provide a source of very strong radar scatterers. In the 'permanent scatterer' technique of InSAR, the phase change information from these scatterers alone is used in a time series of images (typically at least 20–30). By making some assumptions about the nature of the atmospheric effects and with good knowledge of the topography, these sources of error can be removed and a line of sight (LOS) motion history of the set of scatterers can be measured to accuracies of a few millimetres.

GIS

P J Mason, HME Partnership, Romford, UK

Introduction

Geological phenomena vary in space and time and this basic trait makes geology a particularly suitable application field for Geographical Information Systems (GIS). A GIS is a computer-based tool for the mapping and analysis of things that exist on, and events that happen on Earth. It is, therefore, a sophisticated but general-purpose tool and one which can be applied in many ways to many problems, and especially so in geosciences.

There have been a number of technological advances, including the development of GIS, which have transformed the work of the geoscientist over the last 15–20 years. Until the 1980s, GIS was used and developed mainly by the geographical community and generally in government organizations and research institutions. The wider geological community has been, until relatively recently, a little sceptical about its operational success in solving complex geological problems.

The first GIS systems were pretty cumbersome hardware and software suites, with high-end functionality that required programming skills to operate. These have evolved into highly functional desktop systems, which anyone can learn to use, and which are part of a growing, multibillion dollar, worldwide industry. GIS functionality developed very quickly, with the advanced statistical and 3D analytical modules, which had been considered requirements only of the advanced GIS community, becoming the selling points for desktop GIS. Multivariate and geo-statistical methods laid the foundations of the geological application of GIS. Specialized exploration software, in the late 1970s and 1980s, had many features present in current GIS suites, such as those of Zycor, Z-Map Plus, Strat Works, GeoData Works, Earth Cube, and StratSoft's Statistica. The costs of these commercial software packages were generally prohibitive and the wider geological community continued to rely on the more readily and cheaply available geo-statistical packages, many of which were available in the public domain.

The technological developments in GIS were accompanied by, and to a large extent enabled by, huge leaps in computer power and development. Large mainframe machines gave way very rapidly to desktop, laptop, and now palmtop processing. Software evolved in parallel with these changes, and GIS mapping can now be done in your hand, in the field, enabling great savings in time and money. The growth of the World Wide Web (WWW) and wireless communications has enabled the generation of, and access to, accurate and timely information, in addition to fast and reliable transport of information from office to field and vice versa.

The end of GPS selective availability in 2000 and the reduced cost and increased availability of commercial satellite imagery, also make 'remote' digital mapping cheaper, more accurate and more accessible. One milestone in this part of the 'geospatial revolution' was the successful launch of the Earth observation satellite, Landsat 7 in 1997, whose data were

commercially available at unprecedented low prices and, for the first time ever, were browsable on the Internet only a short time after acquisition. The launch of ASTER on TERRA AM-1, in 1999, has broadened geological mapping capabilities and reduced costs even further. Sadly, Landsat 7 is no longer fully functional but ASTER is and this series of satellites is likely to evolve further.

This article not intended to provide an exhaustive technical explanation of what GIS is, how it functions or of the technical details of various software suites. Rather, it aims to give an overview of the state of the art in 'geo-GIS', i.e., those aspects of GIS which are specifically relevant to geoscientists and their activities. The Further Reading section at the end of this article includes a number of standard texts on geographical information systems and science, and on supporting subject matter, in addition to some rather more specific publications of interest to the geoscientist working with GIS.

The Geological Information System

Most geologists would agree that a geological map could be considered a database in its own right, as the information contained on the map and in the legend is, by definition, spatially referenced and attributed. To realize the full potential of that database, the map must be properly converted, and it is at this point that the power and tools of GIS come into play. They enable far more to be gained from the original map than that which first meets the eye. Fundamental to the conversion are the mapped spatial relationships, which are interpreted by the GIS through topological rules. Successful digital conversion requires the understanding of the geological and implied topological relationships described by the map.

Components of a geological map are stored as records, or objects, in a spatially referenced GIS database, which can be displayed spatially, as a map, or in graphical or tabular form (as attribute tables). Standard querying enables selection and extraction and/or the linking of related attribute tables.

Attributes, i.e., any kind of descriptive information, can be attached to a record or object in the database. Geological attributes, attached to a map object can be likened to the association of multi-element geochemical data to a single sample locality. GIS allows this attribute information to be viewed and edited in tabular form, where each object represents a record, and each column represents a field containing a different attribute. The objects can then be reclassified, according to the various attributes, and displayed in map form, revealing patterns and relationships not always detectable in tabular form.

Spatial Data, Models and, Structures

There are two basic methods of representing information in a GIS – raster and vector. Geological maps and data can be displayed using either method, but if a layer is to act as a database, it must be properly converted into or captured in vector format.

i. The raster or 'grid'
   The raster displays spatial information as a series of contiguous cells (or pixels) of uniform size, and each raster grid represents the variance within one attribute. This method of storage and display of information is appropriate for data that has high spatial variability, such as geophysical survey data or satellite images. As the raster grid (or lattice) is regular, spatial relationships are implicit and therefore, explicit storage of spatial (and topological) relationships is not necessary, as it is for the vector data model.
ii. Spatial or vector data comprises any or all of the following basic components:
   - Lines or arcs (e.g., representing contacts and boundaries)
   - Areas or polygons (e.g., representing closed areas and regions defined by surrounding lines)
   - Symbols, points or nodes (e.g., such as a sample point, borehole, or a strike and dip measurement at a specific location).

To correctly display a map in vector form, certain information about the geometric and spatial relationships of the map objects is required and this is where topological rules become necessary. For example, the GIS needs to be able to determine whether a fault is connected to another fault, or where one outcrop borders another. **Figure 1** illustrates the appearance of a simple digital geological map in vector and raster form, and the effect of varying raster resolution, on map detail.

There are advantages and disadvantages to both methods, but the fundamental requirement in both cases is that linear features (e.g., boundaries, contacts, and faults) are digitally captured only once. These linear features are then used to construct the areas or polygon objects (e.g., lithological outcrops) that comprise the map. The result is that all adjacent or connected objects have topological connectivity and contiguity, so that spatial relationships between them are understood by the GIS. Topologically correct data capture and database construction should be done from the outset.

The Open GIS Consortium, Inc. (OGC) leads in the development of open, interoperable, geo-processing computing standards and specifications. OGC is involved with government, private industry, and

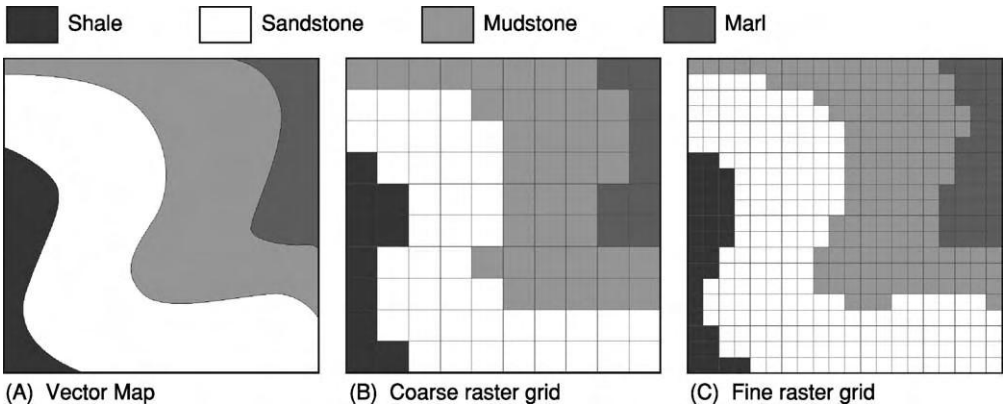

Figure 1 Digital representation of a simple digital geological map; (A) vector or spatial data map; (B) coarse raster grid; and (C) fine raster grid (illustrating the effect of spatial resolution or grid cell size on the detail stored in the representation).

academia, and its adopted GIS standards and specifications provide a valuable resource; they are available at the OGC's website (http://www.opengis.org/about/).

Database Design, Quality, Precision

The design and structure of the GIS database being developed should be governed by the application, and by the intended use of the database. The quality, accuracy, precision, and relevance of the captured data are all significant considerations. It has been said many times that the GIS analysis is only as 'good' as the information that is input.

Georeferencing

To make GIS work, there must be techniques for assigning 'coordinates' of time, location, and attribute in a way that is commonly understood. Basic tabulation, and calendar and time systems are not a problem, so the recording of location is the most vital reference information stored in GIS. Some georeferences are based on names, others on measurements, which are sometimes referred to as 'metric' georeferences. They include latitude and longitude and various other kinds of projected coordinate system, and provide infinitely fine resolution and enable accurate measuring capabilities.

Georeference, geolocation, georegistration, and geocoding are all common terms for the recording of an object's position and shape on a map, in the form of a map projection and datum. The need for map projections is fundamental – the world is a three-dimensional object, roughly oblately spherical in shape, which needs to be represented on a two-dimensional piece of paper or screen. We also need to measure positions, distances, and heights, all of which would be arbitrary and relative, if not made with reference to some known reference datum or ellipsoid. Many coordinate systems, projections, datums, spheroids, and ellipsoids have been developed over the years for various regions of the world and for the whole world. Integrating multisource, multiform data into the GIS presents the fundamental need to ensure coordinate reference system conformality. This can be time consuming but most GIS software contains tools for transforming datasets from one system to another. There are also some very comprehensive reference texts, and now Internet resources, to help deal with this issue.

Visualization

GIS visualization tools (two- and three-dimensional) within GIS enable and rely on the ability to share and integrate multisource data, models, and interpretations. The simplest form of visualization involves the display of two-dimensional images with conventional cartographic symbols. The geological map can be recreated using conventional geological symbology, which can easily be incorporated within the GIS, through the use of special fonts. Thus structural information can be presented to give the appearance of a published geological map (**Figure 2**).

The ability of GIS to bridge the gap between two- and three-dimensional display and analysis is especially useful in geosciences, because depth and 3D structure are fundamental considerations. The ability to integrate surface and sub-surface data is therefore an essential function of any digital mapping technology in geoscience.

GIS enables exploration and interrogation in several dimensions for improved and enhanced understanding of structures and relationships. It is possible to conduct virtual geological field visits, which can assist in the logistics and improve understanding prior to setting foot in the field, thus saving valuable time. Most GIS software provide such visualization tools

Figure 2 Data capture and conversion from a simple field sketch map (left) to the visualization of a digital geological map (right) within GIS.

for the manipulation of surfaces, images, and maps in pseudo three-dimensional space, and the mathematical derivation of other products, such as slope angle, aspect or azimuth, curvature, line-of-sight, watersheds, and catchments. Examples of software providing excellent 3D manipulation and viewing capabilities are ERDAS Imagine's Virtual GIS, ER Mapper, ArcGIS 3D Analyst, and Geomatica Fly.

Visualization in pseudo-3D requires a valuable commodity – a digital representation of a surface, whether it is topography or other feature data, such as an interpreted seismic horizon or geophysical survey data. The attribute information in this 'surface' layer provides the third dimension or 'z' value for the display.

There are many ways to obtain and derive digital surface topographic data or DEMs. Many datasets can now be browsed and obtained on the Internet from organizations such as the United States Geological Survey and the National Imagery and Mapping Agency (NIMA). In February 2000, the Shuttle Radar Topographic Mapping Mission (SRTM) carried out radar interferometric mapping of the Earth between +60 and −60 degrees latitude, in fewer than 11 days. SRTM is an international project, headed by NIMA and the National Aeronautics and Space Administration (NASA), with the objective of generating global DEMs. DEM data, gridded at 90 m are now available for much of the world, and at 30 m for the USA only, and are downloadable, free of charge, from ftp://edcsgs9.cr.usgs/pub/data/srtm. Sophisticated software exists (such as PCI Geomatica, Socket Set, ENVI ASTER module, Virtuozo) to generate DEMs from stereo airborne and space-borne photography and imagery. One such source is Terra-1 ASTER, whose stereo capability means that high-quality DEMs can be readily generated at very low costs and at spatial resolutions suitable for 1:50 000 scale mapping (http://asterweb. jpl.nasa.gov/).

Geological Application Fields

The application areas to which GIS makes a significant contribution are as varied as they are numerous. In geosciences there are some key areas where the necessity for and contribution of GIS are clear and significant. They range from the basic requirement of producing maps through the solving of complex geological challenges, to advanced spatial analysis.

Field Mapping

The most basic of activities for the geoscientist, mapping, has been changed fundamentally through the use of GIS. Though the hammer may remain ubiquitous, weatherworn field slips and notes are being replaced. Field mapping essentials now include laptop and palmtop computers (**Figure 3**), connected to GPS hand sets (and mobile telephones) so that positional data can be fed directly and dynamically into the GIS, to record current positions for waypoints or sample localities. Alternatively, tracks can be recorded as you walk along, so that you can re-trace your steps at any time, and boundaries and contacts can be walked out to provide direct mapping to the GIS database. Even sketches and notes can be immediately input through palmtop graphical interfaces and handwriting transcribers.

