Sometimes, features of oceanic basement are not subducted, but are sheared off against the crystalline crust of the overriding plate, leading to obduction of part of the oceanic crust. This appears to occur most commonly where asperities exist in the oceanic crust that is being subducted, such as seamounts or the ridges flanking transform faults. The Tres Montes Peninsula on the coast of southern Chile, close to the Chile triple junction, was probably brought about by this process. Very large-scale obduction of ocean crust to create ophiolite complexes is associated with continent/continent collision or continent/island-arc collision and may also be a consequence of the closing of back-arc basins following a change in plate motions, with young buoyant ocean crust thrust onto the adjacent plate, as exemplified by the Rocas Verdes complex of southern Chile.

Oblique Subduction

There are several convergent margins, including the eastern end of the Aleutian island arc, Sumatra, the north-west United States (Cascadia), and the northern Pacific margin of Colombia, where the direction of convergence is oblique; in these cases, as well as convergence between the two plates in the direction orthogonal to the plate boundary, there is a component of motion parallel to the plate boundary. At these margins, the directions of thrust-fault outcrops and of fold axes, which form at right angles to the direction of compression, run subparallel to the margin, not at right angles to the direction of convergence of the two plates. The reason for this is that the displacement between the accretionary wedge and the subducting plate is partitioned into a component orthogonal to

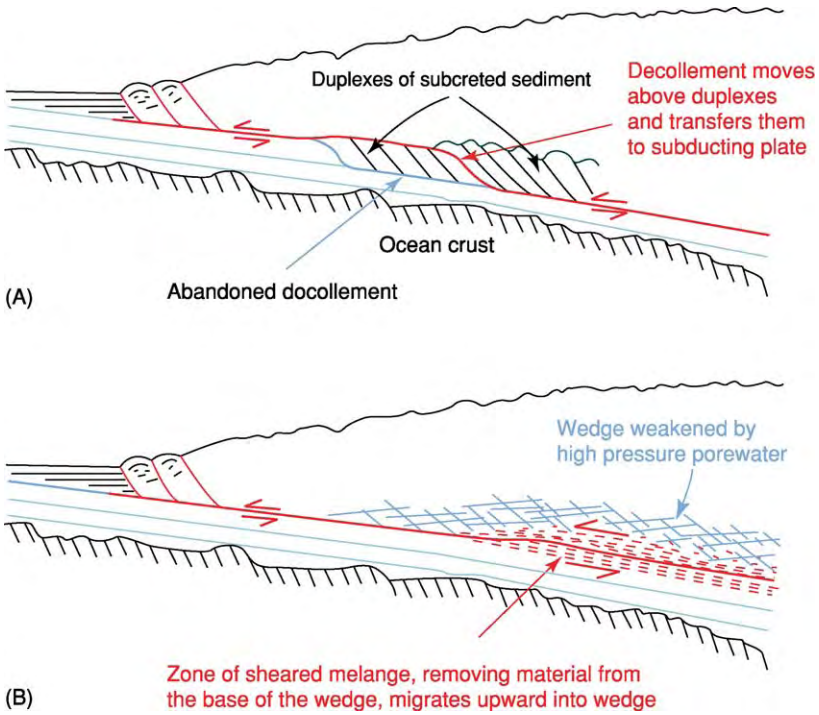

Figure 10 The hypothesis of tectonic erosion from the effect of high pore fluid pressure. (A) Loss of subcreted material from the accretionary wedge by relocation of the active decollement to the upper of the two levels separating the subcreted duplexes, because of an increase in drainage from the lower decollement and/or a restriction in the drainage from the upper level. (B) Material above the main decollement has been weakened by high fluid pressure; a melange of this disaggregated material is incorporated into a shear zone, which transports the material deeper into the subduction zone. Removal of this material makes it easier for high pressure fluid in the shear zone to infiltrate the zone and propagate the process of tectonic erosion upward into the overlying wedge. Copyright Graham Westbrook.

the margin and a component parallel to it. A strike–slip fault, or series of faults, separates the wedge, and often the fore-arc basin as well, from the volcanic arc and the rest of the plate. The horizontal motion between the fore-arc region and the remainder of the plate along this fault compensates the obliquity of plate convergence, so that the relative motion between the subducting plate and the accretionary wedge is nearly orthogonal to the margin (Figure 11). It has been demonstrated theoretically and by experiments with sand-box models that, when the direction of convergence is greater than about 15° from orthogonal to the margin, displacement can be partitioned in this way. This is because the work required to move the subducting plate the shortest distance, orthogonal to the margin, against the frictional resistance of the decollement surface, plus the work to move the fore-arc along the strike–slip fault, is less than the work required to move the plate obliquely a greater distance along the decollement in the direction of convergence between the two plates. The angle of obliquity at which partitioning occurs depends on the shear stress at the base of the wedge, and if this is very low, because of fluid overpressure,

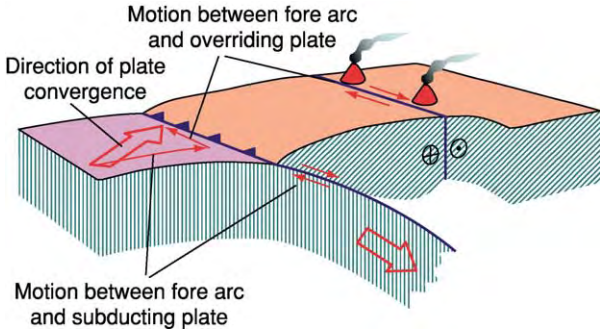

Figure 11 Where subduction is oblique to the margin, motion is partitioned into orthogonal underthrusting of the subducting plate beneath the fore arc (accretionary wedge plus or minus the fore arc basin) and strike slip movement between the fore arc and the overriding plate. The direction of plate motion is shown by the large arrows; the small red arrows on the subducting plate indi cate components of motion normal and parallel to the margin. Copyright Graham Westbrook.

the deviation from orthogonal convergence required to produce partitioning can approach 40°. Where partitioning occurs, the fore-arc can be translated large distances along the edge of the overriding plate

Table 1 Summary of controls on accretion, subduction, and tectonic erosion of sediment

Separation of accreted and subducted sediment	The level of detachment between accreted and subducted sediment is governed by Ratio of shear stress to effective normal stress Presence of a weak horizon, produced by Low intrinsic strength (low coefficient of friction and low cohesion) High fluid pressure from Low permeability High rate of loading, produced by Sufficient sediment supply to trench High subduction rate High angle of dip of subducting plate
Tectonic erosion	By basement topography General relief inherited from mid ocean ridge, and accentuated by normal faulting in outer trench slope; ineffective if sediment cover is thicker than several hundred metres Discrete features of high relief Seamounts Transform ridges and troughs Hotspot ridges (swells) From the effects of high fluid pressure 'Stoping' (disaggregation of base of wedge and incorporation into a shear zone melange) Reactivation and upward migration of detachment surfaces
Accretion vs. tectonic erosion	Progressive accretion is associated with high sediment thickness and low subduction rate Tectonic erosion is associated with low sediment thickness Episodic accretion and tectonic erosion is associated with high sediment thickness and high subduction rate

to become a displaced, or exotic, terrain. A summary of the controls on accretion, subduction, and tectonic erosion of sediment is given in Table 1.

Earthquakes

G J H McCall, Cirencester, Gloucester, UK

Introduction

Earthquakes have many and diverse relationships with other Earth processes, and their study has a wide range of possible applications. Earthquakes will be considered here under the following headings:

1. The nature of earthquakes,
2. The importance of seismological records,
3. The global distribution of earthquakes, and
4. Earthquakes as a hazard – tectonic, volcanic, and man-made earthquakes.

The Nature of Earthquakes

An earthquake is a sudden movement of the Earth's surface, caused by a release of strain built up over long periods on faults. The rocks are elastic and can store energy in the same way as a compressed spring. Earthquakes are focused on faults in the rock mass. Most have foci within the crust but a few, in plate boundary zones and beneath stable cratonic areas (where they are related to events in nearby subduction zones), have foci at great depths, down to about 700 km, in the mantle; beyond this depth the rock mass is insufficiently rigid to rupture. The very deep earthquakes are not well understood. Most earthquakes have foci less than 30 km deep. Not all the built-up strain is relieved by earthquakes; much of it is relieved by continual small adjustments, a process of creep. However, where friction prevents such accommodation, the strain builds up until something has to give, and there is a sudden rupture of the weakest part of the solid rock, the forces being accommodated by sudden dislocation of the rocks on either side of the fault plane (Figure 1). This process can happen on all three types of fault: normal, reverse, and transcurrent. The point directly above the focus is the called the epicentre; here, the effects of the earthquake will be greatest. If the focus is shallow, the effects will be greater than if it is deep – the 1960 Agadir earthquake, Morocco, was not of great magnitude, but it was very shallow and the epicentre was right under the city.

The magnitude is a measure of the amount of energy released by the earthquake. It is calculated from the size or amplitude of the waves traced by the pen of a seismograph, an instrument that picks up the waves at some distance from the epicentre and records them in the form of a wavy trace on a rotating drum (Figure 2) coupled to a clock. The principle of the seismograph is illustrated by a chandelier that swung in the great Lisbon earthquake of 1755 – a freely pivoting horizontal strut is attached to an upright support (Figure 3). A heavy mass at the strut end is attached to the pen, which traces a continuous line on the paper. Most of the time there are no ground movements, so the trace is horizontal. All seismographs have to be standardized so that valid comparisons can be made between their traces. Waves weaken as they travel outwards from the earthquake focus, so allowance has to be made for distance between the focus and the instrument (this can be calculated by measuring the difference between the arrival times of P and S waves). Three seismographs are required to measure north–south and east–west horizontal movements and vertical movements. The Worldwide Standardized Seismograph Network was established in 1962. All the instruments are standardized as if they were situated 100 km away from the focus.

Waves produced by earthquakes spread through the Earth (Figure 4). They comprise body waves and surface waves. Body waves travel through the Earth and are of two types, primary (P) and secondary (S)

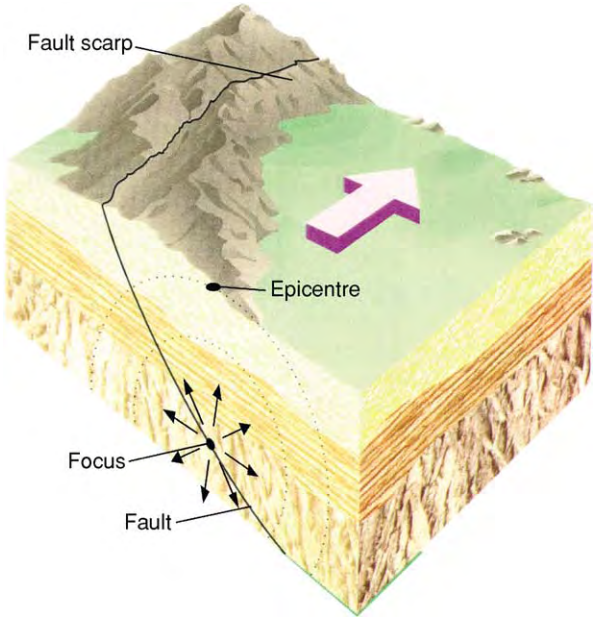

Figure 1 Block diagram showing the relationship between an earthquake focus, epicentre, and fault.

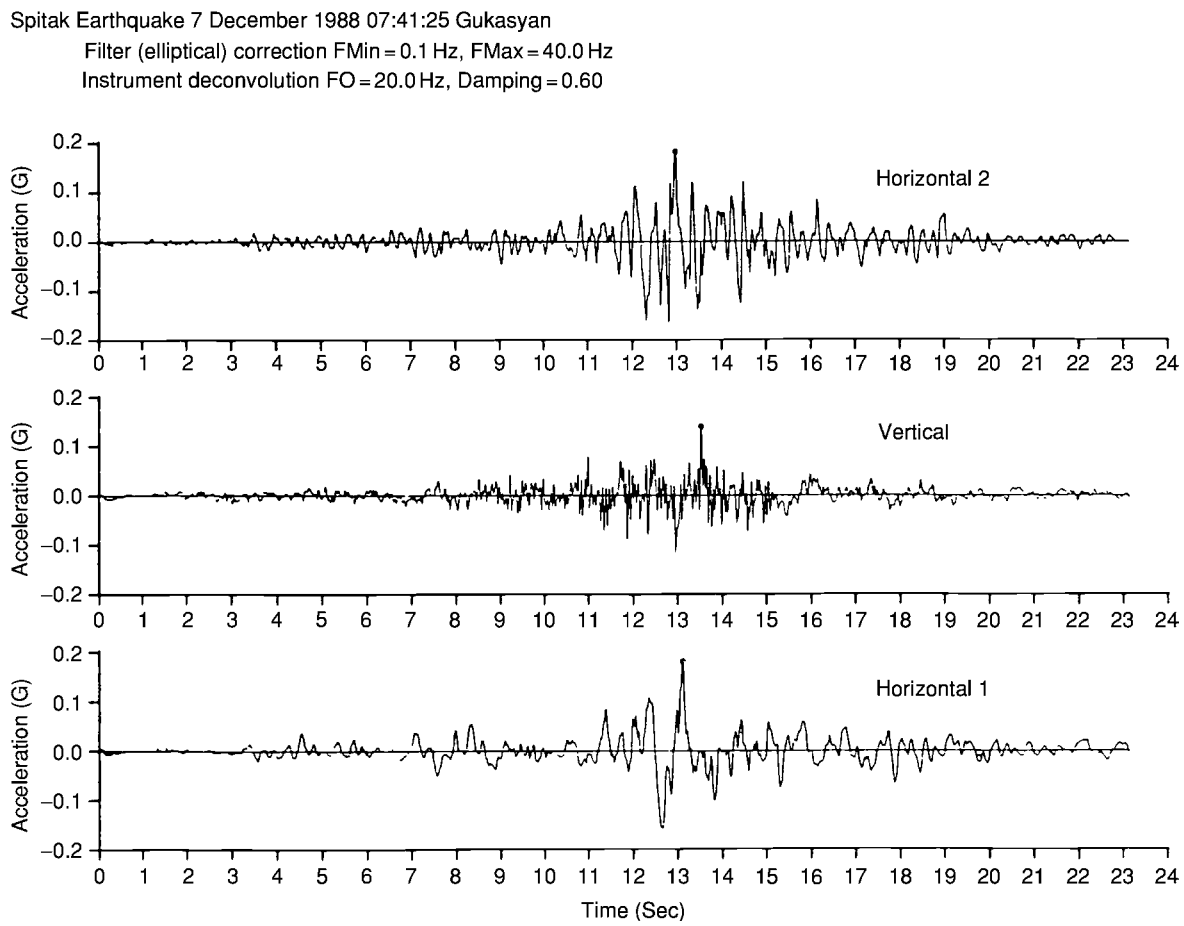

Figure 2 Record on three seismographs of the Spitak 1988 main shock (magnitude 6.9). Reproduced with permission from Rommer and Ambraseys (1989) *Earthquake Engineering and Dynamics*. Chichester: John Wiley & Sons. © John Wiley & Sons Limited.