These processes are commonly facilitated by Earth observation image data (from both satellite and airborne platforms), which are easily integrated in the

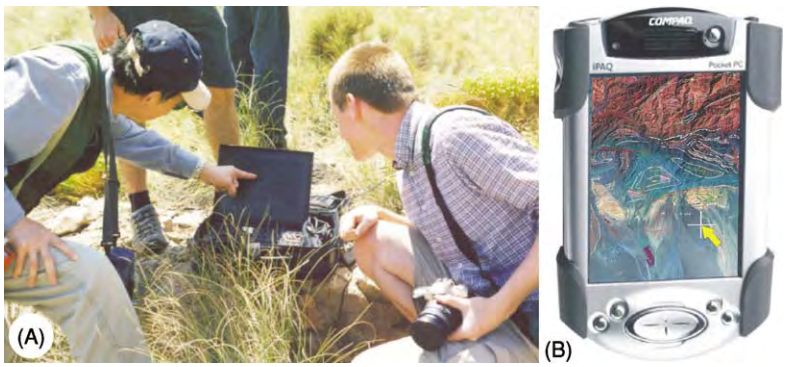

Figure 3 GIS in the field: (A) Staff and students record their observations on a digital map, in real time, using a GPS handset, GIS and laptop, during fieldwork in Spain; (B) Palm top computer, displaying a geo referenced Landsat 7 satellite image being used as a base map, within GIS, for field geological mapping.

GIS. They form ideal basemaps and provide hard evidence of Earth surface features and changes.

Natural Resources

A necessary and important area of growth for GIS is the promotion and employment of GIS in developing countries for the management of all natural resources. One of the most important global challenges, which will affect both developed and developing worlds, is water resource management. GIS can be used for almost all applications related to water resource management, such as groundwater targeting, resource estimation, and groundwater recharge estimation. Groundwater risk assessment can also be carried out; GIS enables mapping and analysis of contaminant plumes (caused by oil, chemical, and radioactive pollutants, for example), ground water vulnerability assessment, and environmental impact evaluation. The United States Geological Survey provides useful web based information on water resources and hydrological data (http://water.usgs.gov/maps.html).

Exploration and Production

The identification of potential new exploration targets is vital for exploration mapping and management and the use of GIS in mineral and petroleum exploration is now widespread. One of GIS's most useful contributions in this context is the capacity for integration of disparate digital datasets into a single database. All available data, geological, geochemical, and geophysical, can be compiled, analysed, and interpreted, to produce exploration potential maps and images (such as in **Figure 4**).

In quantifying prospectivity, through spatial analysis, the development of an analytical model is as important as the quality of the data; identifying significant factors, evaluating their significance, and establishing relevant weights for the layers used in the model are all fundamental considerations. The resultant prospectivity map reflects the depth and accuracy of the input information, the relevance of the model, and the geoscientists experience and local knowledge.

Environment and Geohazards

Environmental Quality

All aspects of environmental monitoring and management are particularly suited to the application of GIS. Using digital terrain models, geochemical and hydrological data, pathways for pollutants can be assessed and the probability of contamination calculated for areas where no sampling has been performed. The Interdepartmental Committee on the Redevelopment of Contaminated Land (ICRCL) publishes guidelines and trigger concentration values, based on appropriate usage in, for example, the UK, on the Internet (http://www.contaminatedland.co.uk/std-guid/icrcl-l.htm). Such values provide an ideal starting point for establishing 'decision rules' within the GIS model. Analytical tools, found in any GIS, enable generation of basic mapping, site selection, and advanced spatial analysis for environmental impact assessments, environmental audits and risk assessment, in addition to soil and groundwater investigation, remediation, and quality control.

Geohazards

The term geohazard is used in reference to those potentially dangerous phenomena that are caused by natural, geological processes, such as landslides, ground subsidence earthquakes, and volcanic eruptions. GIS has an important role to play in understanding and quantifying the spatial variability of the phenomena, in predicting its future behaviour,

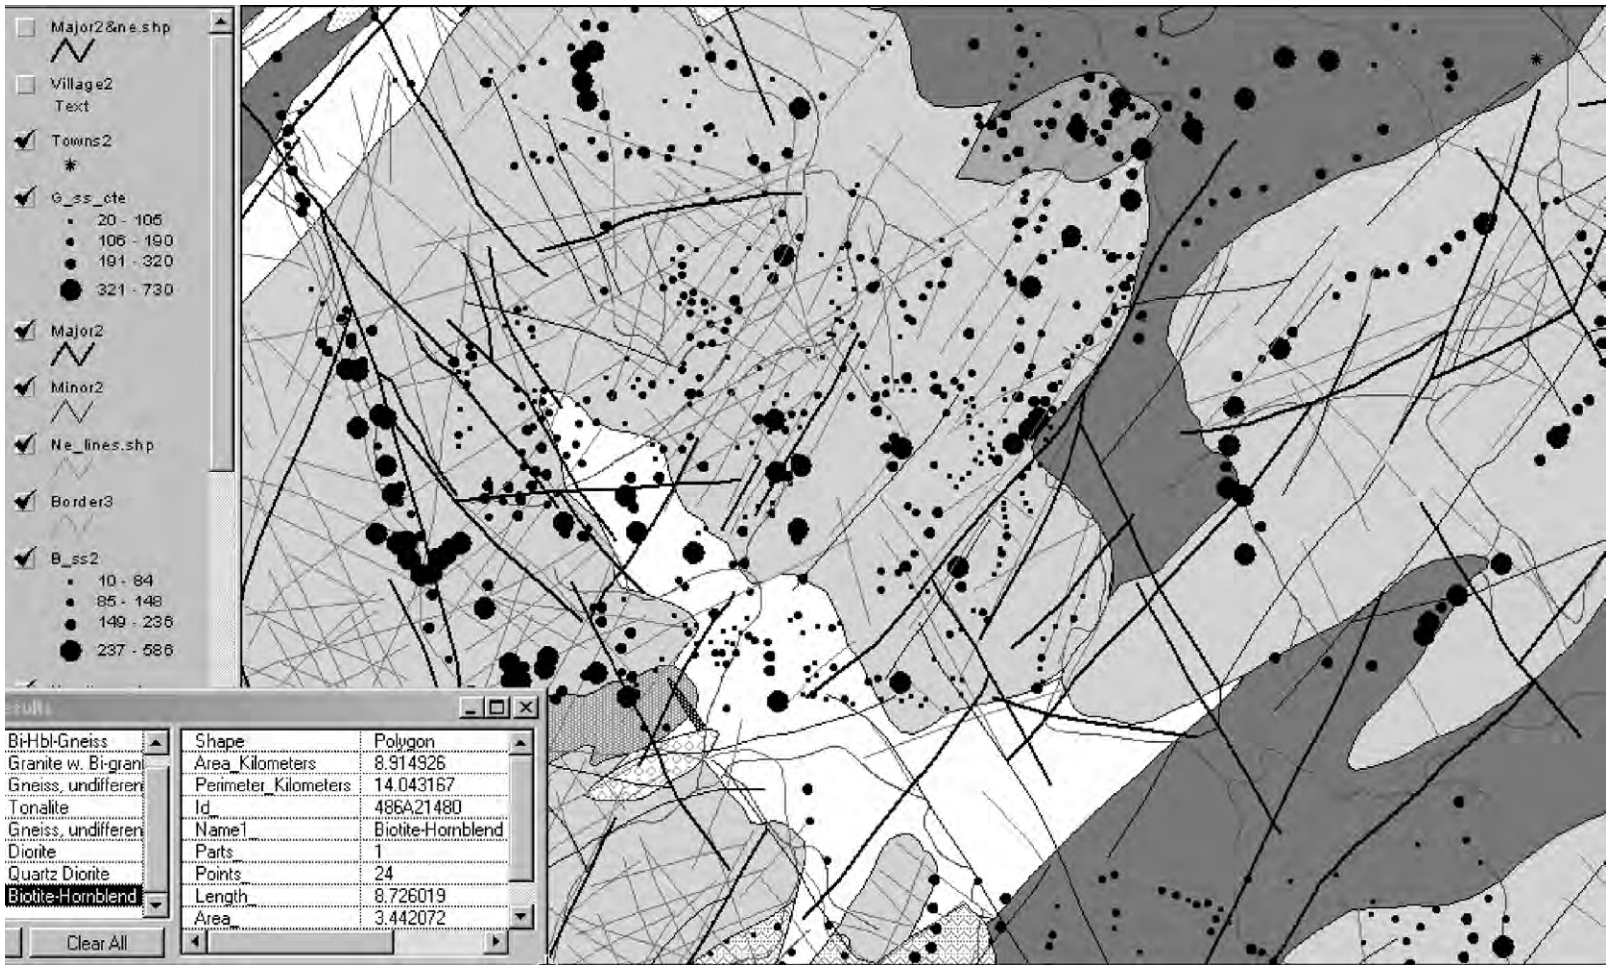

Figure 4 Display of vector polygon (lithological), line (structural features) and point (geochemical sample) data in an exploration GIS database.

and frequently in helping to identify appropriate remediatory activities.

The Integrated Global Observing Strategy (IGOS) is a strategic partnership linking research, and long-term monitoring and management with data users and suppliers, for global environmental observations of the atmosphere, oceans, and land. Its themes include all the main geohazards (earthquakes, volcanoes, subsidence, and landslides) and one of its key objectives is "to develop and integrate Earth observation data, *in-situ* spatial data organisation, spatio-temporal data modelling and analysis, using GIS, for a global, integrated geohazard monitoring system". Information about IGOS, its contributing partners and its goals, can be found on its website at http://www.igospartners.org.

Landslides Landslide hazard assessment involves the classification of the land surface into areas according to the degree of potential hazard posed by mass movements; an example of a landslide hazard assessment map is shown in Figure 5. Many methods and techniques have been proposed and used to quantify causative factors and GIS is commonly used to produce maps representing the probability of occurrences, on the basis of occurrences in the past. This 'direct' method of hazard assessment consists of geomorphological mapping of past and present landslides, and identification of factors leading to instability. GIS is then used for classification, or zonation, to reveal sites where future failures are most probable. The alternative 'indirect' method includes two different approaches, namely the didactic or statistical (data driven) and heuristic (knowledge driven) techniques. The didactic approach involves construction of an abstract model and proposal of hypotheses, followed by experiments and data collection, testing of the hypotheses and finally the construction of landslide instability rules. In the heuristic approach, landslide-influencing factors, such as slope angle, lithology, landform, and land-use, are ranked and weighted according to their expected significance in causing slope instability, and the success of the result is tested against known cases before rules are constructed (*see* **Sedimentary Processes:** Landslides).

Vulcanology GIS contributes many tools to manage field data (such as steam, water, and soil geochemistry), enabling patterns of output and geochemical changes to be identified effectively, and presented graphically. Another important role for GIS is in the modelling and prediction of the behaviour of ejected materials and mass movements after eruptions. Using a Digital Elevation Model (DEM) images, and maps, the existing topography can be analysed, enabling paths, discharge rates, and velocities of potential

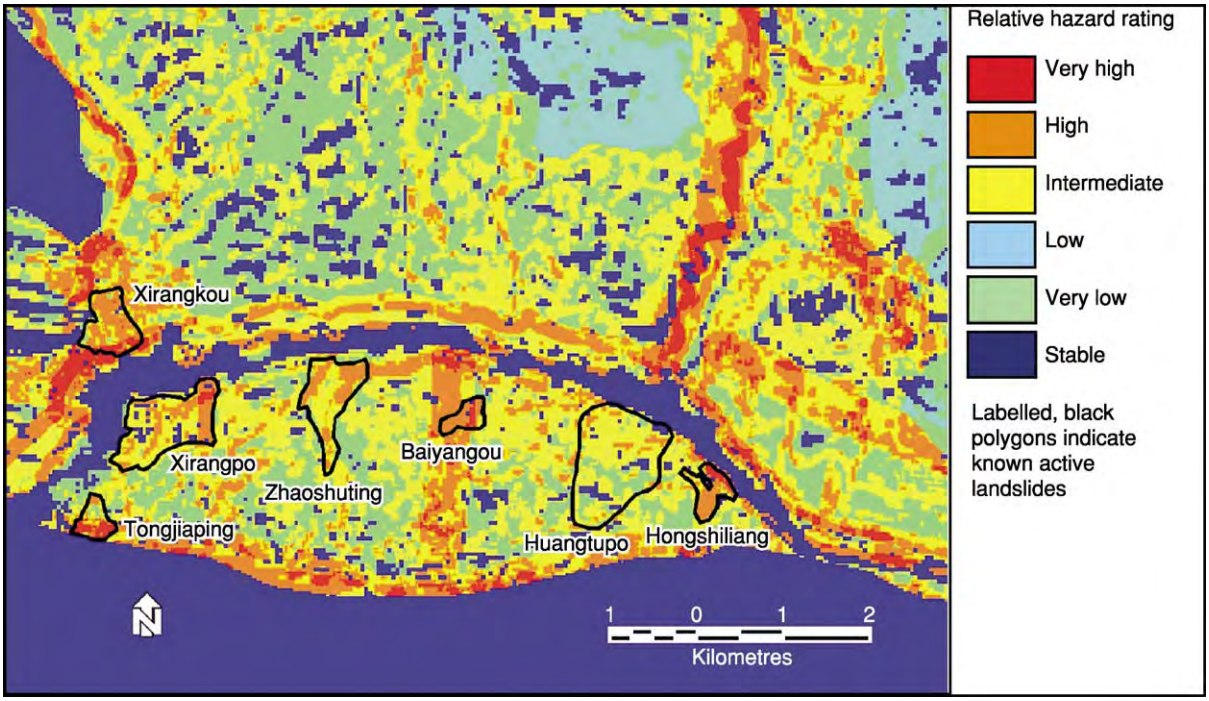

Figure 5 Map showing relative landslide hazard levels as derived from a multi criteria elimination and characterization model, of an area of the Three Gorges region in China. The locations of the landslides, which are known to be active in this area, are indicated by black polygons.

lahars and mudflows to be predicted. Pre- and post-eruption terrain modelling also allows the monitoring and detection of landform changes, and the preparation of susceptibility maps (*see* **Volcanoes**).

Earthquakes Seismic hazards caused by ground motion and failure are characterized by their spectral response, and by peak ground acceleration and velocity. The spatial distribution and patterns of ground motion can be determined using deterministic and probabilistic analysis within GIS. For an event of a certain magnitude, soil conditions and attenuation relationships can be used to predict the amount and distribution of ground shaking. Another significant role for GIS is the modelling and simulation of motion intensity and damage under various scenarios (*see* **Tectonics:** Earthquakes).

An example of the operational use of GIS in this field is the HAZUS programme (HAZards in the United States), under the control of the Federal Emergency Management Agency (FEMA), which has been developed to estimate losses caused by earthquakes, hurricane and wind erosion, and flooding. HAZUS takes the form of a software 'plugin' that exploits functionality within ArcView or MapInfo GIS packages. A new, HAZUS-MH (Multi-Hazard) version is due for release and more information can be obtained from http://www.hazus.org and http://www.fema.gov/hazus.

Tools for Spatial Analysis

Management, integration, manipulation, and visualization of high volumes of data require sophisticated tools for effective storage, interrogation, and analysis, to generate suitability maps based on a hypothesis. A GIS contains a variety of simple and complex tools for analysis of single data layers, pairs of layers, or multiple layers, enabling the extraction of a single composite result.

Individual Layers

Spatial analysis of individual maps and layers involves two-dimensional processing and geo-statistical methods, such as reclassification and thresholding, neighbourhood functions using spatial filters, distance, and buffer calculations, 2D spatial transformations and, importantly, gridding or interpolation.

Geo-statistical methods, involving the application of probabilistic methods to geographically related phenomena, can be used to highlight spatial correlation within a data layer. This idea is based on the assumption that points located close to one another, should also be close in value. Existing data are then used to interpolate into areas where no data exists.

Multiple Layers

Simple tools and processes can also be used effectively to manipulate a multisource, multilayer dataset, to produce a single, composite, and meaningful result. The term 'Map Algebra' is commonly used in reference to mathematical calculations carried out between two or more GIS layers, according to some expression, to produce a new layer. For example, to derive a map showing the depletion of an aquifer over a set period of time, layers representing groundwater levels as measured at set times are required. One layer is simply subtracted from the other to produce a layer representing the changes between the two dates (Figure 6). GIS enables the modification and classification of each layer and the combination of the modified layers, mathematically, to produce the final result. Through the combination of several, simple operations in this way, either collectively or in sequence, complex problems can be addressed using GIS.

Multicriteria Evaluation and Uncertainty

Multisource datasets are rarely complete and, in Earth sciences, are seldom defined by rigid, Boolean-type, observable boundaries. Uncertainties, arising from data and decision rules, are common. GIS provides a number of specialised, multicriteria, analytical tools to deal with these uncertainties, which draw on the principles of, for example, Bayesian probability and fuzzy logic.

Multicriteria evaluation is primarily concerned with the combination of multiple datasets to produce a single index of evaluation. In the simplest cases, such as those involving Boolean constraints, this combination can be achieved using union (logical OR) or intersection (logical AND) rules. For factors that display continuous variability, some form of ranking and weighting is required. As the criteria are measured and recorded on different scales, they also require standardization so that all factors are quantified on the same scale. It is also convenient if they are all positively correlated with 'suitability'. Deciding on ranking and weighting is the most difficult aspect, and it commonly requires discussion, field verification, and iterative modification, for which a common technique is the comparison matrix (illustrated in Table 1).

Quantifying uncertainty Ground truth data rarely provide pure examples of the classes they represent, and boundaries between one type of natural phenomenon and another are rarely crisp or clearly defined; there is usually a continuum between them. Modifications in the choice of function, and the replacement of 'hard' for 'soft' decision rules, are often

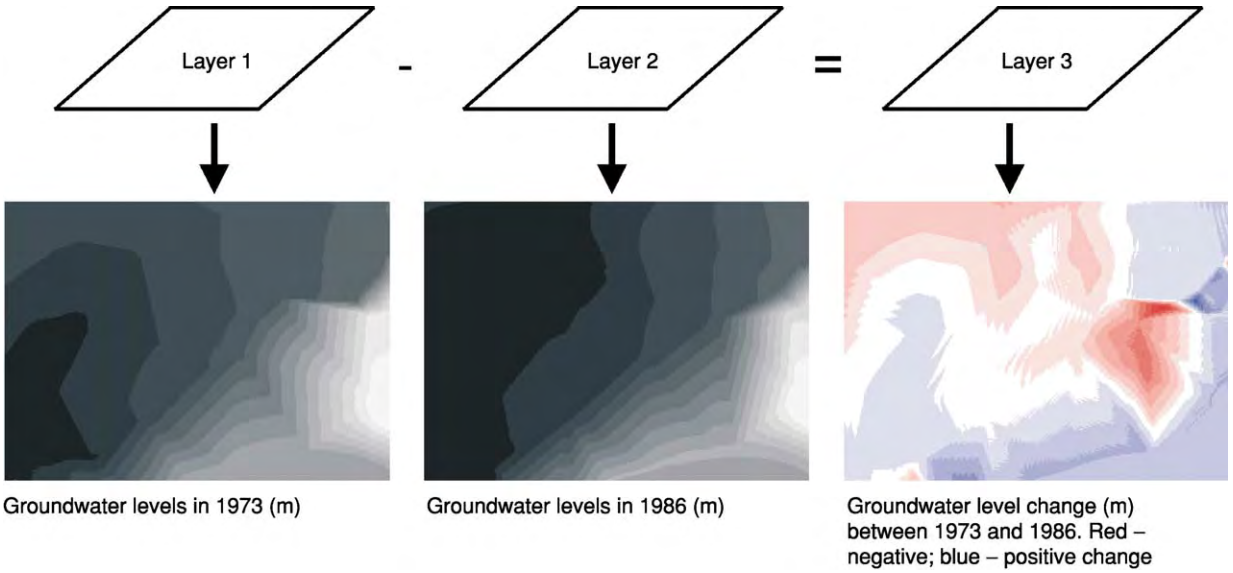

Figure 6 A simple map algebraic example, in which spatial changes in groundwater levels, over a fixed time period (between 1973 and 1986) are derived by layer subtraction.

Table 1 Example of a pairwise comparison matrix, used to assess relative factor significance and to calculate factor weights (for landslide hazard assessment in this case)

	Slope	*Aspect*	*FS*	*DEM*	*Distance (from roads)*	*Distance (from drainage)*	*Soil moisture*	*Iron oxides*	*Clay content*

necessary within the analysis. Bayesian probability theory, Dempster–Shafer theory, and fuzzy set membership are commonly used to incorporate uncertainty in GIS analysis in geological applications, for example, landslide hazard assessment and mineral prospectivity mapping.

Considerable research has been carried out into the extraction of mineral prospectivity maps from multisource datasets. In many cases, identification of the very lowest and very highest prospectivity has not been in dispute but uncertainty arises in definition of the regions of intermediate prospectivity, which then require further analysis and interpretation. Suitability or prospectivity must be treated as a continuous phenomenon representing a measure of confidence in the outcome.

A fuzzy set describes a continuous membership function where 0 represents a non-member and a value of 1 represents a member, and the values between them represent the increasing possibility of membership. The fuzzy set membership function can be most readily appreciated with reference to a simple linear function (Figure 7). The fuzzy function, may in fact be linear, sigmoidal or 'J' shaped, and monotonic or symmetric. The threshold values, which define it, will depend on the phenomenon and desired outcome

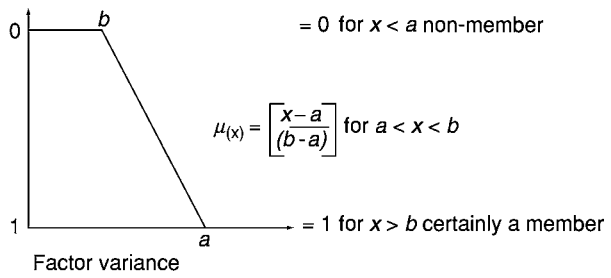

Figure 7 A simple, linear fuzzy set membership function, which can be used to standardize factors and to allow for a measure of uncertainty.

of the operation, i.e., the threshold values applied to each membership function reflect their influence on the result. The resultant fuzzy set layers can be combined in a number of ways, for example, using Boolean logic and fuzzy algebra or 'set theory'.

One novel technique, known as the Vectoral Fuzzy Logic method, produces two maps: one of calculated prospectivity and the other of confidence (represented by the similarity between the two inputs). Using the vectoral fuzzy logic method, null data and incomplete knowledge can be incorporated into the multicriterion analysis.

One of the most widely used statistical, multicriteria techniques is the Weights of Evidence Method. Here the quantitative spatial relationships between datasets representing significant criteria and known occurrences are analysed using Bayesian probability analysis. Predictor maps are used as input evidence and the end-products are maps representing the probability of occurrence of a phenomenon and of the uncertainty of those probability estimates.

The 'weighted linear factors in combination' method is also common, but can, in some instances, be considered too 'liberal' in its handling of the data in the system. Its factor aggregation method can be likened to a parallel connection system, which allows all input criteria to survive to the end. It is also possible that the relationships between the geological factors are not linear, in which case, a more complex model would be required. In many cases, this parallel system may be appropriate but in others a more strict system is required, which enables certain factors or combinations of factors to be eliminated completely from the system. A model based on the simple calculation of the geometric mean of scaled input factors (as opposed to arithmetic mean) can be thought of as a sequential connection system in which the occurrence of a zero rating, at a particular location, terminates the system and eliminates that location from the analysis. The method used to generate the landslide hazard map in **Figure 5**, incorporates this concept. Ideally, the method should incorporate both of these types of data treatment. Commonly the terms factor and 'constraint' are used to distinguish between information which is measured on a relative scale indicating a variable degree of likelihood, and that which is Boolean, respectively.

One difficulty with many of the approaches employed is the assumption that all factors contribute positively towards the suitability; consideration may also need to be given to evidence that appears contradictory. Dempster–Shafer theory provides a method of establishing suitability (or unsuitability) as well as a measure of plausibility for each hypothesis. Bayesian probability allows any new evidence to be incorporated, so updating the probability of suitability each time, but data are required for every possible occurrence, i.e., the absence of evidence is assumed to support the alternative hypothesis (unsuitability). The Dempster–Shafer method allows for 'Ignorance', i.e., the lack of evidence does not necessarily support the alternative hypothesis. A measure of plausibility (and of belief) is incorporated in the outcome. The theory recognizes a total of six concepts–Basic Probability Assignment, Ignorance, Belief, Disbelief, Plausibility, and a Belief Interval. Dempster–Shafer theory, therefore, provides a very useful basis for establishing the value of information and the design of further site investigation, including where new data would be most effective in further reducing the uncertainty.

Data Sharing and the Internet

The alliance between GIS and the Internet is both a natural and an extremely powerful one. Internet GIS databases allow access to vast resources of information, not only geological but also for public interest and attention. Database architectures and data formats, specially designed to be served through intranets and the Internet, enable huge volumes of information to be effectively served to computers anywhere.