waves. P waves can pass through both solid and molten material within the Earth's interior; they travel fastest and are the first to arrive at a given location, and they are also the first to be felt by the man in the street. They are longitudinal or compressional waves, vibrating forwards and backwards in the direction of travel. They travel at about 6 km s^{-1} through continental crust and 8 km s^{-1} through oceanic upper mantle. They may produce booming sound waves in the atmosphere. S waves travel about half as fast as P waves (3.6 km s^{-1} and 4.7 km s^{-1} in continental crust and oceanic upper mantle, respectively); they cannot pass through fluids and thus do not penetrate the liquid outer core. They are shear or transverse waves: as they pass through the rock they move particles both from side to side and up and down, at right angles to the direction of travel. Two kinds of surface waves, which travel just below the surface, are called Love and Rayleigh waves. They arrive shortly after the body waves. Love waves travel faster than Rayleigh waves and push the rock particles sideways, at right angles to the direction of travel. Like S waves, they shear buildings and constructions sideways, causing immense damage, but have no vertical motion. The slowest waves, Rayleigh waves, push particles upwards and backwards; the particles move in the vertical plane, following an elliptical path as the wave passes by.

Charles Richter in 1935, working in California, devised the Richter Scale of magnitude, in which the absolute strength at the focus can be calculated on a logarithmic scale: a rise of one unit of magnitude represents a 10-fold increase in absolute strength (i.e. a magnitude 5 earthquake is 10 times a strong as a magnitude 4 earthquake). The difference in energy release is even greater – an increase of one unit of magnitude represents 30–32 times as much energy being released. Theoretically, earthquakes with magnitudes of more than 10 could occur, but the greatest magnitude so far measured for any earthquake is about 9.5. The Richter scale is given in Table 1. It has been superseded as a scale for measuring the

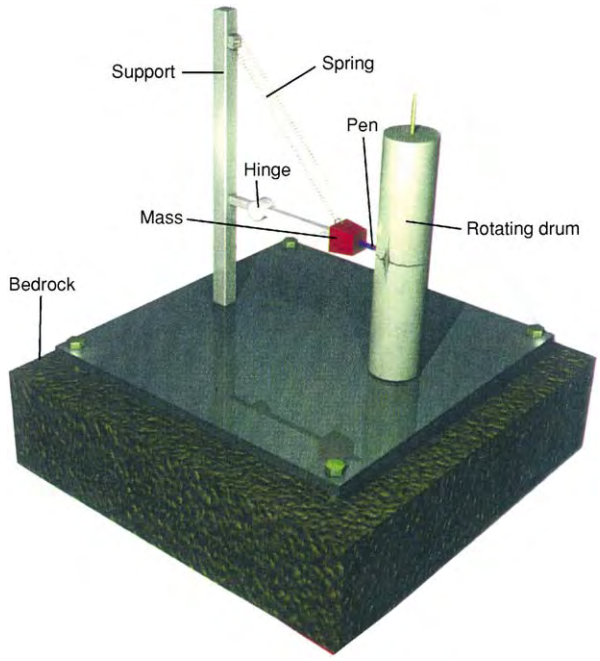

Figure 3 The components of a seismograph designed to record vertical ground movement.

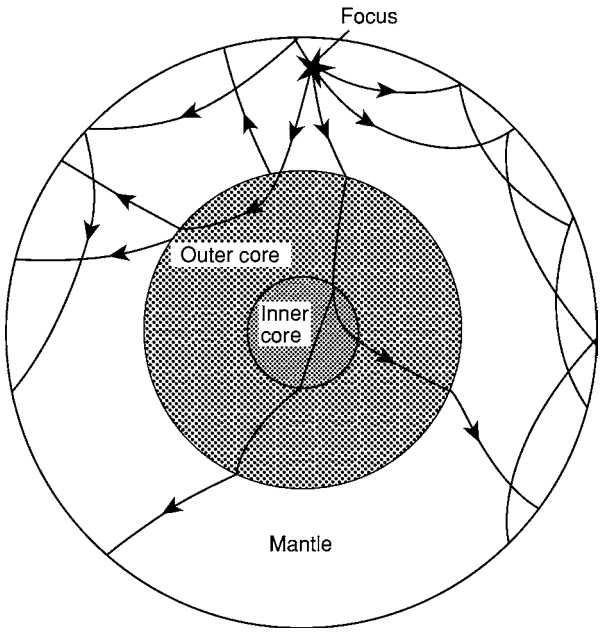

Figure 4 The way in which earthquake waves spread through the globe and are reflected at boundaries, returning to the surface. Measurement of the speed of such return is used to delineate the materials of the inner Earth according to density and physical state. Reproduced from Van Andel TJ (1994) *New Views on an Old Planet.* Cambridge: Cambridge University Press.

comparative intensity at the focus by the moment magnitude scale, but the principles are the same – the moment magnitude scale allows more refined methods of comparison.

Table 1 The Richter scale

Magnitude	*Qualitative description*	*Average number per year*	*Average intensity equivalent close to epicentre*
0 1.9		700 000	I V; recorded but not felt
2 2.9		300 000	I V; recorded but not felt
3 3.9	Minor	40 000	I V; felt by some
4 4.9	Light	6200	I V; felt by many
5 5.9	Moderate	800	V VII; slight damage
6 6.9	Strong	120	VII; damaging
7 7.9	Major	18	IX XI; destructive
8 8.9	Great	1 every 10 20 years	XII; widely devastating

The Importance of Seismological Records

We cannot directly study the rocks of the crust below the limits of borehole drilling (a few kilometres), though ancient rock systems do expose sections of the ancient deep crust (as in the Kapuskasing Belt, Ontario, Canada) and perhaps even the crust–mantle contact (as in Oman and Western Newfoundland). The behaviour of earthquake waves, however, provides us with invaluable evidence about the nature of the lower crust, mantle, and core because the velocities of P and S waves are functions of the density of the material through which they pass. Knowledge of rock density can tell us much about the physical state of the materials deep within the Earth, and the behaviour of S waves tells us that the outer core is molten. In Figure 5, the different densities of common rock materials are plotted against the P-wave velocity.

It is fair to say that earthquake waves form the basis of our knowledge of the mantle and core. Artificially produced seisms can also be picked up by seismographs, and, thus, nuclear explosions can be globally monitored. The explosion in the submarine Kursk in 2000 was picked up by distant seismograph stations in Africa, and this provided valuable evidence of what happened. Tomographic methods have recently been developed, producing three-dimensional images of the deep Earth, including subducted slabs of crust, using a technique akin to the use of tomography in medicine.

Earthquakes occur in sequences: slight foreshocks may give warning of a major earthquake, and aftershocks occur for long after the main shock. Foreshocks and aftershocks are generally of lower intensity than the main shock, but sometimes very

large shocks occur, as in the 1999 Izmit earthquake in Turkey. In the 1988 Spitak earthquake (magnitude 6.9) an aftershock of magnitude 6.2 occurred 4 min after the main shock.

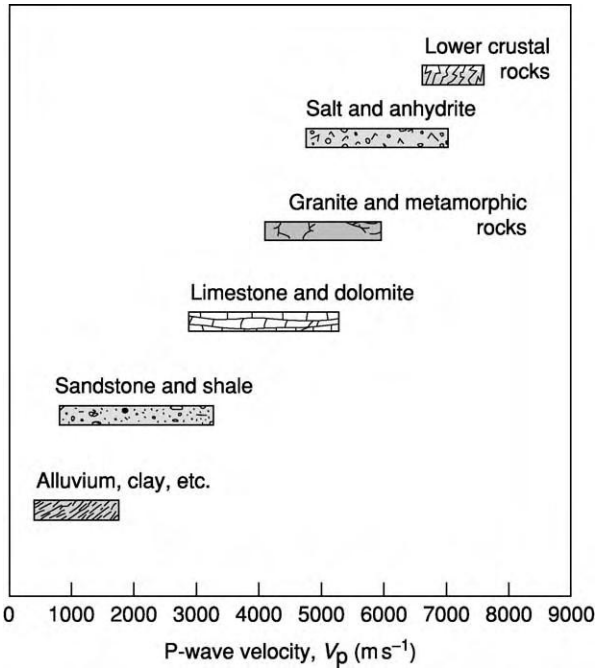

Figure 5 The different densities of common rock types plotted against P wave velocity.

Earthquakes may produce a trace of the rupture on the land surface, dislocating the land for many kilometres. In Figure 6 the trace produced across wheat fields by the Meckering 1968 (magnitude 6.9) earthquake is shown. Such traces are invaluable in studying the sense of the movement and displacement.

The Global Distribution of Earthquakes

Earthquakes do not occur to the same extent all over the globe. The major events are largely concentrated at the boundaries of tectonic plates, and the concentration and magnitude are greater in zones of plate convergence (subduction and collision) than in zones of plate divergence (mid-ocean ridges and rift valleys). This distribution is clearly shown in Figure 7.

Not all earthquakes occur on plate boundaries, however: the destructive Killari earthquake in India in 1993 occurred within a stable cratonic area. The immensely destructive Lisbon earthquake of 1755 was also nowhere near a plate boundary.

Earthquakes as a Major Hazard: Tectonic, Volcanic, and Man-Made Earthquakes

The most damaging earthquakes are not necessarily of high magnitude. The 1994 Kobe earthquake, one

Figure 6 Surface trace of the Meckering 1968 earthquake (magnitude 6.9) in Western Australia. Canberra: Bureau of Mineral Resources, Geology and Geophysics.

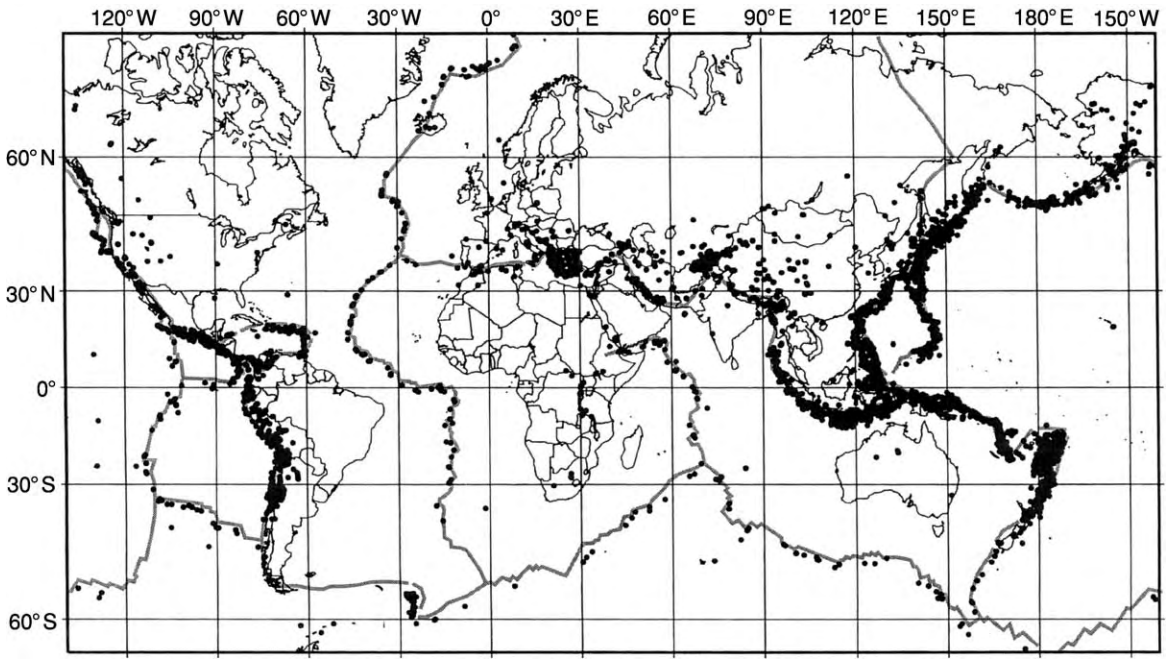

Figure 7 The global distribution of earthquakes that occurred in 1994. Reproduced from US National Earthquake Information Center.

of the most destructive and costly in living memory (55 000 houses destroyed as well as freeway, rail, and port installations), had its epicentre 20 km from the city and had a magnitude of only 6.8. The 1960 Agadir earthquake had a magnitude of only 5.8, but the focus was shallow and right beneath the city.

Thus, magnitude, though a valuable absolute measurement, tells us little about the degree of damage and the loss of property and life, even at the epicentre. The nature of the subsurface rocks can have a significant effect, especially if shock-induced liquefaction occurs, and thus we need another measurement scale. The Mercalli intensity scale measures the relative intensity of the effects felt at a specific site (the intensity will commonly decrease away from the epicentre, but secondary effects such as subsurface variation and shock liquefaction complicate this relationship). In Europe, a modification of the Mercalli scale, the MSK scale (named after Medvedev, Sponheuer, and Karnik), is now used. This scale is given in Table 2.