Over the last few years, data compression software and specially designed internet servers have been developed, for example, Earth Resources Mapping's wavelet transform based data compression format (.ecw) and *Image Web Server*, which enables vast raster image datasets to be served and shared with incredible speed. Examples of the internet map data serving, through the use of intelligent databases and systems, include the NIMA Geospatial Engine (http://geoengine.nima.mil/), US based GIS Data Depot (http://data.geocomm.com/) and the British Geological Survey's Geoscience Data Index

Table 2 Commercially available GIS software suites, their manufacturers and application fields

Manfacturer	*Professional*	*Palmtop mapping*	*Internet mapping*	*Free viewer*
ESRI	ArcInfo, ArcGIS, & ArcView	ArcPAD	ArcIMS	ArcExplorer
Leica Geosystems	ERDAS Imagine		ESRI	Mapsheets Express
MapInfo	MapInfo	MapXtend	MapXtreme	ProViewer
Autodesk	AutoCAD/World	OnSite	MapGuide	AutoCad LT
Intergraph	GeoMedia & GeoMedia Pro	IntelliWhere	GeoMedia Web Map	GeoMedia Viewer

(http://www.bgs.ac.uk/geoindex/index.htm). These allow the user to search, view, and in the case of NIMA, actually download free any globally available geological, image, and map data (*see* **Geological Field Mapping**).

Software

The GIS software suites now commercially available provide a dazzling choice of functionality to suit all applications and budgets. The following table (Table 2) provides a brief overview of the main software products and their variants, as designed for different markets and applications.

Conclusions

GIS provides a very convenient framework for map-analysis and modelling functions which can be applied in many areas of the geosciences. It is expected that there will be continuing demand for GIS functionality to become faster, cheaper, and more complex, with continuing open standards. There will also be demand for the worlds national authorities to release more GIS data, free of charge, to the public. The vision of OGC is "a world in which everyone benefits from geographic information and services made available across any network, application or platform". Geoscience represents an expanding application area for GIS, both for research and commercial development.

A minor, but general, failing of standard GIS software functionality is its inability to properly deal with geological structures in three dimensions. There are, however, other software suites on the market, which are specially designed for this purpose and so the focus of GIS's contribution in geology lies in data integration, management, and spatial analysis.

There are more automated techniques for solving complex, spatial, multicriteria problems, such as neural networks and data mining, but these are in some respects at a disadvantage, compared with GIS, as they require very large and homogeneous datasets for training the systems. Data mining involves the development and use of effective tools for direct access and extraction of appropriate datasets and patterns from very large volume databases and represents a logical step in the evolution of effective data supply and analysis. Both data mining and neural networks have some overlap with GIS in functionality and objectives, and are anticipated to have some impact on GIS in the coming years. Commonly though, the geoscientist prefers a more intuitive, graphical, and less formal approach, so that even in complex analysis, interpretive skills are still important.

GIS owes its power and success to its flexibility and potential for cross-disciplinary application. GIS (and other related technologies) enable the analysis of vast and expanding datasets, allowing a better understanding of terrestrial and anthropogenic processes, the development of economic sustainability, and the improvement of environmental quality.

Passive Sensors

J G Liu, Imperial College London, London, UK

What is a Passive Sensor?

A sensor detects and quantitatively records the electromagnetic radiation (EMR) from an object as 'sensing'. For an object to be sensed, it must either reflect or transmit the radiation impinging on it from an illumination source or radiate its own energy. If a sensor provides its own illumination source it is an active sensor. Synthetic Aperture Radar (SAR) is a typical active sensor system as it sends microwave radiation pulses to illuminate the target area and receives the returned signals to produce an image. If the sensor depends on an independent illumination source, such as the Sun, or the radiation from the target itself, such as the Earth's thermal emission, it is a passive sensor. The most commonly used sensors for remote sensing systems are passive sensors, which are the topic of this article.

A passive sensor images the Earth by recording either the reflected solar radiation or the emitted radiation from the Earth. An ordinary camera is a typical passive sensor system. A daytime outdoor colour photograph taken by a camera is a record of reflected solar radiation in the visible spectral range from the scene that is illuminated by the Sun. A camera can become an active sensor when it is used with a flash light in darkness. In this case, the camera provides its own light source to illuminate the object and then takes a picture.

The Sun is the primary illumination source for the Earth. For Earth observation remote sensing, most passive sensor systems operate under solar illumination during daytime, ranging from aerial photography to satellite multispectral scanners. These sensors pick up the reflected solar energy from the land surface to produce panchromatic and multispectral images. The features in these images are mainly influenced by two types of information: spatial pattern (e.g., topography) and spectral signatures. Ignoring minor factors, we can present such an image as

$$M_r(\lambda) = \rho(\lambda)E(\lambda) \quad [1]$$

where $M_r(\lambda)$ is the reflected solar radiation of spectral length λ by the land surface, or an image of spectral band λ, $E(\lambda)$ is irradiance, the incident solar radiation energy upon the land surface, while $\rho(\lambda)$ is the reflectance of land surface at wavelength λ.

If solar illumination is constant, $E(\lambda)$ is effectively the topography, as it governs the geometry of a surface in relation to illumination. In general, considering solar radiation as a parallel radiation source illuminating the Earth, with constant incident radiant flux density M_s, then the solar irradiance upon the land surface, E, varies with the angle between the land surface and the incident solar radiation, γ. When the land surface is perpendicular to the incident solar radiation M_s, E is at its maximum and equal to M_s. If the solar radiation has an incident angle θ_1 (from nadir) and azimuth angle ϕ_1, then the irradiance upon a land surface with slope angle θ_2 and aspect direction ϕ_2 is determined by:

$$\begin{aligned} E &= M_s \sin\gamma \\ &= M_s[\sin\theta_1\sin\theta_2\cos(\phi_1 - \phi_2) + \cos\theta_1\cos\theta_2] \end{aligned} \quad [2]$$

The spectral reflectance, $\rho(\lambda)$, is a physical property, quantitatively describing the reflectivity of the exposed materials on the land surface at wavelength λ. The selective absorption and reflection of a material result in variation of spectral reflectanc across a sensor's spectral range, giving a unique signature for this substance. It is, therefore, possible to work out the land cover types or mineral compositions of the land surface based on spectral signatures using multispectral image data. Reflective spectral remote sensing is among the most effective technologies to study the Earth surface composition and has become an essential tool for geological mapping.

A thermal sensor is also a passive sensor but the energy that a thermal sensor detects is radiation emitted from the Earth's surface, rather than reflection. Thermal sensing does not need an illumination source as the target itself is the illumination source. The Earth's surface can be approximated as a black body of 30 K and using Wien's law, we can calculate that the radiation peak of the Earth is at about 10 μm. In this spectral range, the radiation can be sensed and measured by temperature, rather than brightness, as measured for the visible spectral range; it is, therefore, called thermal sensing. Different materials on the land surface have different thermal radiation properties; thermal sensors are, therefore, useful tools for geological and environmental studies.

According to Wien's law, the higher the temperature of an object, the shorter the wavelength of its radiation peak. Thus, passive sensors designed for shorter wavelengths, though usually used to detect reflected solar radiation from the land surface, can also be used for detecting emitted energy from targets as long as the temperature of these targets is high enough. For instance, Landsat Thematic Mapper (TM) shortwave infrared band 5 (1.55–1.75 μm) and band 7 (2.08–2.35 μm) are far more effective to map fires on a land surface than the thermal band.

The land surface is also an effective radiator at microwave range, though the microwave emission is significantly weaker than thermal emission. As another type of passive sensor, radiometers are designed to image the emitted radiation from the Earth's surface at this spectral range.

For geological studies, the most effective passive sensor systems are of medium to high spatial resolutions with image pixel size ranging from a few to a few hundred metres and are often called Earth observation systems. The following sections use the most common Earth observation systems as examples for further discussion of passive sensors.

Passive Sensor Imaging Technology

With a few exceptions, most passive sensor systems are essentially an optical camera system. As shown in Figure 1, the incoming energy to the sensor system goes through an optical lens and is focused onto the rear focal plane of the lens where the energy is recorded by a sensor device of radiation sensitive media, such as film or CCD (Charged Coupled Device).

Aerial photography, using a large format camera, was the earliest operational remote sensing technology for topographic survey as well as for geological investigation. The space-borne remote sensing for Earth observation began with Landsat-1 with a MSS (Multi-spectral Scanner) and RBV (Return Beam Vidicon) on board, launched on 23 July 1972. This and subsequent landsat instruments collect, record, and transmit electronically to ground stations, images of the Earth. The images are then distributed to users in a digital format as digital imagery data. The concept and technology of digital imagery gave birth to satellite remote sensing. An Earth observation satellite images the Earth's surface continuously from its orbit and sends the images back electronically to the receiving stations on the ground.

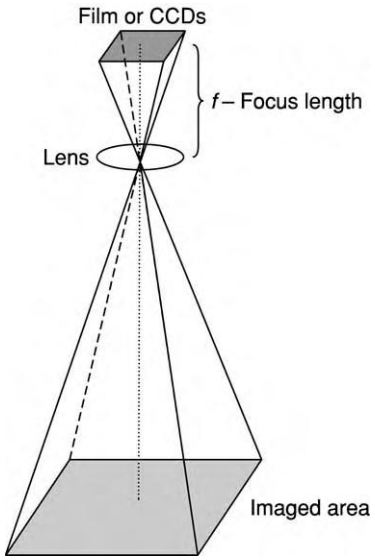

Figure 1 Basic structure of an optical sensor system.

The development of sensor technology is mainly focused on improving the spatial and spectral resolution. For a given sensor system, its spatial resolution is dictated by the minimal energy level of electromagnetic radiation (EMR) that can make a signal distinguishable from the electronic background noise, i.e., dark current, of the instrument. This minimal energy of EMR is proportional to the product of radiation intensity over a spectral range, IFOV (Instant Field Of View), and dwelling time.

The IFOV (Figure 2) is decided by spatial sample density of an optical sensor system and determines the pixel size of the image. For a given dwelling time (equivalent to exposure time) and spectral range, the larger the IFOV, the more energy will be received by the sensor, but the lower the spatial resolution. To improve the spatial resolution, IFOV needs to be reduced while maintaining the same energy level; either dwelling time or spectral range, or both have to be increased. When a sensor, which has its dwelling time fixed by the sensor design and platform orbit parameters, receives the reflected solar radiation from the Earth, it may record the energy in a broad spectral range as a single image. This generates a

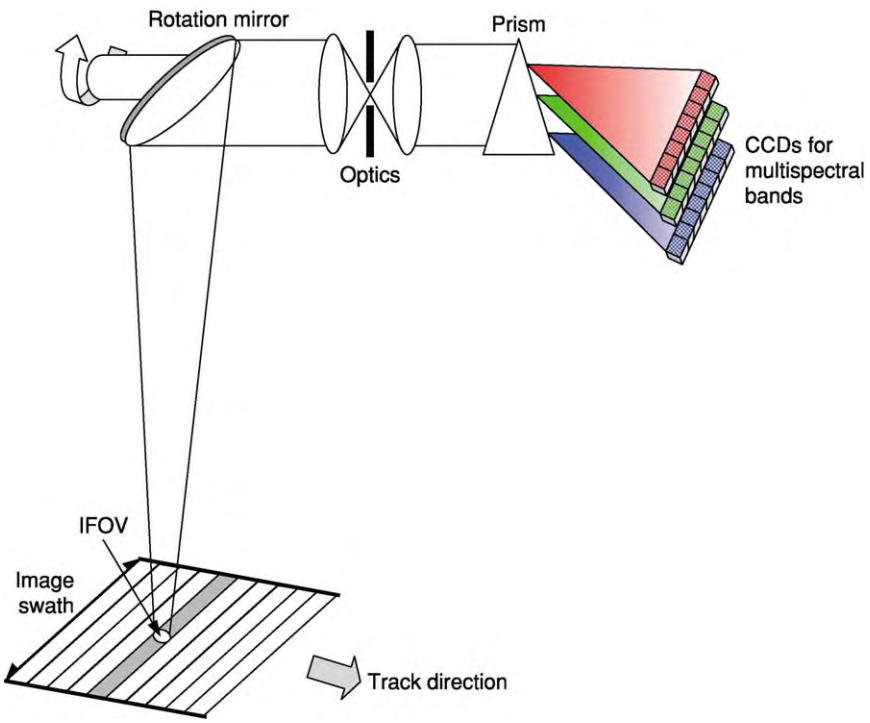

Figure 2 A schematic diagram of an across track mechanical multispectral scanner.

panchromatic image at a relatively high resolution. It may also split the light into several spectral bands and record them separately into several images of narrower spectral range: the multispectral images. In this case, the energy that reaches the CCDs of each narrow spectral range is significantly weaker than in the panchromatic mode. To achieve the same energy level, the only solution is to increase the size of IFOV, or reduce spatial resolution. This is the reason that nearly all the optical imaging systems achieve higher resolution in a panchromatic band than in multispectral bands (Tables 1 and 2). For instance, SPOT 1–3 HRV (High Resolution Visible) Panchromatic bands have 10 m resolution while its XS (multispectral) bands have 20 m resolution.

There is another way to improve the spatial resolution for both panchromatic and multispectral imagery; by increasing the dwelling (exposure) time. This has been an important consideration in sensor design, although the capacity for increasing the dwelling time is limited; for both airborne and space-borne remote sensing, the image is taken from a moving object and so a long exposure time will blur the image.

Across-Track Mechanical Scanner

The early design of space-borne passive sensor systems was constrained by the technology of the key sensor unit: the CCD. In many systems, a mechanical scanner has been an ideal solution to achieve multispectral imaging at relatively high resolution. Such scanners are based on a simple mechanical device using a few CCDs. Figure 2 is a schematic diagram of the principle of an across-track, mechanical multi-spectral scanner. The optical part of a scanner is essentially a camera but the image is formulated pixel by pixel, scanned across track by a rotating mirror, and line by line, as the platform (aircraft or satellite) flies along track over an area. The range of a scan line is called the swath. The light reflected from the land surface reaches the rotating mirror, which rotates at a designed speed and thus views different positions on the ground across a swath during a rotation scan cycle. The rotating mirror diverts the incident light through the scanner optics and then the light is dispersed into several spectral beams by a spectral splitting device (a prism or interference filters). The multispectral beams are then received by a group of CCDs which sample the light at regular time intervals. When the scanner finishes scanning one swath, the satellite or aircraft has moved forward along its track to the position for the next scan. One scan swath can be a single image line or several image lines depending on the sensor design and the synchronisation between flying speed, swath width, altitude of the satellite or aircraft, and required image resolution. In this way, a scanner can image a large area using a limited number of CCDs. A scanner, though mechanically complicated, relies less on CCD technology.

The MSS with 4 spectral bands on board Landsat 1–3 is a classical example of a mechanical scanner. It is a one-way scanner that scans in one direction of mirror rotation only, and with an empty return run. Such a design makes compensation of the Earth's rotation easier, as the Earth rotates a fixed distance along the swath direction for each scanning cycle. However, the inactive return would waste valuable time for imaging, resulting in a shorter dwelling time in the active runs and thus reduce spatial resolution.

The Thematic Mapper (TM) on board of Landsat 4–7 is a significantly improved scanner with six reflective spectral bands and one thermal band (Table 1). It is a two-way scanner that scans in both directions. For the same width of swath, the two-way scan allows the mirror to rotate slower than a one-way scan, thus increasing the dwelling time of CCDs at each sample position. This configuration improves both spatial and spectral resolutions. The geometric correction, to compensate for Earth rotation effects, is more complicated for TM than for MSS, however, because one scan direction is for, and the other, against the Earth's rotation, respectively.

Along-Track Push-Broom Scanner

With the rapid development of CCD technology, a more advanced scanner, the so-called 'push-broom scanner', has become dominant in passive sensor design since the successful launch of SPOT-1 in 1986. As shown in Figure 3, the key difference between a push-broom scanner and a mechanical scanner is that a push-broom scanner does not have a mechanical mirror for pixel-by-pixel scanning across along the swath direction. In a push-broom scanner, a line array panel of CCDs, covering the whole imaging swath, is mounted at the rear of the spectral dispersal device. Push-broom scanner images an area line by line across the whole track when the sensor platform (a satellite or an aircraft) flies along track, like pushing a broom forward to sweep a floor.

Since one image swath is generated simultaneously, the dwelling time for each CCD representing an image pixel can be as long as a whole swath scanning time for a mechanical scanner. With significantly increased dwelling time, a push-broom scanner achieves much higher resolution. Based on advanced CCD technology, the push-broom scanner is simpler than the mechanical scanner in structure, and the geometric correction is less complicated. Without a mechanical part, the system is robust and reliable. The number of CCDs in a line array in swath direction decides the size and the resolution of the imagery data generated. For instance, the SPOT HRV has 6000 CCDs per line for its panchromatic band while 3000 CCDs per line for its multispectral bands. The system, therefore, produces panchromatic images with 6000 pixels per line at 10 m resolution and multispectral images with 3000 pixels per line at 20 m resolution.

The push-broom design also allows greater flexibility to manoeuvre the sensor to point to off-nadir positions. As shown in the Figure 3, a mirror is fixed in front of the lens like a mechanical scanner. This mirror is not for scanning; it has several fixed angle positions. At different angles, the mirror directs the sensor system to view and image different scenes off-nadir along the track.

Digital Cameras

In the last few years, digital cameras have started to compete in the market of traditional film photog-

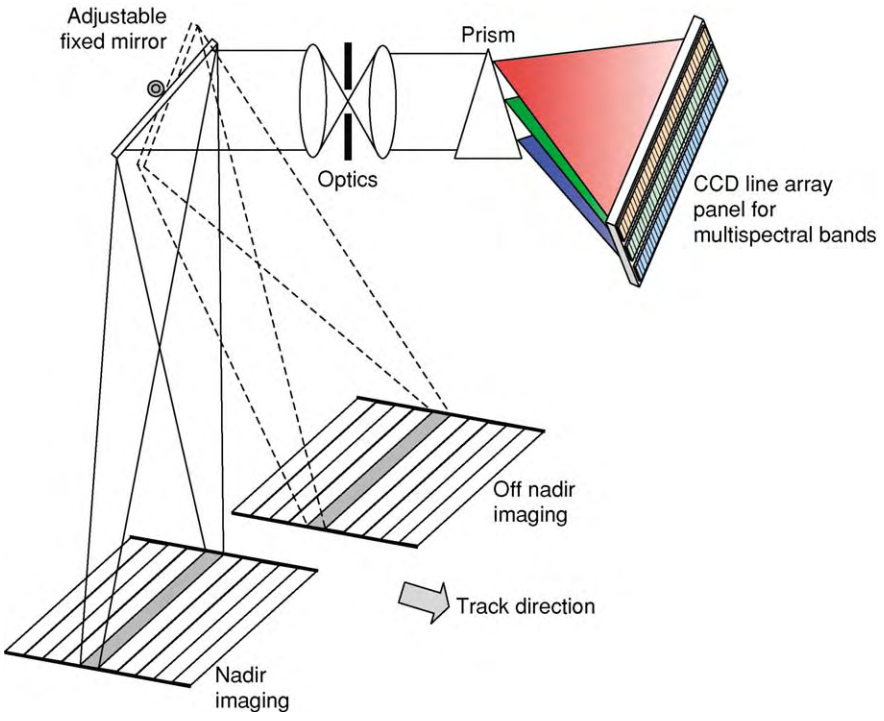

Figure 3 A schematic diagram of an along track push broom multispectral scanner.

raphy. A digital camera is built on a full 2D (two dimensional) CCD panel. The only difference between a digital camera and a film camera is that it records an image through a 2D CCD panel to a memory chip instead of using a film. The new generation of passive sensors will be largely based on digital camera technology that takes an image by an instantaneous frame rather than scanning line by line. The consequence is that the constraints on platform flight parameters can be relaxed, image resolution (spatial and spectral) can be improved, and image geometric correction processing can be further streamlined.

Broadband Reflective Multispectral Imagery

Broadband reflective multispectral sensors and thermal sensors are addressed separately being based on different physics. In practice, however, these two groups of passive sensors are often mounted in the same instrument as different bands. This is true for many sensor systems, such as TM, Enhanced Thematic Mapper Plus (ETM+), and ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) (Table 1), used for geological applications.

Broadband reflective multispectral image data are the most widely used for geological studies and regarded as an effective operational tool for mapping tectonic structures and lithology, for mineral exploration, for logistic planning, and for field survey navigation. Extending the scope of applications from Earth observation to planetary study, this group of sensors are often the major tools for data collection from other planets. A typical example is the exploration of Mars.

The American Landsat satellite family TM, ETM+, and French SPOT (Système Pour 1'Observation de la Terre) satellite family high resolution visible (HRV) are the most commonly used Earth observation systems, providing broadband multispectral and panchromatic imagery data of global coverage. As shown in Table 1, these types of sensor systems operate in: the visible spectral range with bands equivalent to three primary colours; blue (380–440 nm), green (440–600 nm), and red (600–750 nm); the near infrared (NIR) range (750–1100 nm), and the short wave infrared (SWIR) range (1550–2400 nm). The number of bands and the spectral width in VNIR (visible near infrared) and SWIR spectral ranges depend on the atmospheric windows and sensor design. For instance, the spectral width of SWIR bands needs to be much wider than visible bands if the same spatial resolution is to be achieved, as is the case for TM bands 5 and 7, because the solar radiation in the SWIR spectral region is significantly weaker than that in the visible spectral range.

In general, the 'broad' band means that the spectral range is significantly wider than a few nanometres, except in the case of hyperspectral sensor systems described below. Broadband reflective multispectral sensor systems are a successful compromise between spatial resolution and spectral resolution. With relatively broad spectral bands, such a sensor system offers reasonable spatial resolution with high SNR (Signal Noise Ratio) and meanwhile, operating in a wide spectral range from VNIR to SWIR, such a system can provide images of multispectral bands, enabling identification of major ground objects and discrimination of various land cover types. With the dramatic improvement of sensor technology, from mechanical scanners to push-broom scanners, and to CCD digital cameras, the spatial resolution of broadband multispectral imagery is improving all the time. For Sun synchronous near polar orbit satellites, the spatial resolution of this type of sensors has been improved from 80 m (Landsat MSS) in the 1970s to a few metres, on current systems, as shown by the examples in Table 2.

The VNIR spectral range is used by nearly all broadband reflective multispectral sensor systems. This spectral range is within the solar radiation peak and thus allows the generation of high resolution and high SNR images. It also covers diagnostic features of major ground objects such as the few examples below:

- *Vegetation*: minor reflection peak in green, absorption in red, and then significant reflection peak in NIR, often called the 'red edge'.
- *Water*: strong diffusion and penetration in blue and green, and nearly complete absorption in NIR.
- *Iron oxide (red soils, gossans, etc.)*: absorption in blue and high reflectance in red.

Many satellite sensor systems did not use the blue band, in order to avoid strong Rayleigh scattering effects occurring in the atmosphere that can make an image 'hazy'. A popular configuration is to offer three broad spectral bands in green, red, and NIR, such as the case of SPOT and the most recent commercial high spatial resolution space-borne sensors (Tables 1 and 2). In a computer graphic system, we can display the three band images as a colour composite with NIR displayed in red, red in green, and green in blue. Such a colour composite image is called a standard false colour composite. This image is the most effective for mapping healthy vegetation.

The SWIR spectral range is regarded as the most effective for lithological mapping and mineral exploration, because most rock types have high reflectance in 1.55–1.75 μm and clay minerals (often products of

alteration) related to mineralisation, have various absorption features in the spectral range 2.0–2.4 μm. These two SWIR spectral ranges, corresponding to Landsat TM band 5 and 7, are preferred by geologists. SWIR sensor systems are technically more difficult and complicated because the SWIR detectors have to operate at low temperatures, which therefore require a cooling system (a liquid nitrogen coolant or a cryocooler) to maintain the detectors at about 80 K.

With six broad reflective spectral bands, Landsat TM provided the best spectral resolution among broadband sensor systems for many years. The six broad reflective spectral bands are very effective for discrimination of various ground objects but they are not adequate to achieve specific identification in particular rock types and major mineral assemblies relating to mineral deposits. This requires a sensor system with much higher spectral resolution at a few nanometre bandwidth to resolve their subtle spectral signatures. This demand has led to the development of the hyperspectral system.

ASTER (a push-broom scanner for VNIR and SWIR bands), on board the Terra-1 satellite, is a representative of a transitional sensor system between broadband multispectral and hyper-spectral narrowband sensing. It is an integrated system of three scanners: a VNIR push-broom scanner with three broad spectral bands; a SWIR push-broom scanner with six narrow spectral bands; and a TIR across-track mechanical scanner with five thermal bands (Table 1). The system combines good spatial resolution in the VNIR bands and high spectral resolution in SWIR and thermal bands and was specifically designed for geological applications. The three 15 m resolution VNIR bands are adequate for distinguishing broad categories of land cover such as vegetation, water, red soils, urban areas, superficial deposits, and rock outcrops, while the six narrow SWIR bands of 30 m resolution provide potential for mapping major mineral assemblies of rock types and alterations. Another unique advantage of ASTER is that it has along track stereo capability. The VNIR scanner has a backward viewing telescope to take NIR images beside its nadir telescope for the three VNIR bands. Thus nadir and backward viewing NIR images are taken simultaneously, forming along track stereo image pairs. The along track stereo image pairs enable generation of DEM (Digital Elevation Model) data.