Tectonic Earthquakes

Earthquakes may be divided into tectonic earthquakes, volcanic earthquakes, and man-made earthquakes. In considering the natural-hazard aspect, it is the tectonic earthquakes that are by far the most destructive natural hazards. This hazard largely affects urban populations, and human design and construction has a unique role in mitigating this hazard.

The actual physical process of ground motion presents little threat to humans in the open: most casualties (other than the casualties of secondary tsunamis) occur inside buildings that partially or totally collapse. The correct design of buildings and constructions such as bridges and viaducts can thus greatly mitigate the damage and casualties resulting from an earthquake.

The vulnerability of a building to earthquake damage varies according to many factors. Vertical ground motion is the principal damaging component causing collapse, burial of people, and death. Lateral ground motion breaks or deforms power lines, pipelines, water pipes and sewers, roadways, railways (Figure 8), and bridges. Quite small lateral offsets can be very damaging. In the Mexico City earthquake of 1985, much damage was caused by adjacent high-rise buildings swaying with different wave motions and knocking each other down. It is noticeable that in Beijing, an earthquake-prone city, the high-rise buildings are widely spaced, with intervening areas of low-rise buildings, so that they cannot interact in this way. In the case of Kobe, the sixth floor of one high-rise building pancaked (Figure 9). The lower floors were built of steel-encased reinforced concrete and the upper floors of pure reinforced concrete; the junction on the sixth floor acted as an element of weakness.

Though earthquakes are mainly an urban hazard, catastrophic earthquakes may strike village populations where low-rise housing is substandard – as in

Table 2 The modified Mercalli (MSK) intensity scale

Intensity	*Effects*
I	Felt rarely. Sometimes dizzyness and nausea. Birds and animals uneasy. Trees, structures, liquids sway.
II	Felt indoors by a few, especially on upper floors. Delicately suspended objects swing.
III	Felt indoors, especially on upper floors by several people. Usually rapid vibration as if a lightly loaded lorry passing. Hanging objects and standing motor cars rock slightly.
IV	Felt indoors by many and outside by a few. Some awakened. No one usually frightened. Sensation of heavy object striking building. Vibration as of heavy lorries passing. Crockery, windows, doors rattle. Walls and frames creak. Hanging objects and standing motor cars sway.
V	Felt indoors by almost everyone, outdoors by most people. Many awakened, a few frightened and run outdoors. Buildings tremble. Crockery and windows sometimes break. Pictures and doors clatter. Small objects move. Some liquids spilt. Clocks stopped. Trees shaken. Animals anxious.
VI	Felt by all indoors and outdoors. Many frightened, some alarmed. All awakened. People, trees, bushes shaken. Liquids set in motion. Small bells ringing. Crockery broken. Plaster cracks and falls. Books and vases fall over. Some furniture moved. Domestic animals try to escape. Minor landslides on steep slopes.
VII	All frightened, run out of doors, general alarm. Some people thrown to ground. Trees shaken quite strongly. Waves and mud stirred up in lakes. Sandbanks collapse. Large bells ring. Suspended objects quiver. Much damage to badly constructed buildings and old walls. Slight damage to well built buildings. Chimneys crack. Much plaster, tiles, loose bricks fall. Heavy furniture overturned. Concrete ditches damaged.
VIII	Alarm approaches panic. Vehicle drivers disturbed. Trees broken and shaken. Sand and mud spurt from the ground. Marked changes to springs and wells. Much damage to ordinary and older buildings. Walls, pillars, chimneys, towers, statues, gravestones crack and fall. Very heavy furniture overturned.
IX	General panic. Ground cracked open (10 cm). Much damage to structures built to withstand earthquakes. Frequent partial or total collapse of other buildings. In reservoirs, underground pipes broken. Buildings dislodged from foundations, rock falls.
X	Widely cracked ground, fissures up to 1 m wide. Frequent river bank and coastal landslides and shifted sands. Water levels change. Water thrown onto riversides. Serious damage to dams, embankments, bridges. Severe damage to well built wooden structures. Masonry structures destroyed along with their foundations. Rails bent. Open cracks or waves on roads. Pipes torn apart.
XI	Widespread serious ground disturbance, broad fissures, landslips, landslides. Muddy water spurts upward. Tsunamis develop. Severe damage to all wooden structures. Great damage to dams. Few masonry structures remain upright. Pillars of bridges and viaducts wrecked. All pipelines wrecked. Rails badly bent.
XII	Total damage to all constructions. Great disturbance to ground with many shearing cracks. Many landslides on slopes, rockfalls common, rock masses dislocated, water channels altered and dammed. Ground surface waves like water and ground remains undulating. Objects thrown into the air.

the case of the Cairo earthquake in 1992 and the Killari, central India, earthquake in 1993. In the case of the Cairo earthquake, poorly constructed extra storeys had been added to moderate-rise housing. In Killari, stone-built low-rise houses were poorly constructed (**Figure 10**). In the catastrophic Bam earthquake of December 2003, the mud bricks of the low-rise dwellings crumbled and collapsed, leaving few air spaces to allow buried victims to breathe; another factor responsible for the scale of the fatalities was the fact that all the dwellings in southern Iran have basements cooled by wind towers designed for the sweltering summer heat, and many victims would have been asleep in them.

Some of the most devastating historic and recent earthquakes are listed in **Table 3**.

Where cities are situated in plate-boundary zones the effects are most disastrous. The San Francisco earthquake of 1906 (**Figure 11**) provides an example of this. The Kobe earthquake of 1995, in which the financial loss was US $200 billion, occurred in a city that experiences a tremor every few days. An analysis of the locations of 100 of the largest cities in the world, which accommodate 10% of the global population, shows that they can expect to experience an earthquake of intensity VI or more on the MSK scale within 50 years.

The earthquake hazard extends beyond high-risk cities such as those sited on plate boundaries. Entire countries may be at quite low risk, yet have some vulnerability. The UK is a low-risk country, and earthquakes of more than magnitude 5.5 are extremely unlikely (**Figure 12**). Charles Davidson published a list of 1191 recorded shocks in Britain between AD 974 and AD 1924. In Lincoln in 1185, "great stones were rent; houses of stone fell; the metropolitan church of Lincoln was rent from top to bottom" and there is a similar report from the cathedral city of Wells in 1248. Two apprentices were killed in London in 1580 as a result of an earthquake in the Dover Straits. The Colchester earthquake in 1884 (magnitude 4.7) peaked in intensity near the epicentre (between Pelden and Langenhoe) (**Figure 13**) at MSK VIII and caused widespread damage, which was

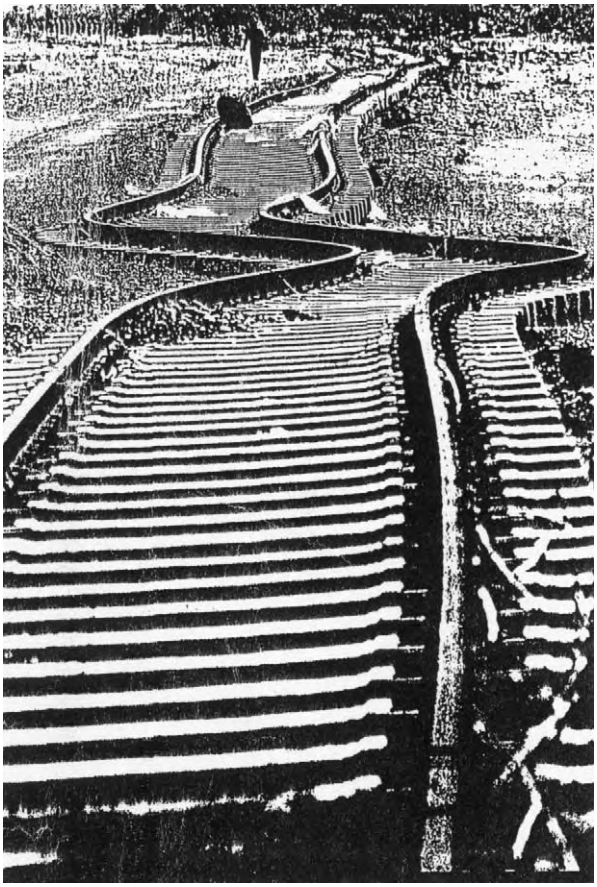

Figure 8 A railway track in the western USA twisted and shortened by lateral motion during an earthquake.

compensated by a Mansion House Fund that paid out £9000 (equivalent to £500 000 today). The Roermond earthquake in the Netherlands in 1998 (magnitude 5.8) caused £30–40 million of damage, despite the single fatality. It is predicted that a magnitude 5.7 earthquake focused at a depth of 5 km directly under Manchester would cause havoc. The increasing size of conurbations and cities increases their vulnerability: the Colchester area would suffer much more nowadays from a comparable earthquake to the 1884 event, because the population and industry are now much denser than at that time.

Earthquakes can occur in areas that are not considered to be at risk. The Spitak earthquake in Armenia in 1988 is such a case. The region was not considered to be at high risk, and a nuclear power station was planned for the Spitak area. This earthquake caused the whole process of earthquake risk assessment in the Soviet Union to be revised.

The New Madrid, Missouri, earthquakes of 1811–1812 are even more surprising. There is a reliable historical record of three earthquakes spaced over two months with magnitudes 8.2, 8.1, and 8.3. They rang the bells of Boston and rattled Quebec and provide a remarkable example of major interplate seismicity.

Secondary effects The secondary effects of earthquakes can be as destructive and lethal as the primary effects, or more so.

(B) Improved training in building similar low rise buildings in the Yemen. Reproduced from Degg MR (1995) Earthquakes, volcanoes and tsunamis: tectonic hazards in the built environment of southern Europe. *Built Environment* 21: 94 113. Courtesy of the Geological Society, London.

Tsunami The so-called tidal wave generated by earthquakes is probably the most lethal secondary effect: during the twentieth century earthquakes in Chile caused fatalities in Hawaii and Japan. The effects of tsunamis may be felt thousands of kilometres from the earthquake epicentre, but can be mitigated by systematic warning systems.

Fire Tokyo in 1923, San Francisco in 1906, and Kobe in 1995 all suffered from the secondary effects of fire. This was exacerbated by the fact that water supplies were cut off. In Tokyo there was a firestorm. In San Francisco, 70% of the damage was due to fire.

Liquefaction of sands, silts, and clays Another important secondary effect is that thixotropic sands and silts, which liquefy on shock, greatly increase the damage: examples of this are the waterfront area in the Messina earthquake, Sicily, of 1908, in which 98% of the houses were ruined and 160 000 died; Mexico City in 1985, where the worst damage was in building developments founded on old lake deposits (the wave amplitude was magnified 8–50 times here); and Anchorage, Alaska, where a magnitude 8.4 earthquake with an epicentre 130 km away caused devastation in a housing development founded on the thixotropic Bootlegger Clay

Table 3 Some important earthquakes in the last 2000 years (various sources): note that magnitudes are on various scales. An earthquake at Gujarat, India, in 2001, which killed more than 50 000 people has been omitted from the table

Year AD	*Place*	*Casualties*	*Estimated loss*
342	Antioch	40 000	
454	Sparta	20 000	
565	Antioch	30 000	
856	Corinth	45 000	
1170	Sicily	15 000	
1290	Chihli, China	100 000	
1456	Naples	60 000	
1556	Shensi, China (M 8.3?)	830 000	
1716	Algiers	20 000	
1737	Calcutta	300 000	
1755	North Persia	40 000	
1755	Lisbon (M 6.9?)	60 000	
1759	Baalbek	20 000	
1783 1786	Calabria	50 000	
1797	Quito	41 000	
1822	Aleppo	22 000	
1828	Honshu	34 000	
1896	Sanriku, Japan	28 000	
1897	Assam (M 8.7)	1542	6 major towns and all villages in 30 000 sq. miles leveled
1906	San Francisco (M 7.9?)	700	US$ 400 million
1908	Messina, Reggio (M 7.5)	160 000	98% of houses ruined
1915	Avezzano, Italy (M 7.0)	30 000	
1920	Kansu, China (M 8.5)	180 000	Vast landslides
1923	Tokyo (M 8.2)	143 000	Firestorm killed 38 000, 25 000 houses destroyed
1932	Kansu, China (M 8.5)	70 000	
1933	Long Beach, CA	120	US$ 50 million
1933	Sanriku, Japan	3000	8800 houses destroyed by tsunami
1935	Quetta (M 7.5)	60 000	
1939	Concepcion, Chile (M 8.5)	30 000	
1939	Erzincian, Turkey (M 8.0?)	40 000	30 000 dwellings destroyed
1948	Soviet Iran border	19 000	
1960	Agadir (M 9.5?)	60 000	
1960	Chile (M 9.5?)	10 000	58 600 houses destroyed
1964	Anchorage (M 8.4)	114	
1970	Peru (M 7.9)	80 000	Devastating rock and ice falls
1971	San Fernando, CA	64	US$ 1 billion
1975	Haicheng, China (M 7.5)	1328	
1976	Guatemala (M 7.5)	22 000

Formation (Figure 14). Here, the risk was well known but there was a lack of communication between the geologists and the planners.

Landslides and rock falls Very damaging landslides or rock falls can be triggered by earthquakes and may occur some time after the main shock or aftershocks. In Montana in 1985, 30 million tonnes of rock were

Figure 14 Destruction of the housing development at Turnagain Point above the Bootlegger Clay, Anchorage, 1994. The bluff moved 606 m towards the bay, and 75 homes were destroyed. Sand lenses in the clay lost strength (photograph National Geophysical Data Center, USA).

set in motion, fatally burying 36 people at a camp site. In Peru in 1970, rock and ice slides triggered by an earthquake killed 20 000 people.

Disease The risk of disease is a major concern after earthquakes, particularly in hot climates. Water supplies may be cut off and the populace may resort to using polluted supplies of water mixed with sewage and drainage effluents, which may be contaminated by corpses.