Thermal Infrared (TIR) Sensors

Various minerals, rock types, and other ground objects have different thermal properties, such as thermal inertia, thermal emission, and thermal absorption. For instance, quartz has distinctive high emissivity around 9 μm and strong absorption in 10–11 μm; dolomite can be distinguished from limestone by its significant lower emissivity in 8–11 μm.

There are several airborne thermal IR sensor systems for example, the Thermal Infrared Multispectral Scanner (TIMS) with 6 bands in the 8.2–12.2 μm spectral region developed in 1982. Of the satellite systems, the Landsat Thematic Mapper system has a broad thermal band, TM band 6, at a wavelength range of 10.4–12.5 μm. So far the only space-borne multispectral thermal system is ASTER on board of Terra-1 satellite, which has 5 thermal bands as shown in Table 1.

In general, a broadband TIR sensor operating in the 8–14 μm spectral range images the radiation temperature of the land surface while the narrower band of the multispectral thermal imagery data detect the thermal spectral signatures of materials on the land surface. It is important to note that daytime thermal images are fundamentally different from the night time thermal images. Daytime thermal images are dominated by topographic features, governed by the geometry between slopes and solar radiation described previously, while night time thermal images are solely determined by emission from the Earth surface. They therefore detect the thermal properties of ground materials more efficiently.

For both systems, TM and ASTER, the spatial resolutions of their thermal bands are significantly lower than their reflective multispectral bands, as shown in Table 1. One reason is that the interaction between thermal energy (or heat) and the atmosphere is more complicated than the case of VNIR and SWIR energy. Heat can be transmitted in air, not only by radiation, but also by air circulation. Both solar radiation to the Earth in TIR spectral range and direct thermal emission from the Earth are very weak, compared with the energy intensity of the Earth reflected solar radiation in the VNIR and SWIR spectral ranges.

Most thermal sensors are of cross-track mechanical scanner type, as shown in Figure 4. The major difference of a thermal scanner from a reflective multispectral scanner is that it needs a cooler system to maintain the TIR detector at very low temperature for maximum sensitivity. For instance, the thermal sensor of Landsat Thematic Mapper is surrounded by liquid nitrogen at 77 K stored in an insulated vessel. In the ASTER system, a cryocooler is used to maintain the detectors for TIR bands at 80 K. A blackbody plate is used as an on-board calibration reference that is viewed before and after each scan cycle, providing estimation of instrument drift. This is essential to maintain the accuracy and consistency of a TIR instrument. The temperature sensitivity of a modern TIR sensor system can be as high as 0.1 K.

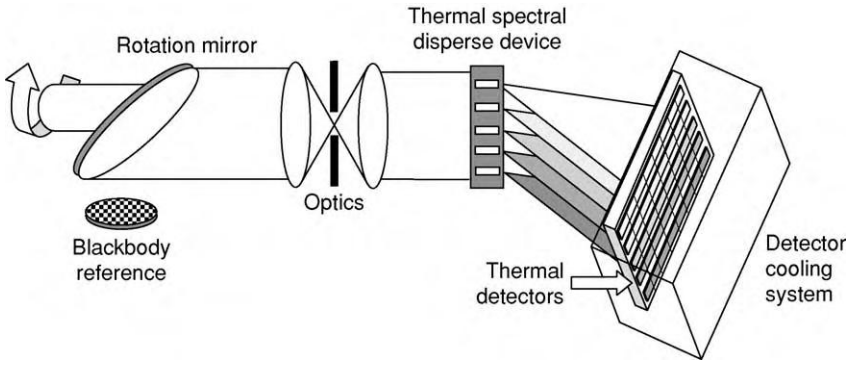

Figure 4 A schematic diagram of a thermal scanner.

To fully represent the sensitivity, many thermal IR sensors use 10–12 bit quantisation to record data, for example, ASTER multispectral thermal band images are 12 bit integer data.

Hyper-Spectral Sensors (Imaging Spectrometers)

The development of passive sensor technology is always aimed at higher spatial and spectral resolutions. Hyperspectral sensor systems represent a revolutionary development increasing passive sensor spectral resolution to as high as a few nanometres. This means that they are capable of generating nearly continuous spectral profiles for land surface materials. A hyperspectral sensor system is an imaging spectrometer. It combines the spatial imaging capacity of an imaging system with the spectral analytical capabilities of a spectrometer. Such a sensor system may have up to several hundreds narrow spectral bands with spectral resolution on the order of 10 nm or narrower. Imaging spectrometers produce a complete spectrum for every pixel in the image. The resulting dataset allows identification of materials rather than mere discrimination as with broadband sensor systems. The data processing methodology and strategy are, therefore, different from that employed for broadband images in many aspects. It is more important to analyse the spectral signature for each pixel, rather than to perform general image enhancement to improve visualization, though the latter is still essential for data overview.

One of the earliest and the most representative hyper-spectral systems is JPL's Advanced Visible Infrared Image Spectrometer (AVIRIS) (Table 3). Figure 5 shows the general principle of hyperspectral systems. The incoming EMR from the land surface goes through the sensor optics and is then split into hundreds (e.g., 224 for AVIRIS) of very narrow spectral beams by a complicated spectral dispersion device (e.g., interference filters) and finally the spectral beams are detected by arrays of CCDs corresponding to, say 224, spectral bands. A hyperspectral system can be either an across-track mechanical scanner with a small number of detectors for each band, or an along-track push-broom scanner with a panel of hundreds of line arrays of CCDs. Hyperspectral sensors are so far operating in either VNIR only or VNIR and SWIR spectral ranges (Table 3), although a similar evolution is taking place in TIR systems.

There is only one experimental, space-borne hyperspectral sensor, Hyperion. Several satellites with a hyperspectral system on board have failed, for various reasons, before the sensor system even started to operate (Table 2). Nevertheless, with the success of several airborne hyperspectral systems (Table 3), it is only a matter of time and money before hyperspectral satellite system become operational.

Table 3 Some airborne Hyper spectral sensors

Passive Microwave Sensors

Thermal radiation from natural surfaces, such as the land surface, extends from its peak in the thermal infrared region into the microwave region. An Earth observation microwave imagining radiometer operates in this spectral region to receive the microwave radiation from the Earth. As a passive sensor system, it is important to understand that a microwave radiometer is fundamentally different from a radar sensor, that is a ranging system. The only resemblance between the two is that they both operate in the microwave spectral range. A passive microwave sensor system, a microwave imaging radiometer, works more like a thermal sensor system. It collects emitted energy radiated from the Earth in the microwave spectral range that provides useful information relating to surface temperature, topography, and material dielectric properties. This type of sensor has been used for global temperature mapping, polar ice mapping, and regional soil moisture monitoring.

A space-borne microwave imaging radiometer is often a multichannel scanner, such as the SMMR (Scanning Multichannel Microwave Radiometer), which was on board of Seasat and Nimbus in 1978 and the Microwave Imager on board the Tropical Rainfall Measuring Mission (TRMM) satellite in 1997. It is composed of an antenna together with its scanning mechanism, a receiver, and a data handling system. The received emitted microwave signals are highly related to the observation angle and the path length in the atmosphere. Ensuring that these scanning parameters are constant, thus they can significantly increase the accuracy of the derivation of surface parameters from the microwave brightness temperature. A conical scan configuration is, therefore, popular for passive microwave scanners. As shown in Figure 6, the antenna observation direction is offset at a fixed angle from a nadir rotating scan around the vertical (nadir) axis and thus sweeps the surface of a cone. If the scan is configured for a full 360°, double coverage fore and aft of the spacecraft is obtained. With the moving forward of a satellite along its orbit, a belt of land surface is imaged. Obviously, in a conical scanning geometry, the observation angle and distance to any scanned position are constants.

Space-borne passive microwave scanners are usually of low spatial resolution from several kilometres to several tens of kilometres, because of weak signals in the microwave spectral range.

ROCK MECHANICS

JP Harrison, Imperial College London, London, UK

Introduction

Although rock has been used as an engineering material since time immemorial, rock mechanics as a specialist engineering discipline has existed only since about the middle of the twentieth century. The particular engineering endeavours in which rock mechanics is used run from traditional applications such as mining and tunnelling, through more modern applications such as large underground caverns for various civilian uses (e.g., fuel storage and transport infrastructure), to deep wellbores for petroleum extraction, and on to novel issues such as underground disposal of nuclear waste. There is also a growing realization that the principles of rock mechanics as used by engineers are applicable to problems in geological science, such as fault movement, seismicity, and plate tectonics. So, techniques that have their origin in engineering are more and more being applied to problems such as the stability of natural slopes, fracture development in extensional basins, and fluid flow through deforming rock.

Rock mechanics arose, and continues to develop, because, as far as engineers are concerned, rock is an awkward material. By this is meant that it is not like the usual well-specified and controlled engineering materials of steel, concrete, or polymers. Its natural basis means that it is likely to be variable in its character and to contain features that are weak; both of these properties present particular difficulties to an engineer. Thus, rock mechanics as an engineering discipline is concerned with the development of an understanding of rock as an engineering material, such that safe and economic design approaches can be identified. Generally, the geology of a particular rock is of secondary importance in rock mechanics: it is the behaviour of the rock, rather than its geological characteristics, that is of principal interest to the engineer. Notwithstanding this, an understanding of the geological setting of a rock is useful in rock mechanics, because a range of geological processes (e.g., the development of schistosity, or the form of a weathering profile) can impact greatly on the behaviour of rock as an engineering material.

It is now recognized that a key issue in understanding and applying rock mechanics is that, on the scale of most engineering projects, rock is fractured. As a result, rock often cannot be considered as a continuum, and a rational approach for dealing with the resulting discontinuum is to consider rock mechanics as a subject that comprises a number of clearly defined topics. To help understand the subject, these topics can be placed into three major categories: (1) the basic components of *in situ* stress, and the physical characteristics and behaviour of both fractures and intact rock; (2) rock masses as an amalgamation of these components; and (3) the interaction between rock engineering activities and rock masses.

The Basic Components: *In Situ* Stress, Fractures, and Intact Rock

The Earth's crust is almost everywhere subjected to a non-zero state of *in situ* stress. This state of stress is disturbed when any engineering operation takes place, and the perturbed stresses can cause a range of unwanted effects, such as stress-related failure of the rock. As a result, assessment of the *in situ* state of stress is a critical component of rock mechanics. Over the years, various techniques have been developed that allow engineers to determine, with varying degrees of completeness, the state of stress in a rock mass. Two of the most commonly used techniques are hydraulic fracturing and various so-called overcoring methods. In hydraulic fracturing, a short length of a borehole is filled with fluid and is pressurized. A fracture forms in the rock of the borehole wall when the fluid pressure reaches a critical value, and the magnitude of this pressure is used to calculate the *in situ* stress (Figure 1). Overcoring makes use of sophisticated strain measuring devices that are fixed with epoxy cement into a small-diameter borehole (Figure 2). A larger diameter borehole is then drilled coaxially with the first, and the device recovered. Continuous recording of the strains induced within device, and hence within the core of rock, then allows the *in situ* stress to be calculated.

Existing fractures are particularly important to engineers because they are usually much weaker than is the intact rock, and are hydraulically very conductive (i.e., readily permit fluid flow). Assessing the geometry, mechanical, and hydraulic characteristics of the fractures at a project site are thus key engineering activities. Simplified models are usually used to describe such characteristics. For example, fractures may be considered to be planar and of infinite extent, and to occur in sets in which the fractures are mutually parallel. The complete rock mass may then be considered to comprise a number of such sets. For

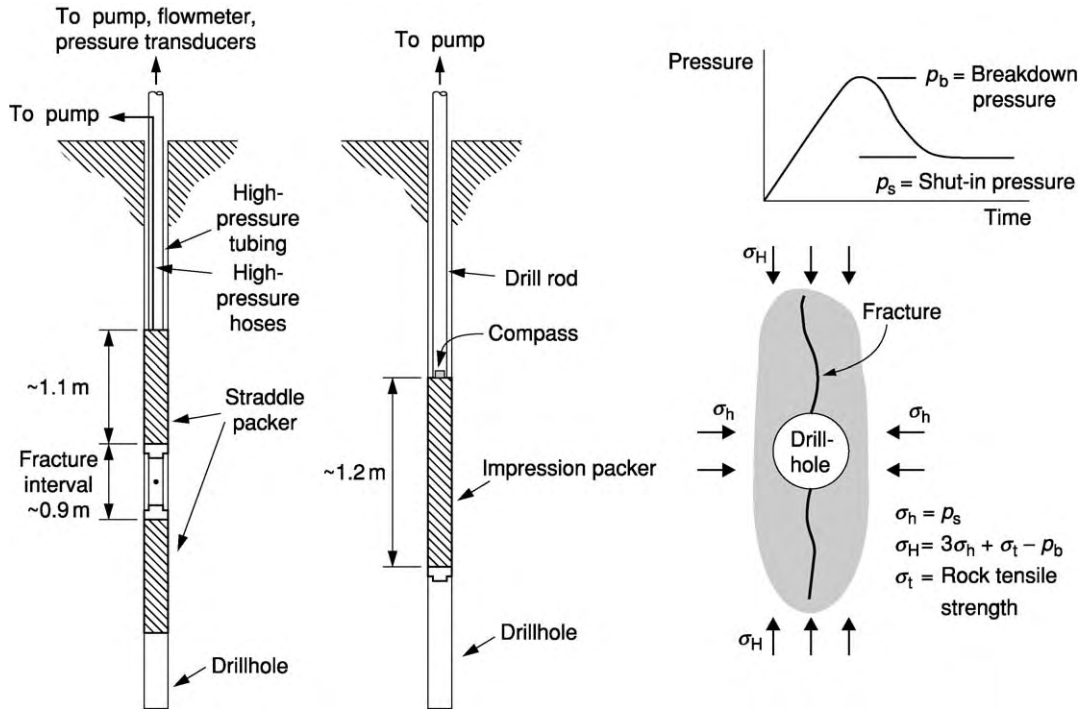

Figure 1 Hydraulic fracturing for estimation of *in situ* stress. Two longitudinal sections of the boreholes show the downhole equipment; the cross section shows the form of the induced fracture and the equations governing its development.

mechanical characteristics, a simple zero-cohesion Coulomb model is often used for frictional strength, with the shear and normal stiffnesses of a fracture being modelled as linear or non-linear springs. Hydraulic models range from those whereby each fracture is simply represented by a pair of smooth parallel plates, through to sophisticated statistical models in which the complex variation of fracture aperture is reproduced. Although many of the models of fracture geometry and strength are simple, they nevertheless allow valuable insight into the behaviour of fractured rock masses. For example, superposition of the frequencies of a number of fracture sets allows assessment of the variation of frequency with orientation through the rock mass (Figure 3), with the result that the direction in which a borehole, for example, would intersect most fractures can be seen. This has ramifications for optimal borehole orientation in endeavours such as water, petroleum, and geothermal energy extraction.

Most rock mechanics investigations involve determination of various mechanical properties of rock, particularly strength and elastic moduli. Laboratory testing of intact rock primarily makes use of cylindrical specimens, loading them in a state of triaxial compression in specialized servo-controlled machines that allow strain, rather than stress, to be the independent variable (Figure 4). Using strain as the independent variable allows the post-peak behaviour of a rock to be determined; this is critical for accurately establishing the engineering behaviour of structures, such as support pillars in underground mines, that undergo strain-controlled loading. Mechanical testing of fractures is usually undertaken using a shear box, in which a specimen of rock containing a through-going fracture is mounted and subjected to both normal and shear loads (Figure 5).

The strength of intact rock is often modelled using a linear Coulomb criterion, but because the relation

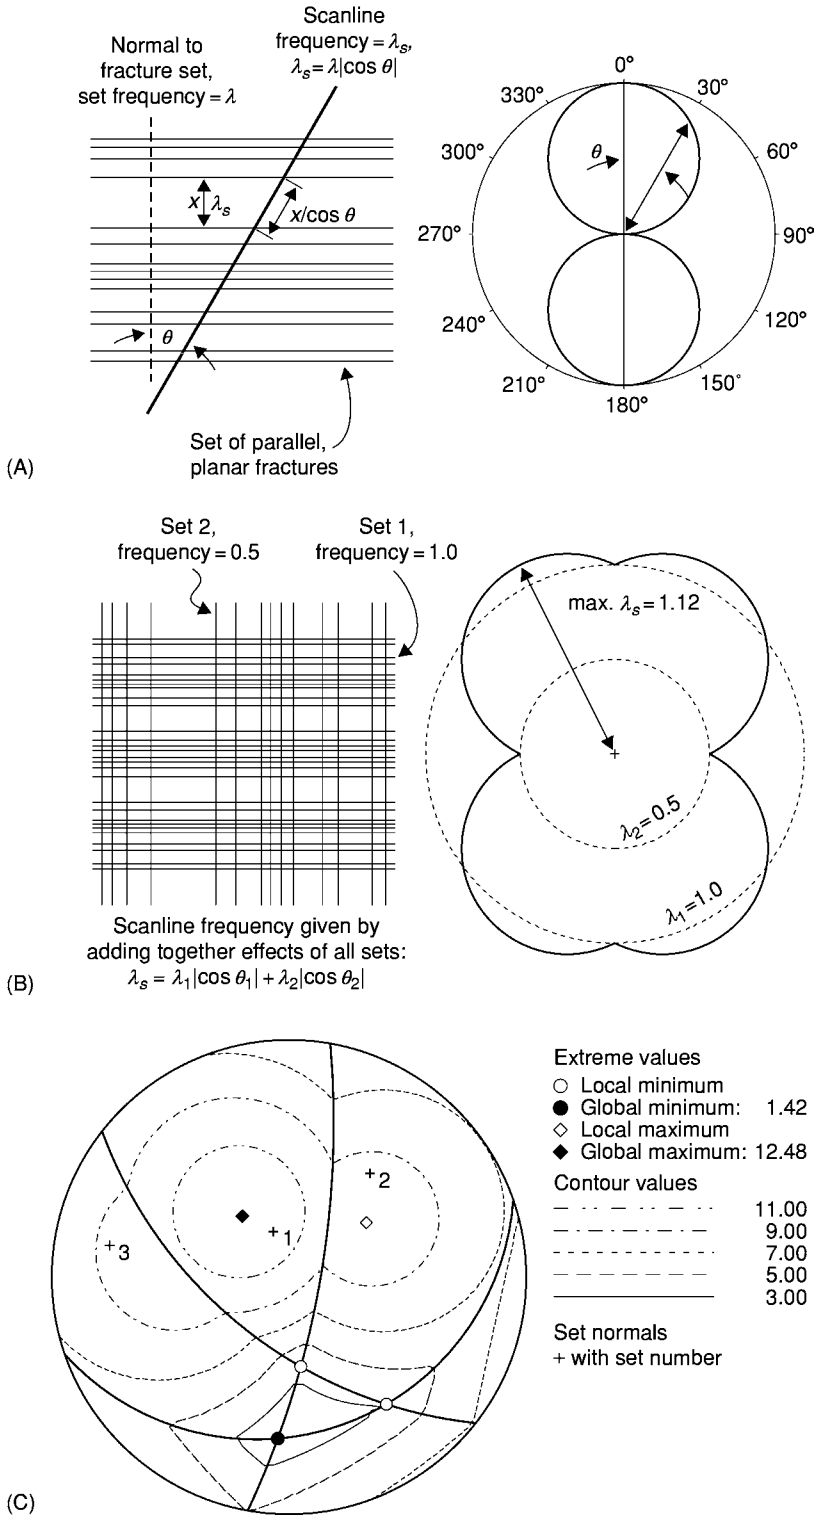

Figure 3 Predicting fracture frequency within a rock mass. (A) Frequency variation due to one set. (B) Frequency variation due to two orthogonal sets. (C) Frequency variation in three dimensions due to three sets. The fracture set orientation (dip direction/dip angle) and frequency values are as follows: set 1, 161/23 and 7.72 m ^{1}; set 2, 218/58 and 3.07 m ^{1}; set 3, 100/75 and 5.34 m ^{1}.

between strength and confining stress is known to be non-linear, increasing use is made of empirical non-linear strength criteria. One of the most popular of these is the Hoek-Brown criterion (Figure 6). Although the shear strength of fractures is similarly non-linear, for ease of calculation a simple linear Coulomb criterion is usually used for modelling.

The Engineering Material: Rock Masses

Rock masses can be usefully considered as being a composite material that comprises blocks of intact rock surrounded by fractures. Because both of these elements have their own mechanical characteristics, an estimate of the strength of the composite rock mass can be obtained by superposition of the component behaviours (Figure 7). This single-plane-of-weakness theory is widely used both for understanding the general strength of a rock mass and for determining the forces that tunnel support is required to supply. Although this approach can be used to examine the effect of more than one set of fractures, the usual approach for predicting the strength of fractured rock masses is through the use of non-linear empirical criteria. Over the years, many such criteria have been developed, but the one that appears to have become most widely used is the Hoek-Brown criterion. In its simplest form, this is a straightforward extension of the criterion used for intact rock, but with the addition of a parameter that describes the degree of fracturing of the rock mass (Figure 8).

Figure 4 A servo controlled testing machine. To the left is the stack of control electronics. In front of the loading frame (to the right) is an assembly comprising a triaxial test cell, axial strain transducers, and load cell.

It is often appropriate to consider intact rock as being impermeable, with the result that any fluid flow through a rock mass occurs along the fractures. A full, three-dimensional analysis of flow through a rock mass is not trivial, but a two-dimensional analysis can be undertaken relatively simply using a computer spreadsheet to solve simplified equations of flow. Figure 9 shows the results of an analysis undertaken for a two-dimensional network, in which the fractures have been modelled as pairs of parallel smooth plates, all with the same aperture. Rather than simply assessing the strength of a rock mass, an alternative approach is to assess its general engineering behaviour. Although this is a more nebulous concept compared to strength, through the use of a few, easily determined properties of a rock mass, a number of rock mass classification schemes have been developed that allow calculation of a single parameter that somehow uniquely quantifies the mass. Two of the most popular schemes in widespread engineering use are the so-called Q and rock mass rating (RMR)

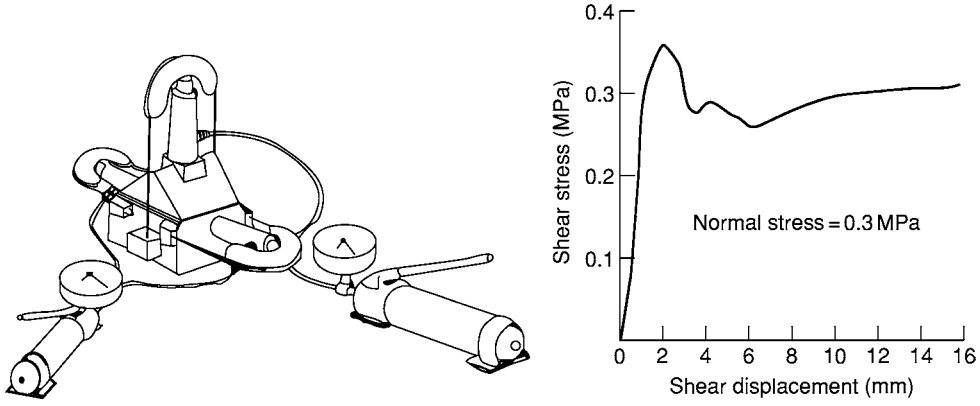

Figure 5 Schematic of a shear box for strength testing of fractures and a typical stress/shear displacement curve. The shear box is loaded by means of the hydraulic hand pumps (one for normal, the other for shear load).

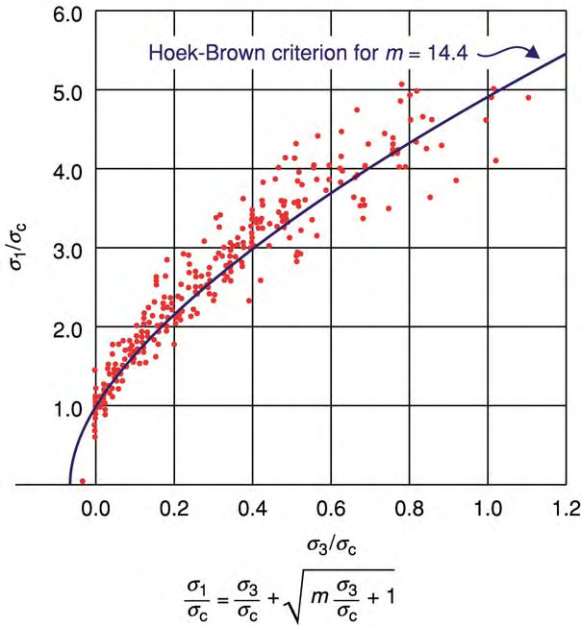

Figure 6 The equation and plot of the Hoek Brown criterion for intact rock, where σ_c is unconfined compressive strength of the particular rock under consideration.

systems (Figure 10); for both of these, extensive tables are readily available that indicate what parameter values should be used for particular conditions. Over the years, correlations have been developed between these rock mass classification values and various engineering aspects such as ease of mechanical excavation, blasting requirements, and tunnel support requirements. As a result, and due to their inherent simplicity, the use of rock mass classification schemes is widespread.