Starvation Normal food supplies may be cut off and transport arteries may be blocked, so it is important to bring in food supplies immediately from the world outside.

Exposure The 1988 Spitak earthquake in Armenia illustrates the problem of exposure. Many people lost their dwellings and were living in the open in very cold December climatic conditions. The need for tents, warm clothing, and blankets was urgent.

Looting Looting is prevalent after earthquakes.

Mitigation The potential for mitigation of the earthquake hazard is limited. The main ways of mitigating the hazard are through good building and constructional design, planning development away from at-risk areas, and warning. However, warning is a very difficult matter. Research into earthquakes is at an interim stage, and the scientific community is at present by no means in consensus about the physical processes involved. There is the problem of how threatened populations react to warnings: if the event fails to occur, especially more than once, the population may not heed future warnings; alternatively, giving a warning to evacuate may engender panic. In countries with controlled political systems, such as China, warning and evacuation may be easier than in a democratic Western country. The Chinese did evacuate the city of Haicheng twice in 1974 and 1975, on 4 December and again on 4 February, based on seismology, community monitoring levels, radon gas in water, water temperature, tiltmeters, magnetometer readings, and patterns of animal behaviour. An earthquake of magnitude 7.3 struck at 7.36 AM on 4 February. However, the great Tangshan earthquake of 1976 struck without any prediction or warning and killed at least 240 000 people (possibly many more).

Millions of US dollars have been spent on research into earthquakes in California, and some improvement in prediction has been achieved, yet the existence of the Northridge Fault, the site of the 1994 earthquake, which killed 60 people and caused 20 billion dollars worth of damage, was not even known before the event.

The best mitigation procedure would be to have international teams ready with emergency supplies and equipment, trained personnel, and sniffer dogs, at a distance from earthquake-prone regions, ready to been flown in by plane and helicopter.

Research into earthquakes The most important research into earthquakes has involved statistical,

geographical, geological, theoretical, and mathematical studies of seismicity. An example is a study by Lya Tuliani in Russia, which addressed problems of geodynamics and seismology, tectonosphere layering, and lithostructure in seismically active regions in order to develop risk estimates. The procedure involved mathematical data processing. It was claimed that this study allowed highly accurate prediction of the coordinates of high-risk sites. This statistical, mathematical, and office-based approach contrasts with research in the USA (which involves actually drilling down to earthquake foci on faults), research into the Boothiel lineament, the site of the New Madrid earthquakes (which has revealed sand boils caused by the earthquake), and excavations in the alluvium of the rice paddies west of Beijing, China (where the actual earthquake fault of a seventeenth century event has been exposed cutting the clayey alluvium in open pits). Research has been carried out into much older earthquakes in Iran, based on the dislocation of qanats (horizontal wells). All these approaches and many more are invaluable, but the problem of predicting earthquakes is extremely complex and may never be completely solved.

Volcanic Earthquakes

There can be a connection between major tectonic earthquakes and volcanic eruptions. In Chile in 1960, a major earthquake triggered the eruptions of several volcanoes, and in Sicily there is a record of Etna erupting a day or two before a major tectonic earthquake. However, the swarms of small seisms that usually precede volcanic eruptions (though there may be no such prelude) pose little threat to life and property. They do, however, provide valuable warnings of forthcoming eruption, and arrays of instruments are mounted on dangerous volcanoes for this purpose.

Man-Made Earthquakes

Small seismic disturbances can be triggered by human activity. In the USA, the Boulder Dam and Lake Mead are constructed in a region that is highly strained; many small shocks have been correlated with changes in water depth. In Colorado, the injection of liquid wastes down boreholes has also been shown to trigger small seisms.

Moonquakes and Seisms on Other Planets

Very small earthquakes do occur on the largely quiescent Moon when it undergoes maximum tidal stresses resulting from the attraction of the Earth and Sun. Similar stresses must operate on the Earth and cause minor seisms, but the effect is of no importance in such a dynamic body. Moonquakes and artificial seisms produced on the surfaces of other extraterrestrial bodies – Mars, Venus, and Mercury – can provide a valuable insight into their internal make up. A fascinating project would be to site an instrument from an unmanned spacecraft on Io, Jupiter's volcanically active satellite, to obtain detail of its interior configuration – Io must be seismically active.

Faults

S Stein, Northwestern University, Evanston, IL, USA

Introduction

Faults are surfaces in the Earth along which one side moves or has moved with respect to the other. They are identified either when an earthquake occurs or by geological mapping showing that motion across the fault has occurred in the past. Many faults are inactive, in the sense that there has been no motion across them within some defined time interval, typically the past million years or less. Other faults are active, in the sense that recent motion has occurred and hence motion might be expected in the future. Faults, and the earthquakes on them, are studied to understand both the regional tectonics and the mechanics of faulting.

Typically, earthquakes occur on previously identified faults, demonstrate that the fault is active, and provide information on the fault's geometry and the motion on it. For example, in the famous 1906 San Francisco earthquake, one of the first earthquakes to be carefully studied, several metres of relative motion occurred along several hundred kilometres of the San Andreas Fault. Hence, H Reid proposed the elastic-rebound theory of earthquakes, in which materials on opposite sides of the fault move relative to each other, but friction 'locks' the fault and prevents it from slipping (**Figure 1**). Eventually more strain accumulates than the fault rocks can withstand, and the fault slips in an earthquake. The motion is sometimes revealed after earthquakes by linear features, including roads and rows of trees (**Figure 2**). Those who study earthquakes seek to understand both the geological processes causing earthquakes and the physics of faulting. These issues are important for society because knowing where and when earthquakes are likely and the expected ground motion during them can help to mitigate the risk that they pose.

The largest earthquakes occur at plate boundaries. We view them as the most dramatic part of the seismic cycle, which takes place on segments of the plate boundary over hundreds or thousands of years. During the interseismic stage, which makes up most of the cycle, steady motion occurs at a distance from the locked fault. Immediately prior to rupture there is the preseismic stage, during which small earthquakes (foreshocks) and other possible precursory effects may occur. The earthquake is the coseismic phase, during which rapid fault slip generates seismic waves. During these few seconds, metres of slip on the fault 'catch up' with the few millimetres per year of motion that have occurred over hundreds of years at a distance from the fault. Finally, a postseismic phase occurs after the earthquake, during which aftershocks and transient afterslip occur for a period of years before the fault resumes steady interseismic behaviour.

Because this cycle extends over hundreds of years, we do not have observations of it in any one place. Instead, our view of the seismic cycle is based on a combination of observations from different places. It is far from clear how good this view is and how well our models represent the complexity of the seismic cycle. As a result, earthquake and fault studies remain active research areas that integrate a variety of techniques. Seismology is used to study the motion during earthquakes. Historical records often provide data on the earthquake cycle for a given fault segment. Field studies provide information about the location, geometry, and history of faults. Geodetic measurements are used to study ground deformation before, during, and after earthquakes and thus provide information about the processes associated with fault locking and afterslip. Results for individual earthquakes are combined with those from other analyses, including laboratory studies of rock deformation, to understand how the earthquakes in a region reflect the large-scale tectonic processes causing them and to study the physics of faulting.

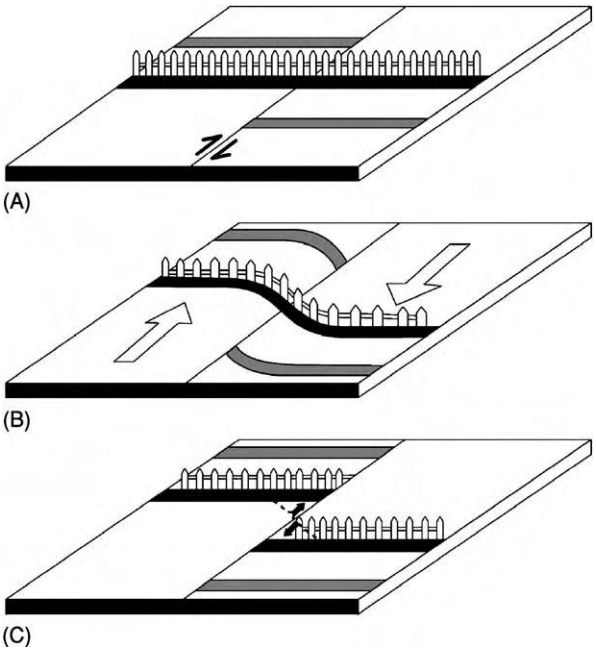

Figure 1 The elastic rebound model of earthquakes assumes that between earthquakes material at a distance from the fault undergoes relative motion. Because the fault is locked, features across it that were originally linear (A), such as a fence, are slowly deformed with time (B). Finally, the strain becomes so great that the fault breaks in an earthquake, offsetting the features (C). Fault Geometry

We treat faults as planar surfaces across which relative motion occurs during earthquakes. Geological observations of faults that reach the surface show that this is often approximately the case, although complexities are common. This assumption is usually also consistent with seismic data.

As shown in Figure 3, the fault plane is characterized by **n**, its normal vector. The direction of motion is given by **d**, the slip vector in the fault plane. The slip vector indicates the direction in which the upper side of the fault, known as the hanging-wall block, moves with respect to the lower side of the fault, known as the foot-wall block. Because the slip vector is in the fault plane, it is perpendicular to the normal vector.

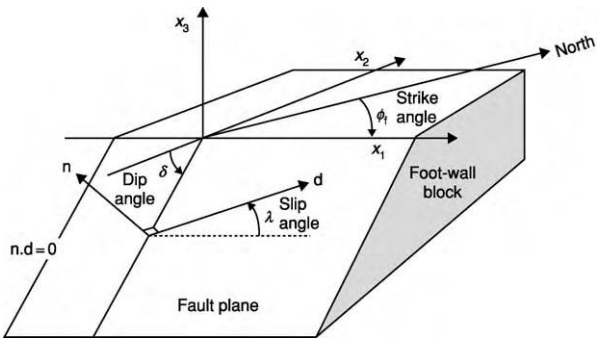

Figure 3 Fault geometry used in earthquake studies. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

A coordinate system for studying faults has the x_1 axis in the fault strike direction, the intersection of the fault plane with the Earth's surface. The x_3 axis points upwards, and x_2 is perpendicular to the other two axes. The dip angle, δ, gives the orientation of the fault plane with respect to the surface. The slip angle, λ, gives the motion of the hanging wall with respect to the foot wall. Fault geometries are described by the slip angle (Figure 4). When the sides slide by each other, pure strike-slip motion occurs. When $\lambda = 0°$, the hanging wall moves to the right, and the motion is called left-lateral. Similarly, for $\lambda = 180°$, right-lateral motion occurs. To tell which is which, look across the fault and see which way the other side moves. The other basic fault geometries describe dip-slip motion. When $\lambda = 270°$, the hanging wall slides downwards, causing normal faulting. In the opposite case, $\lambda = 90°$ and the hanging wall goes upwards, yielding reverse or thrust faulting. Seismologists often use the terms reverse fault and thrust fault interchangeably, whereas structural geologists reserve the term thrust fault for a shallow-dipping reverse fault. Most earthquakes consist of some combination of these motions and have slip angles between these values.

If we treat a fault as rectangular, the dimension along strike is called the fault length and the dimension in the dip direction is known as the fault width. Actual fault geometries can be much more complicated than a rectangle. The fault may curve, requiring a three-dimensional description. Rupture may occur over a long period and consist of several subevents on different parts of the fault with different

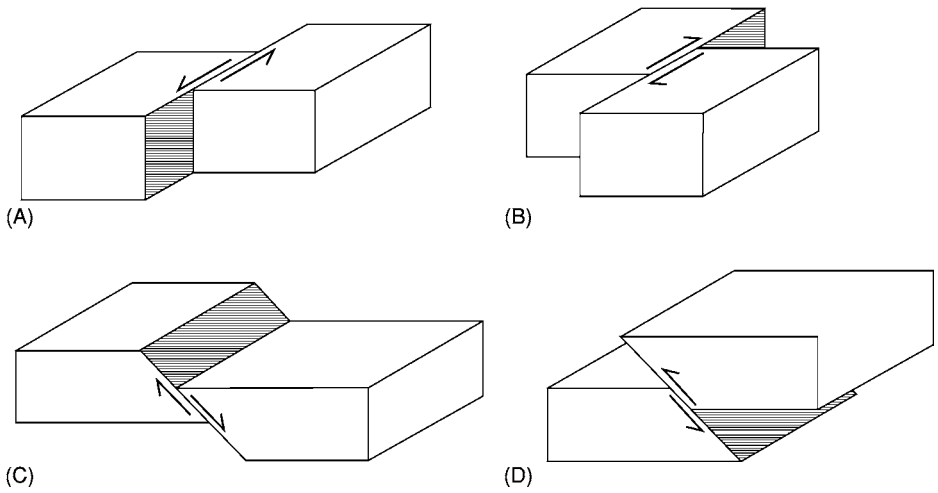

Figure 4 Basic types of faulting. (A) Left lateral strike slip fault, λ 0°. (B) Right lateral strike slip fault, λ 180°. (C) Normal dip slip fault, λ 90°. (D) Reverse dip slip fault, λ 90°. Figure 5 First motions of P waves observed at seismometers located in various directions about the earthquake provide information about the fault orientation. The nodal planes separate compressional ('up') and dilatational ('down') first arrivals. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

orientations. Such complicated seismic events, however, can be treated as a combination of simple events.

Seismological and Geodetic Studies

Seismological studies provide much of our information about earthquakes and the faults on which they occur. The arrival times of seismic waves at seismometers at different sites are first used to find the location of an earthquake, known as the focus or hypocentre. This location is often shown by the epicentre, the point on the Earth's surface directly above the earthquake. Next, the amplitudes and shapes of the radiated seismic waves are used to study the size of the earthquake, the geometry of the fault on which it occurred, and the direction and amount of slip.

The geometry of faulting during an earthquake, known as the focal mechanism, is found by using the fact that the pattern of radiated seismic waves depends on the fault geometry. Seismic waves are divided into P or compressional waves, in which material moves back-and-forth in the direction of wave propagation, and S or shear waves, where material moves at right angles to the propagation direction. P waves travel faster than S waves, so the first pulse to arrive is a P wave. The simplest method uses the first motion, or polarity, of the first-arriving P wave, which varies between seismic stations at different directions from an earthquake. As illustrated (Figure 5) for a strike-slip earthquake on a vertical fault, the first motion is either compression, for stations located such that material near the fault moves 'towards' the station,

or dilatation, where the motion is 'away from' the station. The first motions define compressional and dilatational quadrants, divided by two perpendicular nodal planes – the fault plane and the auxiliary plane, which is perpendicular to the fault plane. If these planes can be found, the fault geometry is known, and can be plotted using the familiar stereographic or 'beachball' representation.

Because the first motions from slip on the actual fault plane and the auxiliary plane would be the same, first motions alone cannot resolve which is the actual fault plane. However, additional information can often settle the question. Sometimes geological or geodetic information, such as the trend of a known fault or observations of ground motion, indicates the fault plane. Often, smaller aftershocks occur on and thus delineate the fault plane. If the earthquake is large enough, the finite time required for slip to progress along the fault causes variations in the waveforms observed at different directions from the fault; such directivity effects can be used to infer the fault plane.

More sophisticated techniques use the amplitudes and shapes of the seismic waves. These waves can be body waves, which travel through the Earth's interior, or surface waves, which propagate along paths close to the Earth's surface. The approach is to compare the observed body and surface waves with theoretical, or synthetic, waveforms computed for various source parameters, and find a model that best fits the data. Such analysis also gives information about the earthquake depths and rupture processes, which cannot be extracted from the first motions.

Figure 6 shows how body waves can be used to check the mechanism and estimate the depth. Synthetic seismograms were computed for various focal depths. The left-hand panel shows the expected timing and amplitudes of various arriving phases, and the right-hand panel shows the synthetic seismogram resulting from including the effect of the earthquake source and seismometer. The data are fitted well by a source at a depth of about 30 km.

Modelling surface waves can also help to resolve earthquake focal mechanisms and depths. Depending on the fault geometry, more energy is radiated in some directions than others. Figure 7 shows theoretical radiation patterns for the two kinds of surface waves, Love and Rayleigh, corresponding to several focal mechanisms with a fault plane striking north. The patterns are distinctive: a vertical strike-slip fault has two four-lobed patterns, such that Love-wave amplitude has maxima in the north, east, south, and west directions, whereas the Rayleigh-wave amplitude has maxima in the north-east, south-east, south-west, and north-west directions. In contrast, a dip-slip fault dipping at 45° has a four-lobed Love-wave pattern and a two-lobed Rayleigh-wave pattern. Such patterns can be generated for any fault geometry and compared with observations to find the best-fitting source geometry.

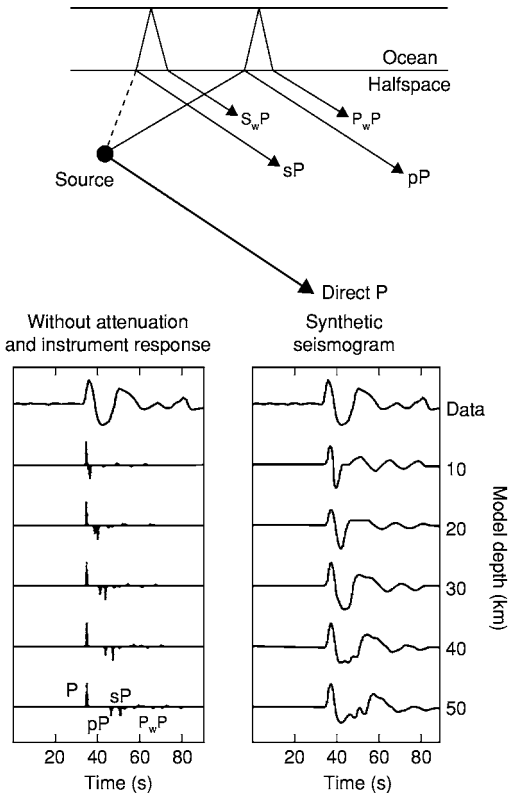

Figure 6 Body wave modelling for depth determination. Synthetic seismograms for an assumed fault geometry, including the effects of the seismometer and attenuation, are calculated for various depths. The data are best fitted by a depth of approximately 30 km. (Reproduced from Stein S and Wiens D (1986) Depth determination for shallow teleseismic earthquakes: methods and results. *Reviews of Geophysics and Space Physics* 24: 806 832.)

For earthquakes on land, additional information is derived by measuring the deformation of the Earth resulting from the earthquake using geodesy, the science of the Earth's shape. Most such techniques rely on detecting the motion of geological or manmade features or of geodetic monuments, which are markers in the ground. Until recently, these measurements were typically made by triangulation, which measures the angles between monuments using a theodolite, or trilateration, which measures distances with a laser. Vertical motion was measured using a precise level to sight on a distant measuring rod. However, the advent of geodetic methods using signals from space permits all three components of position to be measured with sub-centimetre precision. As a result, geodetic measurements before and after earthquakes can now determine

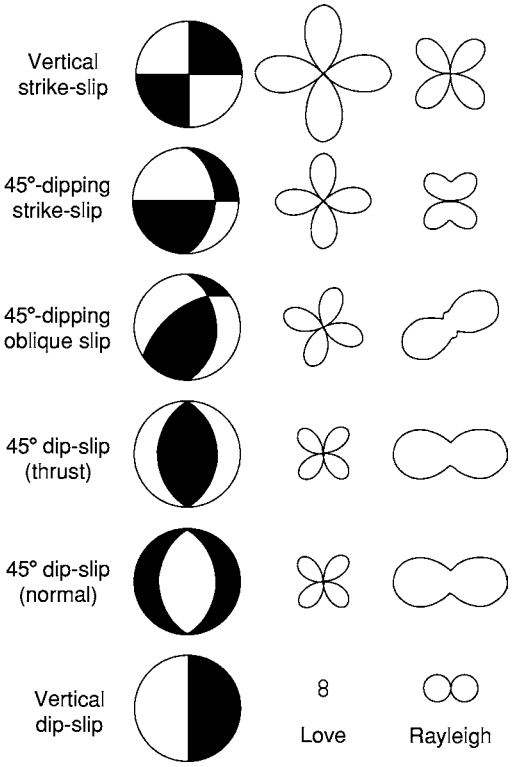

Figure 7 Focal mechanisms and surface wave amplitude radiation patterns for six fault geometries. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

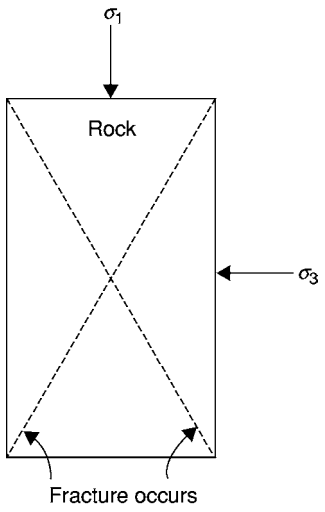

Figure 8 Schematic illustration of an experiment in which a rock sample is compressed along the direction of the maximum principal stress until fracture occurs. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

coseismic motion with high precision much more easily than was previously possible.

Faults and Stresses

The simplest theory for fracture predicts that faulting will occur on the plane on which the shear stress is highest. Although this is not exactly true, it provides an insight into the relation between fault orientations and regional tectonics. Consider an experiment in which a rock is compressed (Figure 8) with principal stresses $|\sigma_1| \geq |\sigma_2| \geq |\sigma_3|$. We expect fracture on the planes of maximum shear stress, which are 45° from the maximum and minimum principal stress axes and include the intermediate principal stress axis. Alternatively, if the experiment involves a situation known as uniaxial compression, where $|\sigma_1| \geq |\sigma_2| = |\sigma_3|$, failure should occur on any plane at 45° to the maximum principal stress (σ_1) axis. Experiments support the idea that fracture is controlled by shear stress, but in a more complicated way, so the fracture plane is often about 25° rather than 45° from the maximum principal stress direction.

For simplicity, however, we often assume that faults in the Earth form on the planes of maximum shear stress. The three basic fault geometries – strike-slip, normal, and thrust – are related to the stress axes (Figure 9). If the vertical principal stress is the most compressive, the fault dips at 45°, and normal faulting occurs. If, instead, the vertical principal stress is the least compressive, the fault geometry is the same but reverse or thrust faulting occurs. When the vertical principal stress is the intermediate principal stress, strike-slip motion occurs on a fault plane 45° from the maximum principal stress. Thus, the geometry of faults, which can be mapped geologically or inferred from seismograms of earthquakes, can be used to study stress orientations.

Fault Strength

Using seismic waves alone limits what we can learn about the earthquake process. The seismic waves radiated from an earthquake reflect the geometry of the fault and the motion on it, and so can give an excellent picture of the kinematics of faulting. However, they contain much less information about the actual physics, or dynamics, of faulting. Hence seismological results are combined with experimental and theoretical studies of rock friction and fracture to explore the physics of faulting.

Consider the strain that results from compressing a rock specimen. For small stresses the resulting strain is proportional to the applied stress, so the material is purely elastic (Figure 10A). Once the stress reaches the rock's fracture strength, σ_f, the rock breaks. Such brittle fracture is the simplest model

for an earthquake on a fault. Other materials show a change in the stress–strain curve for increasing stresses (Figure 10B). For stresses less than the yield stress, σ_o, the material acts elastically. If the stress is released, the strain returns to zero. However, for stresses greater than the yield stress, releasing the stress relieves the elastic portion of the strain but leaves a permanent deformation (Figure 10C). If the material is restressed, the stress–strain curve now includes the point of the permanent strain. The portion of the curve corresponding to stress above the yield stress is called plastic deformation, in contrast to the elastic region where no permanent deformation occurs. Materials showing significant plasticity are called ductile.

At low pressures rocks are brittle, but at high pressures they behave ductilely, or flow. Figure 11 shows experiments where a rock is subjected to a compressive stress that exceeds a confining pressure. For confining pressures less than about 4 Kb the material behaves brittlely – it reaches the yield strength and then fails. For higher confining pressures the material flows ductilely. These pressures occur not far below the Earth's surface – each 3 km increase in depth corresponds to a 1 Kb increase in pressure, so 8 Kb is reached at about 24 km.

How fault behaviour varies with depth is often discussed in terms of the strength – the maximum difference between the horizontal and vertical stresses that the rock can support. At shallow depths rocks fail either by brittle fracture or by frictional sliding on pre-existing faults, and strength increases with depth. However, at greater depths, rocks deform ductilely, as described by flow laws, which show that strength decreases as the temperature increases. This temperature-dependent behaviour is the reason that the cold lithosphere forms the planet's strong outer layer and that earthquakes occur only to a given depth. These variations are described by strength plots known as strength envelopes.

Figure 12 shows strength envelopes appropriate for old oceanic lithosphere and a stable continental interior. In the frictional region, curves are shown for various values of the ratio of pore pressure to lithostatic pressure, because higher pore pressures result in lower strengths. Ductile flow laws are shown for quartz and olivine, minerals often used as models

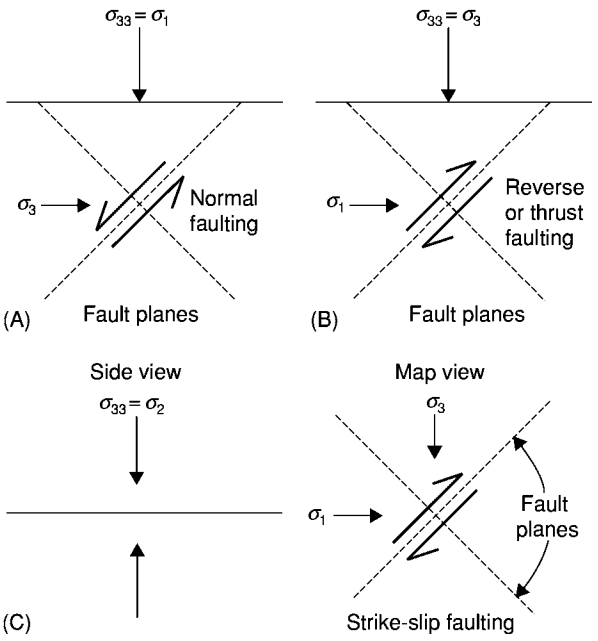

Figure 9 Stress fields associated with the three types of faulting, assuming that the earthquake occurred on a plane of maximum shear stress. (A) Normal, (B) reverse, (C) and strike slip faulting involve different orientations of the principal stresses. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

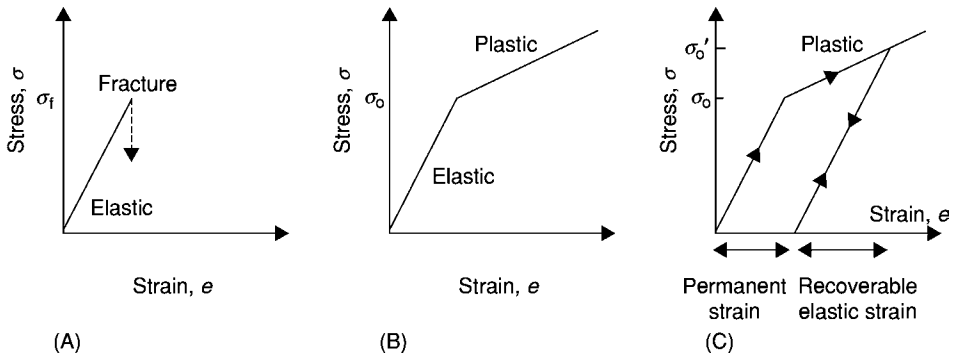

Figure 10 (A) Stress strain curve for a material that is perfectly elastic until it fractures when the applied stress reaches σ_f. (B) Stress strain curve for a material that undergoes plastic deformation when the stress exceeds a yield stress, σ_o. (C) Permanent strain results from plastic deformation when the stress is raised to σ_o' and released. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