Basing an appreciation of rock masses on the concept of a composite material comprising intact rock and fractures as two separate materials leads automatically to an awareness of the variability of rock masses with respect to location and orientation. Techniques for the treatment and understanding of variability are still in their infancy, but two acronyms that are useful in helping to concentrate on the issues are CHILE and DIANE. The first of these represents 'continuous, homogeneous, isotropic, and linearly elastic' behaviour; the second, which is somewhat more contrived, represents 'discontinuous, inhomogeneous, anisotropic, and not elastic' behaviour. CHILE rock is a hypothetical material, but its existence is relied on extensively in rock mechanics. For example, the presence of a CHILE material may be

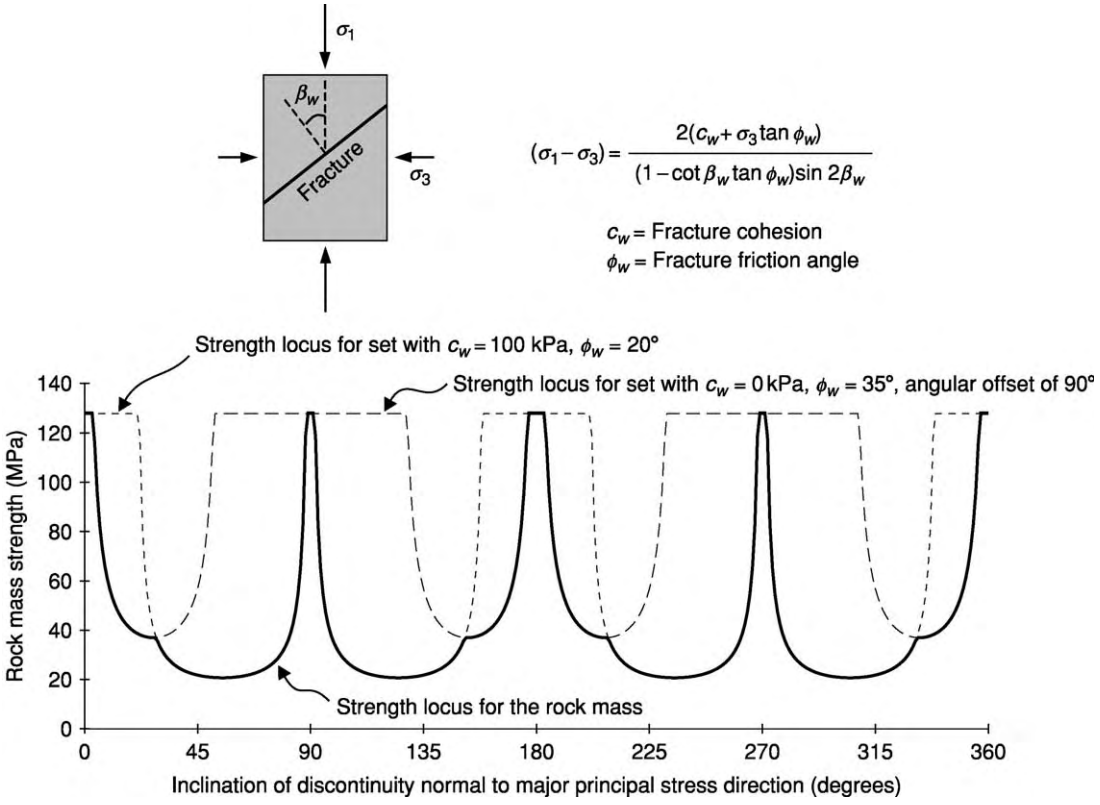

Figure 7 The single plane of weakness theory and its extension to the strength of a fractured rock mass.

The Hoek–Brown criterion for fractured rock masses $\frac{\sigma_1}{\sigma_c}=\frac{\sigma_3}{\sigma_c}+\sqrt{m\frac{\sigma_3}{\sigma_c}+s}$	Values of s	Dolomite, limestone, marble	Mudstone, siltstone, shale	Sandstone, quartzite	Andesite, dolerite, rhyolite	Gabbro, gneiss, granite
		Values of m				
Intact rock samples Laboratory-sized specimens free from fractures	1.0	7	10	15	17	25
Very good quality rock mass Tightly locking undisturbed rock with unweathered fractures, spacing 1 to 3 m	0.082	2.40	3.43	5.14	5.82	8.56
Good quality rock mass Fresh to slightly weathered rock, slightly disturbed fractures, spacing 1 to 3 m	0.00293	0.575	0.821	1.231	1.395	2.052
Fair quality rock mass Several sets of moderately weathered fractures, spacing 0.3 to 1 m	0.00009	0.128	0.183	0.275	0.311	0.458
Poor quality rock mass Numerous weathered fractures, spacing 30 to 500 mm and with some gouge	0.000003	0.029	0.041	0.061	0.069	0.102
Very poor quality rock mass Numerous heavily weathered fractures, spacing less than 50 mm, gouge filled	0.0000001	0.007	0.010	0.015	0.017	0.025

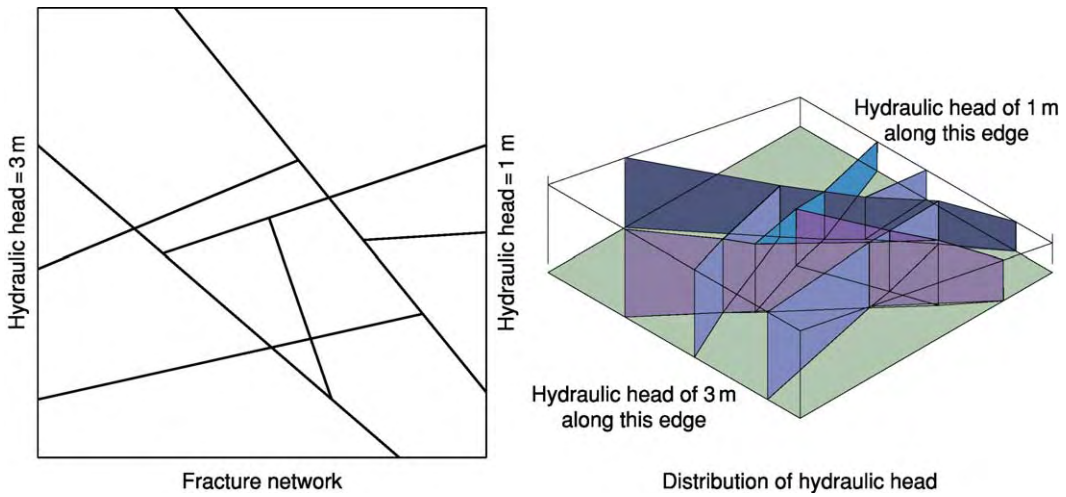

Figure 9 Distribution of hydraulic head in a two dimensional fracture network.

invoked in the determination of *in situ* stress, characterization of intact rock, and analysis of stresses induced around underground excavations. The DIANE nature of real rock masses means that the effects of fractures, variability with respect to location and orientation, and the fact that stress changes will usually lead to irreversible deformations in the material must always be considered. A further important consequence of the DIANE nature of rock masses is the scale effect. In general, because of the presence of fractures, it is found that large volumes of rock and small specimens of intact rock have different properties. This means that *in situ* rock mass strength and stiffness will be much lower than that determined in the laboratory. Similarly, the large-scale permeability of a fractured rock mass is very likely to be much greater than that of a specimen of intact rock. The scale effect is thought to apply to other properties, such as *in situ* stress, but in these cases the consequence of it is less predictable. For example, under

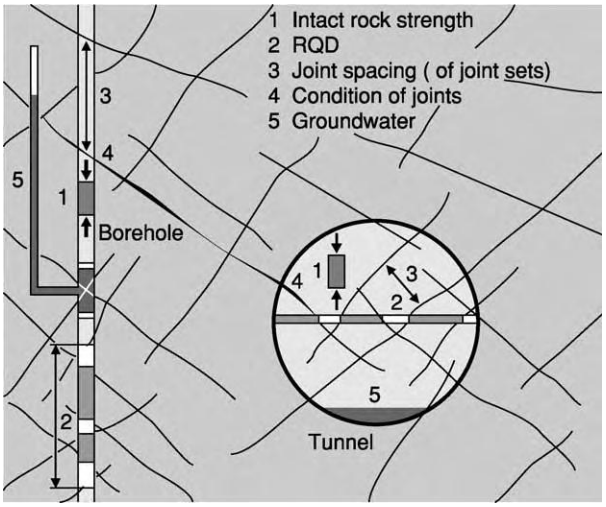

Figure 10 Schematic of typical rock mass properties included in a rock mass classification scheme, and how they may be assessed in both boreholes and tunnels. RQD, Rock quality designation.

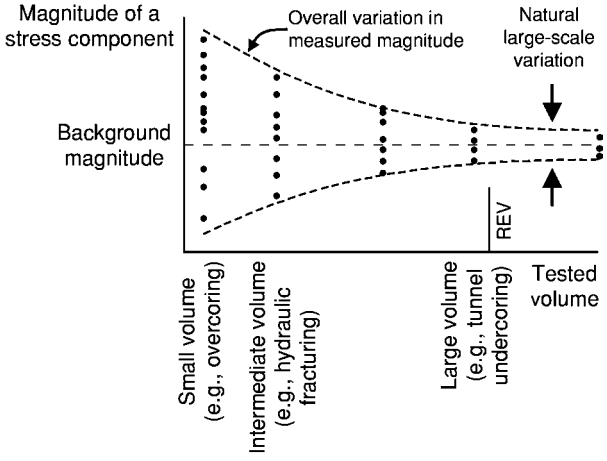

Figure 11 Illustration of scale effect and the representative elemental volume (REV) for *in situ* stress.

different circumstances, the measured state of stress in a small volume of rock could be less, the same as, or greater than the actual state of stress in a large volume. In all cases with the scale effect, the concept of a representative elemental volume (REV) is useful. As Figure 11 shows, there may be substantial variation in measured values or properties at small scales, but as the REV is approached the variation reduces until, at the REV and above, the variation is sufficiently small that it can be disregarded. Figure 11 also shows that the distribution of values at any particular scale may differ from those at another scale. This implies that it is usually not possible to use measurements of properties at one scale to estimate properties at another scale, and hence exemplifies the ideal requirement of performing rock mechanics tests on a volume of rock comparable to that of the final engineering structure. Unfortunately, this is seldom possible due to the constraints of cost and time.

Rock Engineering Topics

The development of rock mechanics concepts has in large part been driven by the requirement to solve problems in rock engineering. For example, although the rock engineering associated with mining and quarrying operations has a long history, the desire to exploit reserves at greater depths and hence in more onerous geomechanical environments has required a more rigorous approach than custom and practice can deliver. Endeavours such as the drilling of wellbores thousands of metres deep for petroleum extraction, or the requirement to ensure the long-term stability of steep rock slopes many tens of metres high adjacent to highways, has required additional developments in rock mechanics. Development efforts continue, driven by problems without precedent, such as those concerning the ultra-long-term stability of engineering designs for radioactive waste repositories. Regardless of the specific engineering application and its environment, the fundamental effects that an excavation has on a rock mass must always be borne in mind. These are summarized in Figure 12.

Fundamental techniques used in rock engineering are applicable to a range of engineering topics. These

$$F_W = \frac{\sin 101}{\sin 36} \times \frac{\tan 29}{\tan 32} = \frac{0.982}{0.588} \times \frac{0.554}{0.625} = 1.48$$

Figure 13 Illustration and analysis of wedge instability in a rock face. (A) Basic equation for factor of safety against sliding, where β and ξ are shown in the sketch, ψ_i is the plunge of intersection and ϕ is the friction angle of the fractures. (B) The factor of safety against wedge sliding, F_W, is 1.48 for the case of two fractures of orientation 046/69 and 182/52 and a friction angle of 29°. Dashed line plane whose normal is the intersection of planes 1 and 2.

techniques can conveniently be classified in terms of those applicable to rock that is obviously discontinuous, and those that are strictly valid only for continuous rock. This effectively separates the applications into those for near-surface structures (such as slopes, foundations, and tunnels) and those for structures at depth (such as mine excavations and petroleum wellbores).

Engineering in Fractured Rock

Near-surface engineering is often controlled entirely by the strength and geometry of fractures. It is common, and conservative, to assume that the strength of fractures is purely frictional, i.e., the fractures have zero cohesion. This has an added advantage in that, in the absence of any external forces such as those generated by water pressure, an analysis of static equilibrium reduces to one that is governed by the orientation of the fractures. These orientations may conveniently be determined using standard hemispherical projection techniques. Of course, the blocks of rock that exist in a rock mass may possess a great many shapes and sizes. In order to develop a tractable problem, only tetrahedral blocks of the maximum size that can fall or slide into an excavation are analysed. Such tetrahedral blocks are generally formed from either two fracture surfaces and two excavation surfaces or from three fracture surfaces and one excavation surface. Polyhedral blocks (i.e., those possessing five or more surfaces) are usually ignored, both for analytical convenience and because such a block can be cut from, and hence will be smaller and less critical than, a tetrahedral block.