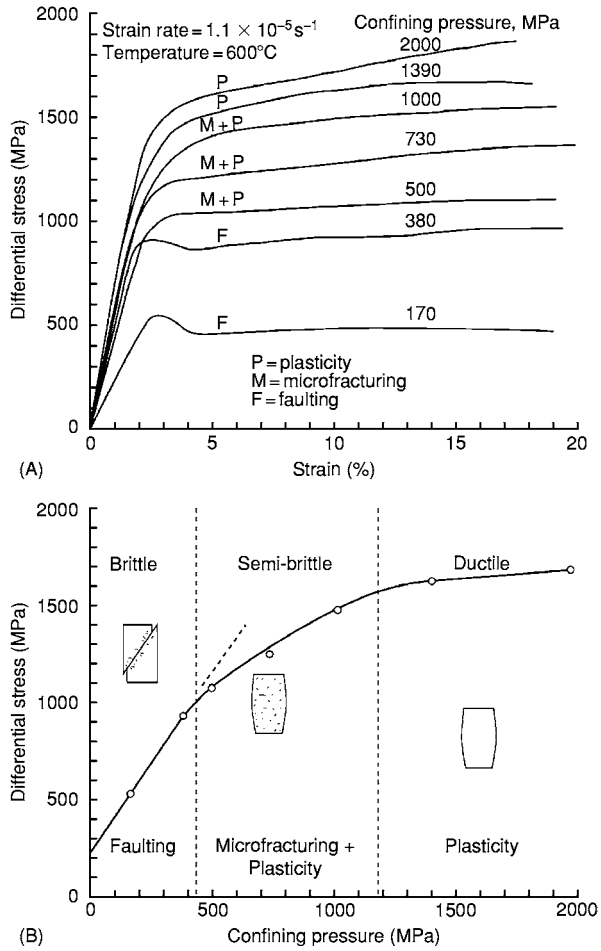

Figure 11 Results of an experiment in which rocks were subjected to a compressive stress greater than the confining pressure. (A) Differential stress strain curves (c.f. **Figure 10**) for various confining pressures. (B) At low (less than 4 Kb) confining pressures the material fractures and its strength increases with pressure. At higher pressures the material is ductile and its strength increases only slowly with pressure. A semi brittle transition regime, in which both microfractures and plasticity occur, separates the brittle and ductile regimes. (Reproduced from Kirby SH (1980) Tectonic stresses in the lithosphere: constraints provided by the experimental deformation of rocks. *Journal of Geophysical Research* 85: 6353–6363.)

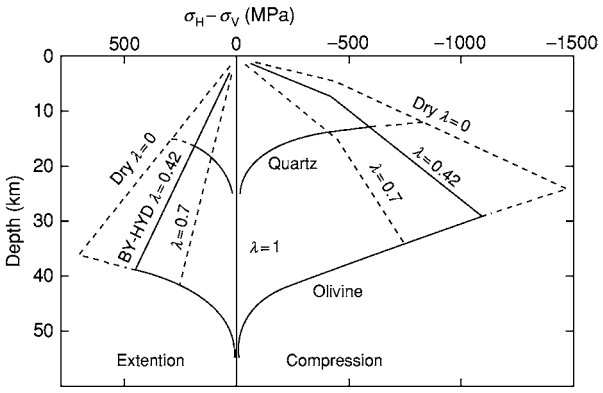

Figure 12 Strength envelopes as a function of depth for various values of λ, the ratio of pore pressure to lithostatic pressure. At shallow depths, strength is controlled by brittle fracture; at greater depths ductile flow laws predict rapid weakening. In the ductile flow regime, quartz is weaker than olivine. In the brittle regime, the lithosphere is stronger in compression (right side) than in extension (left side). (Reproduced from Brace WF and Kohlstedt DL (1980) Limits on lithospheric stress imposed by laboratory experiments. *Journal of Geophysical Research* 85: 6248–6252.)

for continental and oceanic rheologies, respectively. Strength increases with depth in the brittle region owing to the increasing normal stress, and then decreases with depth in the ductile region owing to increasing temperature. Hence strength is highest at the brittle–ductile transition. Strength decreases rapidly below this transition, so the lithosphere should have little strength at depths greater than about 25 km in the continents and 50 km in the oceans. As a result, the limiting temperature for continental seismicity is lower than for oceanic seismicity.

Faulting and Rock Friction

It is natural to assume that earthquakes occur when tectonic stress exceeds the strength, so steady motion across a plate boundary would give a series of successive earthquakes at regular intervals (**Figure 13**). However, the time between earthquakes on plate boundaries varies even though the plate motion causing the earthquakes is steady. Some of the variation may be due to the intrinsic randomness of the failure process, such that some small ruptures cascade into large earthquakes whereas others do not. Another cause of the variation may be features of rock friction.

Interesting insight emerges from considering an experiment in which stress is applied to a faulted rock, where motion occurs once the stress reaches a certain level. As stress is reapplied, this pattern of jerky sliding and stress release continues. This stick–slip pattern looks like a laboratory version of earthquakes on a fault: as the fault is loaded by tectonic stress, occasional earthquakes occur. The analogy is strengthened by the fact that at higher temperatures (about 300°C for granite) stick–slip does not occur. Instead, stable sliding occurs, in much the same way as earthquakes do not occur at depths where the temperature exceeds a certain value. Stick–slip results from a familiar phenomenon: it is harder to start an object sliding against friction than to keep it sliding. This is because the static friction stopping sliding exceeds the dynamic friction that opposes motion once sliding starts.

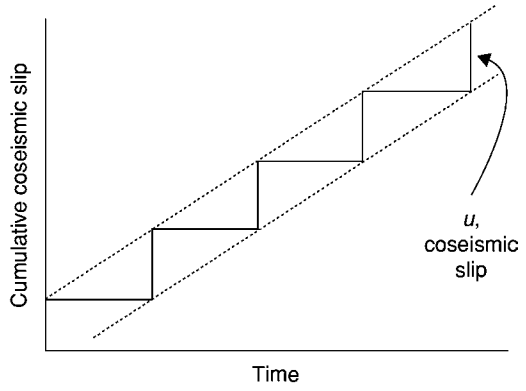

Figure 13 Slip history for an idealized earthquake cycle on a plate boundary, in which all earthquakes have the same coseis mic slip. (Reproduced from Shimazaki K and Nakata T (1980) Time predictable recurrence model for large earthquakes. *Geophysical Research Letters* 7: 279 282.)

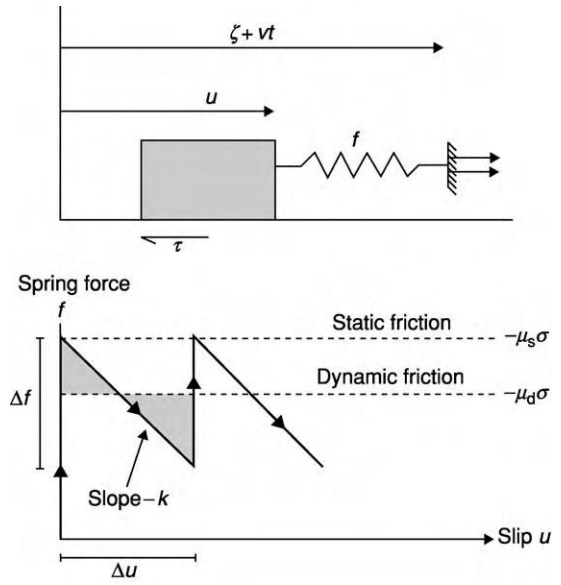

Figure 14 A simple spring and block analogue illustrating stick slip as a model for earthquakes. (Reproduced from Stein S and Wysession M (2003) *Introduction to Seismology, Earthquakes, and Earth Structure*. Blackwell Publishing.)

To gain an insight into stick–slip as a model for earthquakes, consider the experiment illustrated in Figure 14. If an object is pulled across a table with a rubber band, jerky stick–slip motion occurs. This situation can be modelled by assuming that a block is loaded by a spring that applies a force, f, that is proportional to its stiffness, k, and extension. If loading results from the spring's far end moving at velocity v, the spring force increases with time. The block starts sliding once the spring force exceeds the frictional force $\mu_s\sigma$ where μ_s is the static friction coefficient and σ is the normal stress due to the block's weight. Once sliding starts, the friction drops to its dynamic value μ_d, and the driving force decreases as the spring shortens, until it becomes less than the friction force. The block slows and eventually stops once the shaded area above the spring-force line equals that below the line, or when the work done accelerating the block equals that which decelerated it. If the spring end continues to move, loading continues until the spring force again equals the static friction force and another slip event occurs.

Laboratory experiments show that the difference between static and dynamic friction is more complicated than is assumed in this simple model. We can think of the lower dynamic friction as showing either velocity weakening, decreasing as the object moves faster, or slip weakening, decreasing as the object moves further. Frictional models, called rate-dependent friction and state-dependent friction, with a variable coefficient of sliding friction are used to describe these effects. Velocity weakening permits earthquakes to occur by stick–slip, whereas for velocity strengthening stable sliding is expected. Laboratory results show that for granite the transition occurs at about 300°C, which should be the limiting temperature for earthquakes. Thus, the frictional model predicts a maximum depth for continental earthquakes that is similar to that predicted by the rock-strength arguments.

These results can be used to simulate the earthquake cycle. Figure 15 shows the slip history as a function of depth and time for a model in which a strike-slip fault is loaded by plate motion. The fault has rate- and state-dependent frictional properties such that stick–slip occurs above 11 km. From time A to time B, stable sliding occurs at depth and a little precursory slip occurs near the surface. The earthquake causes 2.5 m of sudden slip at shallow depths, as shown by the curves for times B and B′. As a result, the faulted shallow depths 'get ahead' of the material below, loading that material and causing postseismic slip from time B to time F. Once this is finished, the 93-year cycle starts again with steady stable sliding at depth.

Such models replicate many aspects of the earthquake cycle. An interesting difference, however, is that the models predict earthquakes at regular intervals, whereas earthquake histories are quite variable. Some of the variability may be due to the effects of earthquakes on other faults or other segments of the same fault. Figure 16 shows this idea schematically for the block model. Assume that after an earthquake cycle the compressive normal stress is reduced. This 'unclamping' reduces the frictional force resisting sliding, so it takes less time for the spring force to rise to the level needed for the next slip event. Conversely,

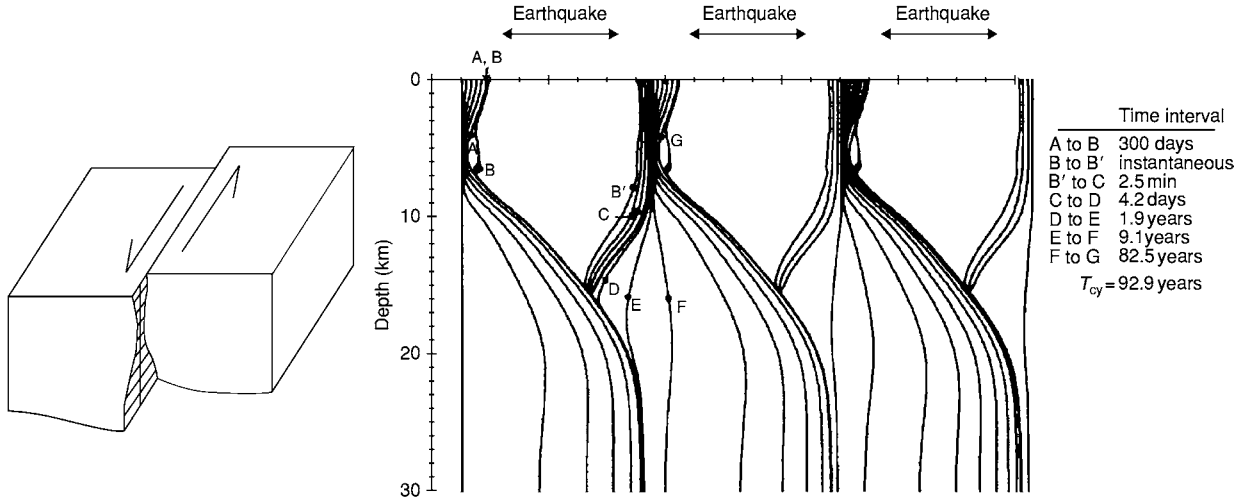

Figure 15 Earthquake cycle for a model in which a strike slip fault with rate and state dependent frictional properties is loaded by plate motion. The slip history for three cycles as a function of depth and time is shown by lines representing specific times. Steady motion occurs at depth, and stick slip occurs above 11 km. (Reproduced from Tse ST and Rice JR (1986) Crustal earthquake instability in relation to the depth variation of frictional slip properties. *Journal of Geophysical Research* 91: 9452 9472.)

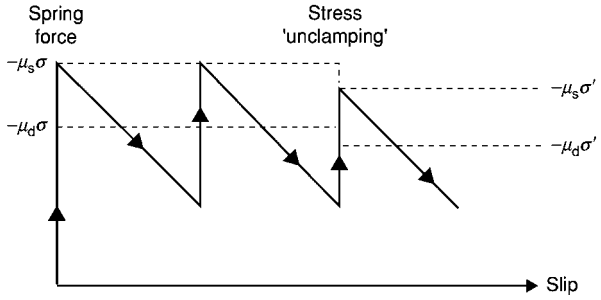

Figure 16 Modification of the block model shown in **Figure 14** to include the effects of changes in normal stress. Reduced normal stress reduces the frictional force, 'unclamping' the fault and decreasing the time to the next slip event. (Reproduced from Stein S and Wysession T (2003) *Introduction to Seismology, Earthquakes, and Earth Structure.* Blackwell Publishing.)

increased compression 'clamps' the block more, increasing the time to the next slip event. This analogy implies that earthquake occurrence on a segment of a fault may reflect changes in the stress on the fault resulting from earthquakes elsewhere. Some earthquake observations provide support for this idea.

Folding

J W Cosgrove, Imperial College London, London, UK

Introduction

A fold is defined as "...a curved arrangement of originally parallel surfaces ..." and a large range of terms have been used to describe geological folds. These including folds, flexures, inflexions, bendings, plications, undulations, and crenulations. Although today most geologists use the term fold for buckle folds and many reserve flexure for layer deflections caused by bending, the terms are also used as synonyms.

Folds form on all scales, from those with a wavelength of a few mm that can only be seen in rock thin sections under the microscope, to folds with wavelengths in excess of 10 km. The mechanisms of formation are independent of size; however, for large-scale folds it is important to take into account the effect of gravity when analysing their folding behaviour.

Folds in rocks form under a wide variety of conditions. For example, folds can occur at all depths in the crust from early, near-surface folding linked to the slumping of water saturated, uncemented sediments down continental slopes, to folding of rocks under the high pressures and temperatures encountered in the lower crust. Folding of rocks occurs by various processes, the three most important being buckling, bending, and flowing. Buckling, which is the most common type of fold, requires the rock to possess a mechanical anisotropy, usually layering, and for the maximum compressive stress to act parallel or subparallel to the layering. In contrast, bending is defined as a transverse deflection of a layer or beam by a transverse couple. Flow folding occurs during the flow of a material such as lava, salt, or ice. No mechanical anisotropy is necessary for this type of folding, only passive marker bands that reveal the flow patterns within the material.

Although folds are structures that are characteristic of ductile deformation, they are often found in association with fractures (*see* **Tectonics:** Fractures (Including Joints)). The fractures result from the same stress field responsible for folding and the resulting fracture patterns, which are controlled by the mechanisms by which the folds form, can play an important role in hosting mineralization and in the storage of fluids such as water and hydrocarbons.

Fold Geometry

The main geometric parameters relating to the three-dimensional geometry of a fold are shown in Figure 1A. However, although folds are three-dimensional structures they are most commonly exposed as two-dimensional sections on joint surfaces. Consequently, their detailed classification is based on the geometry of a section. Because of the dependence of fold geometry on the orientation of the section (Figure 1B), a particular section is used to determine the geometry, namely the profile section, i.e., the section at right angles to the fold hinge. Historically, the problem of describing layer shape developed around two geometrical models, the parallel fold and the similar fold (Figure 2A and B). As the name implies, in parallel folds the orthogonal thickness of the layer remains constant. In similar folds, the layer thickness, parallel to the hinge surface remains constant. Although similar folds show considerable variations in layer thickness, this type of folding can produce folds which can extend indefinitely in the profile section, whereas with parallel folds this is not possible (Figure 2A and B).

As can be seen from Figure 2C, these two fold types are examples from a complete spectrum of possible geometries. The spectrum has been divided into five classes based on the pattern of dip isogons, i.e., lines

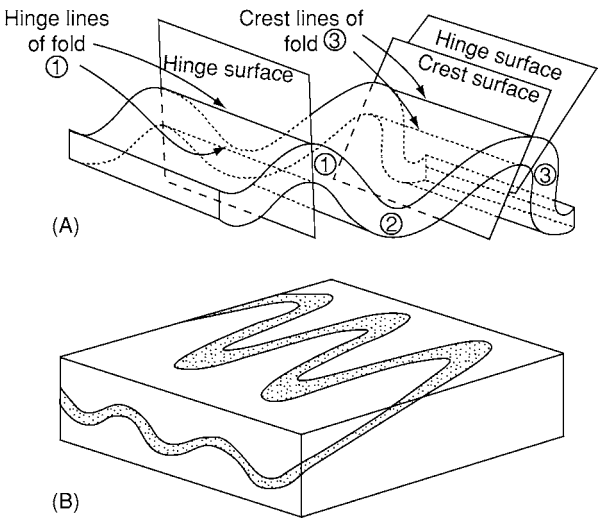

Figure 1 (A) Geometric features of a fold. Fold 1 is symmetric and folds 2 and 3 asymmetric. (B) Diagram showing the dependence of fold outcrop pattern on the orientation of the plane of exposure.

joining points of equal dip on the two surfaces defining the folded layer. The parallel folds and similar folds are class 1b and 2, respectively.

Mechanisms of Folding

The two most important mechanisms by which folds form in rocks are buckling, the result of compression parallel or sub-parallel to the rock layering and bending, the result of compression at a high angle to the layering, (Figure 3A and B, respectively).

Buckle Folds

The most commonly formed folds in the Earth's crust are buckle folds. In order for these folds to form, the rock must possess a mechanical anisotropy. This is generally a planar mechanical anisotropy because a variety of geological processes give rise to such materials. Rocks can be intrinsically anisotropic because of the process of their formation such as, for example, a bedded sedimentary succession, or the anisotropy can be induced as a result of subsequent deformation and metamorphism during which time they can develop planar and linear mineral fabrics as they are converted to slates, phyllites, schists, and gneisses. Buckling systems can be sub-divided into four groups, namely folds formed by: (i) the buckling of a single interface, (Figure 3C); (ii) the buckling of two interfaces, which define a single layer in a matrix (Figure 3D); (iii) the buckling of several layers (Figure 3E); and (iv) the buckling of a mineral fabric such as a slate or schist (Figure 3F).

Interface Buckling

Interface buckling occurs on many scales, from large buckles that form at the boundary between the Mesozoic cover rocks and older basement in the French Alps as a result of the collision of the African and

European plates (Figure 4A), to small-scale examples directly observable in the field (Figure 4B) and formed in analogue models in the laboratory (Figure 4C). The folds start as symmetric sinusoidal deflections but as they amplify change their geometry into the marked cusp geometry seen in Figure 4. The cusps always point into the stronger of the two materials.

Single Layer Buckling

Single layers occur commonly in nature, for example, an isolated sandstone or limestone bed in a thick shale or marl sequence or a sheet of igneous rock intruded into an unlayered matrix (Figure 5A), and they are commonly observed to buckle. Theoretical analyses

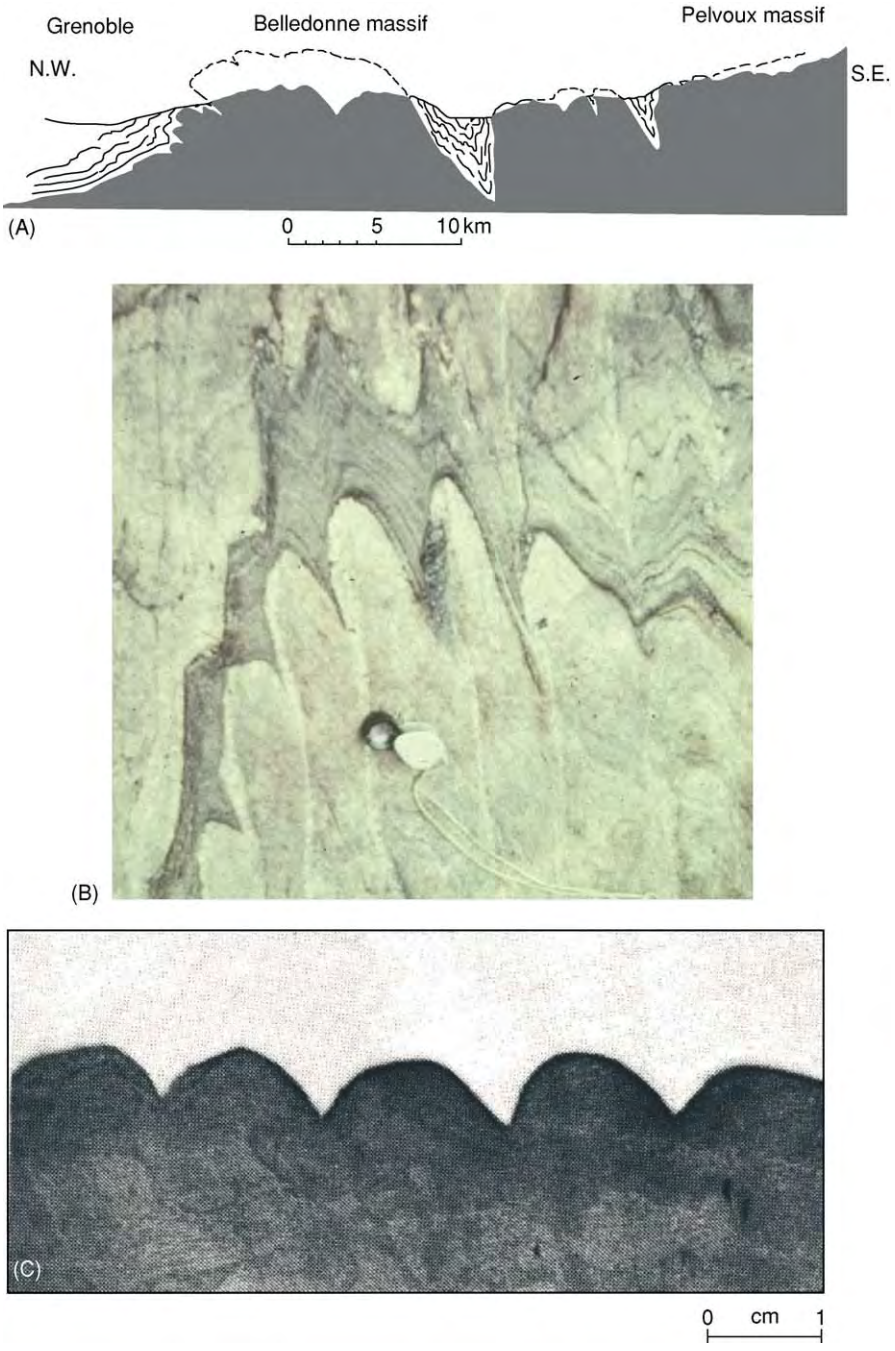

Figure 4 (A) The cuspate interface between the strong Hercynian basement rocks (black) and the weaker Mesozoic cover rocks, caused by the horizontal compression linked to the collision of the African and European plates. (B) Cusp structures formed at the interface between quartz rich (light) and mica rich (dark) bands, Loch Monar, Scotland. (C) Cusps generated by compression parallel to the interface between strong (black) and weak (light) plasticine.

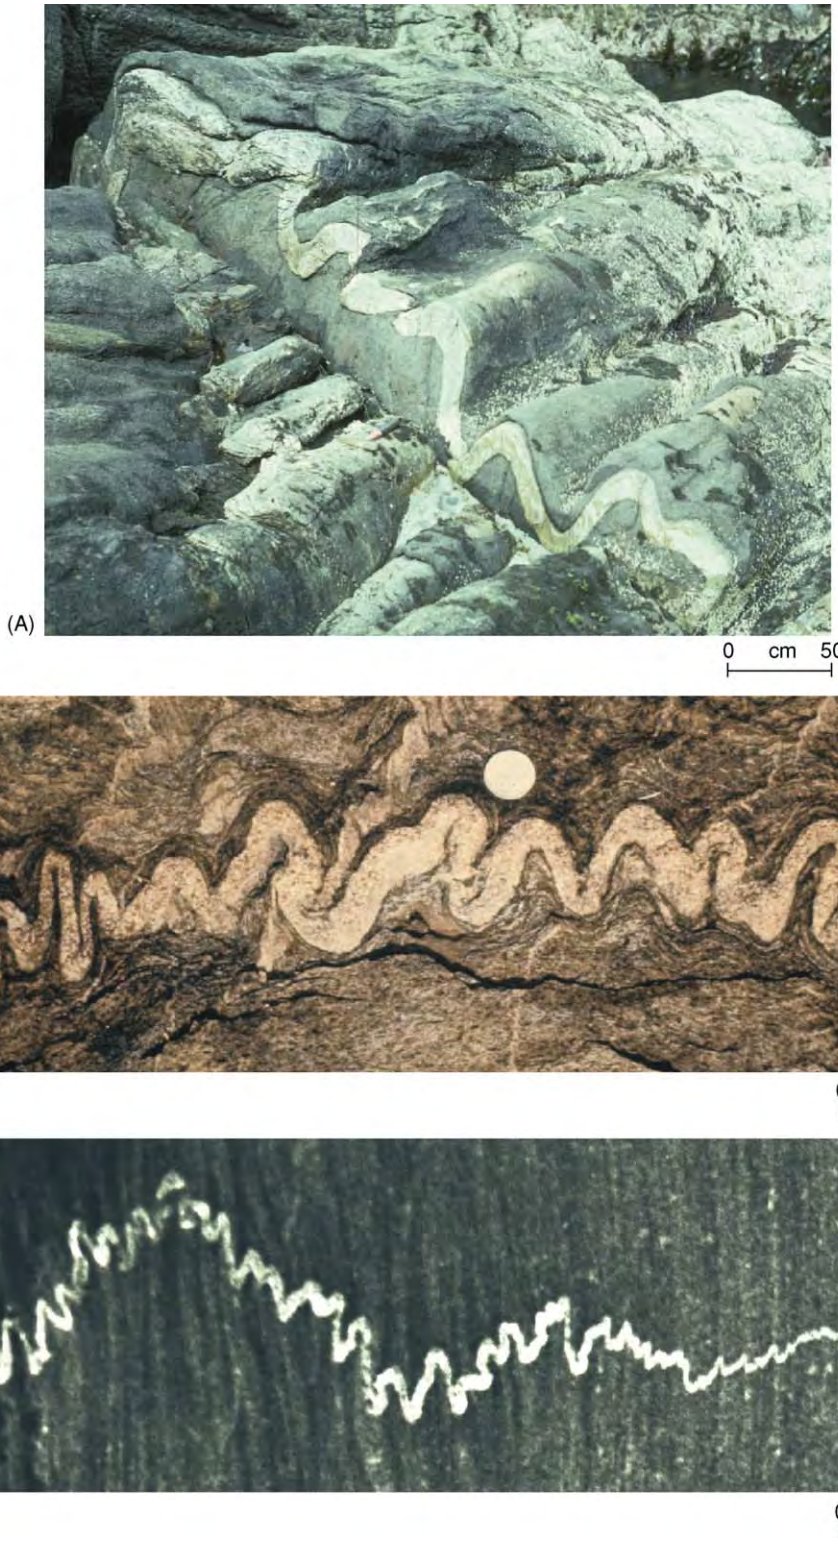

Figure 5 (A) A folded aplite dyke cutting a dolerite body, Outer Hebrides, Scotland. (B) A folded single layer, in which the folds are isoclinal. No further shortening of the layer can occur by limb rotation. Further compression may result in homogeneous flattening of the folds or in the folding of the layer into larger wavelength folds (see C). (C) A tapered quartz vein showing buckling on two scales. On both scales, the wavelength is seen to decrease with decrease in layer thickness.

predict and field observations confirm that there is a direct relationship between the wavelength (W) of folds that develop and the thickness (t) of the buckling layer (Figure 5C).

$$W = 2\pi t(\mu_1/6\mu_2)^{1/3} \quad [1]$$

The single layer buckling equation shows that in addition, the wavelength is also controlled by the ratio of the strength of the layer and matrix (μ_1/μ_2). The impact of the strength ratio (competence contrast) on fold style can be seen by rearranging eqn 1.

$$W/t = 2\pi(\mu_1/6\mu_2)^{1/3} \quad [2]$$

The wavelength/thickness ratio is determined by the relative strength of the layer and matrix. Folds with a range of W/t ratios are shown in Figure 6, which shows the control of the competence contrast between the layer and the matrix on the geometry of the buckles that form.

Once buckling has been initiated, layer shortening can continue by rotation of the fold limbs until the limbs become parallel to each other (i.e., the folds are isoclinal, Figure 5C), and no further shortening by limb rotation can occur. Shortening may continue by homogeneous flattening of the buckled layer and matrix, or alternatively continued compression may cause the buckled layer to buckle again. It has an effective thickness that is considerably greater than the original thickness of the layer and so, in accordance with the buckling equation eqn 1, will buckle with a larger wavelength (Figure 5C).

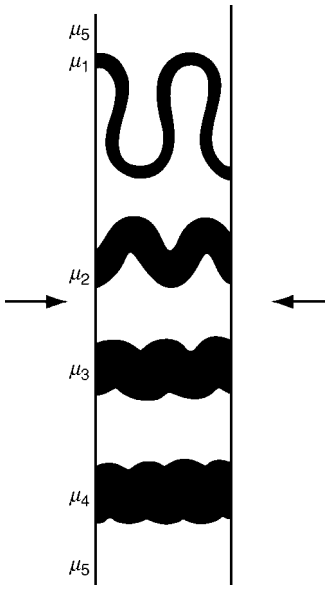

Figure 6 The effect of the ratio of the strength of the layer and the matrix on fold style. As the contrast decreases the wave length/thickness ratio also decreases. (After Ramsay (1982).)

Multilayer Buckling

The most common type of geological layering is that of a multilayer, i.e., a succession of different layers. Often the multilayer is made up of the regular alternation between two or three rock types. The regularity of these multilayers reflects the processes by which they were formed. For example, turbidites are formed as a result of the periodic, fluid-induced collapse of a sedimentary accumulation on the edge of the continental shelf. The fluidised sediments flow as dense turbidity currents down the continental slope, depositing first the heavy sands followed by the slower settling out of the fine shale particles. In this way a sequence of alternating sandstones and shales can be built up to form a turbidite.

The buckling behaviour of multilayers is controlled by the spacing of the strong units it contains. Figure 7A and B are both physical multilayers. However, their buckling behaviours are very different. The multilayer shown in Figure 7A behaves mechanically as a series of single layers, each layers folding

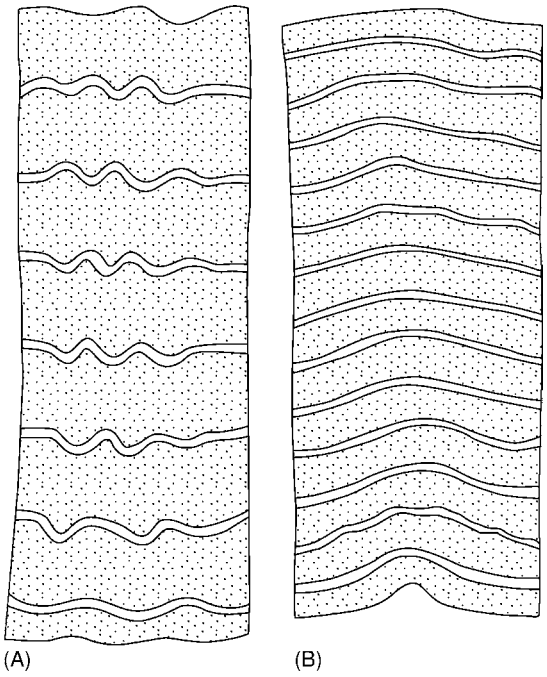

Figure 7 (A) and (B) show two compressed multilayers of alternating competent (white) and incompetent (stippled) rubber layers. The widely spaced layers (A) behave mechanically as single layers and form disharmonic folds; the more closely spaced layers behave mechanically as a multilayer and all layers form the same wavelength. (After Ramberg (1963).)

according to the single layer buckling equation, (eqn 1). This results in 'disharmonic folding'. In contrast, the multilayer shown in Figure 7B behaves mechanically as a multilayer, i.e., all the layers develop the same wavelength and amplitude. Such folding is called 'harmonic folding'.

These two types of buckling behaviour can be readily explained by considering the strain that develops in the matrix around a single, competent (i.e., strong with respect to the surrounding matrix) layer as it buckles. The zone of disturbance on each side of the buckling layer is known as the zone of contact strain. If the competent layers of a multilayer are sufficiently far apart for there to be no significant overlap of their zones of contact strain, then each layer will buckle as a single layer. If, however, the zones of contact strain of adjacent competent layers do significantly overlap, the layers can no longer buckle independently of each other. The zones of contact strain and associated zones of contact stress of adjacent layers must be compatible and, as a result, all the layers are subjected to the same stress field and develop the same wavelength.

In order to determine how close the competent layers of a multilayer must be for multilayer as opposed to single layer buckling to occur, it is necessary to know how far the zone of contact strain extends away from the layer into the matrix. For a viscous matrix it is found that the disturbance has died down to approximately 1% of its maximum value at a distance one wavelength from the layer (Figure 8).

The Buckling of Anisotropic Materials

The most complex buckling occurs in materials possessing a pervasive mechanical anisotropy. The anisotropy may be an intrinsic property of the rock resulting, for example, from the bedding parallel alignment of clay particles in a shale or induced during metamorphism when, for example, a slate or schist is formed from a mudstone. Theoretical studies and experimental work on such materials shows that there is a range of structures that can form when they are compressed parallel to the mineral fabric or layering. The two end members of this range are upright folds and box folds (Figure 9). The type of structure that forms is determined by the mechanical anisotropy of the material. As the anisotropy increases so the upright folds (Figure 9A), give way to folds with gently diverging axial planes (Figure 9B) and finally to box folds (Figure 9C).

It should be noted that if a geological multilayer has a sufficiently high mechanical anisotropy, it will buckle to form a box fold. An example of this is shown in Figure 10A, where a box fold with a wavelength of several 100 m has developed in Carboniferous turbidites from south-west England.

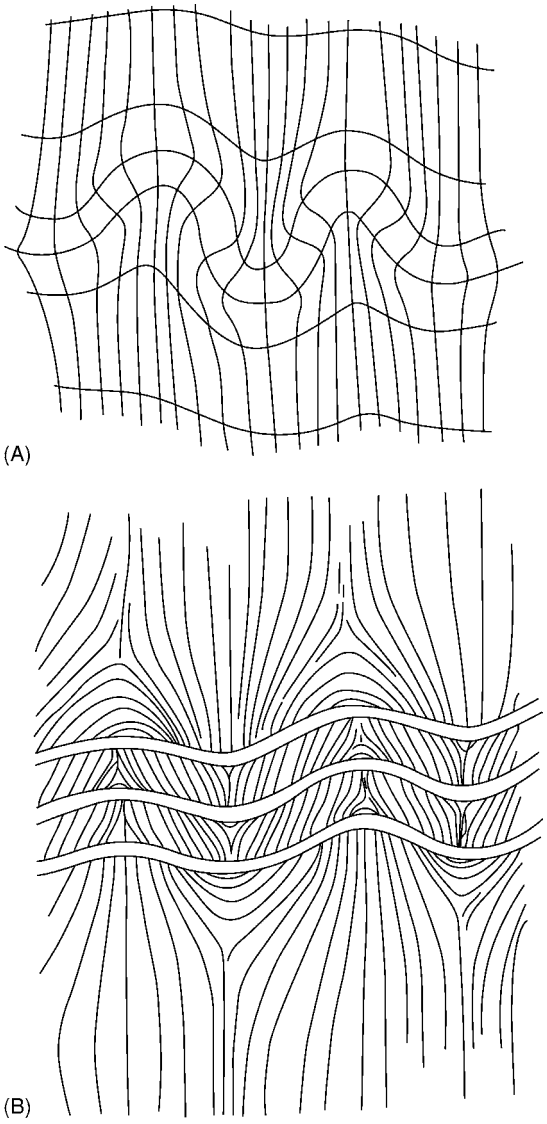

Figure 8 (A) Experimentally produced buckles in viscous materials showing the disturbance of the matrix (the zone of contact strain) by the buckling single layer (B) Folded multilayer where the proximity of the layers caused an overlap of the zones of contact stain and therefore the formation of multilayer buckles.

Experimental Work on Folds

One of the disadvantages of theoretical studies of folding is that they are often only valid for the first increment of buckling. Once buckling has been initiated, the assumptions of the analysis are violated and the theory cannot be used to predict the way in which the fold amplifies into a finite fold. In contrast, experimental work on models made from rock analogue materials such as gelatine, are ideal for the study of the amplification of folds. In addition, unlike

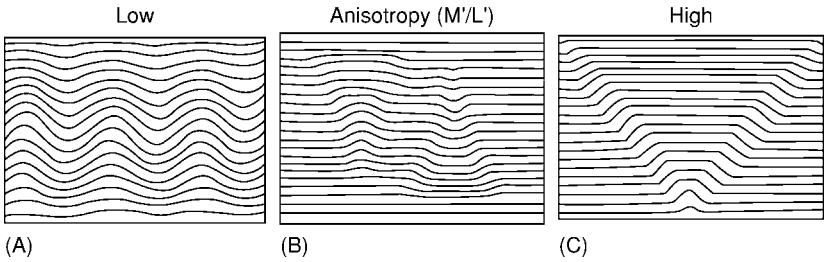

Figure 9 The structures that can form when a mechanically anisotropic material such as a mineral fabric of sedimentary layering is compressed parallel to the layering. Depending upon the anisotropy they range from upright folds with axial planes normal to the principal compression to box folds where the axial planes are inclined to the compression.

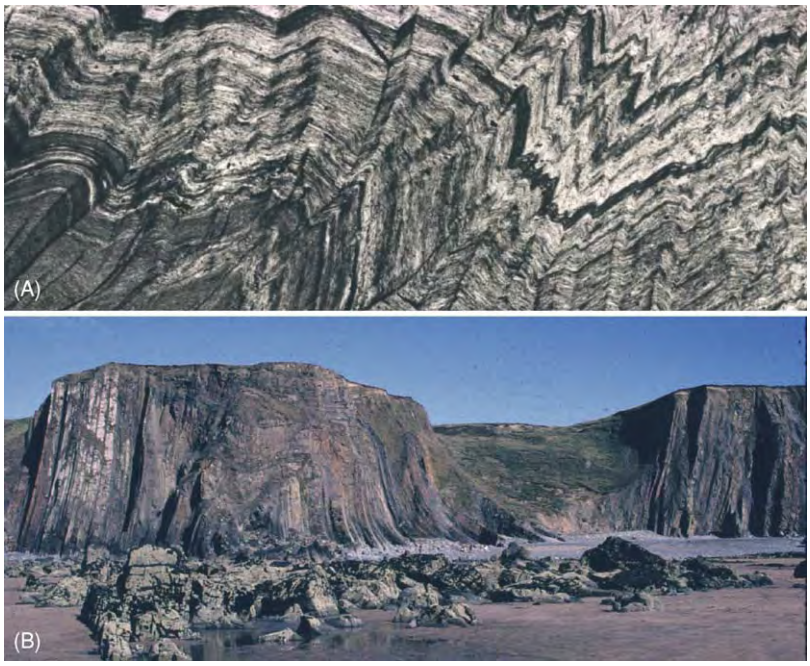

Figure 10 (A) Small scale box fold formed in a micaceous fabric and (B) large scale box fold formed by the buckling of a turbidite.

the theoretical treatments of folding which assume that the layered system is stressed instantaneously (i.e., that the process of stressing the material plays no part in the buckling), the experiments show that the process of stressing the layered system can influence the process of folding. Such experiments show that folds that form during the compression of the models do not generally develop synchronously. They form in a serial manner, either one after the other where the amplification of one fold stimulates the initiation and amplification of another next to it (Figure 11A), or one after the other at random positions within the model. Figure 11B shows such randomly positioned folds in the Jura mountains of Switzerland.

In the complex multilayers that occur in nature, it is often found that all types of buckling occur in the same multilayer. For example, in the multilayer shown in Figure 12, which is a finely laminated evaporite, examples of single layer buckling can be seen (layers 1 and 2) where the wavelength is determined by the thickness of the layers. The two layers are far enough apart for them to fold independently and they have done so producing an example of disharmonic folding. In area 3 of the multilayer, examples of multilayer folding where the folds have axial planes oriented at right angles to the layering can be seen (Figure 7B and 9A) and in area 4, box folds have formed with axial planes inclined to the layering (Figure 9C, 10A and B).

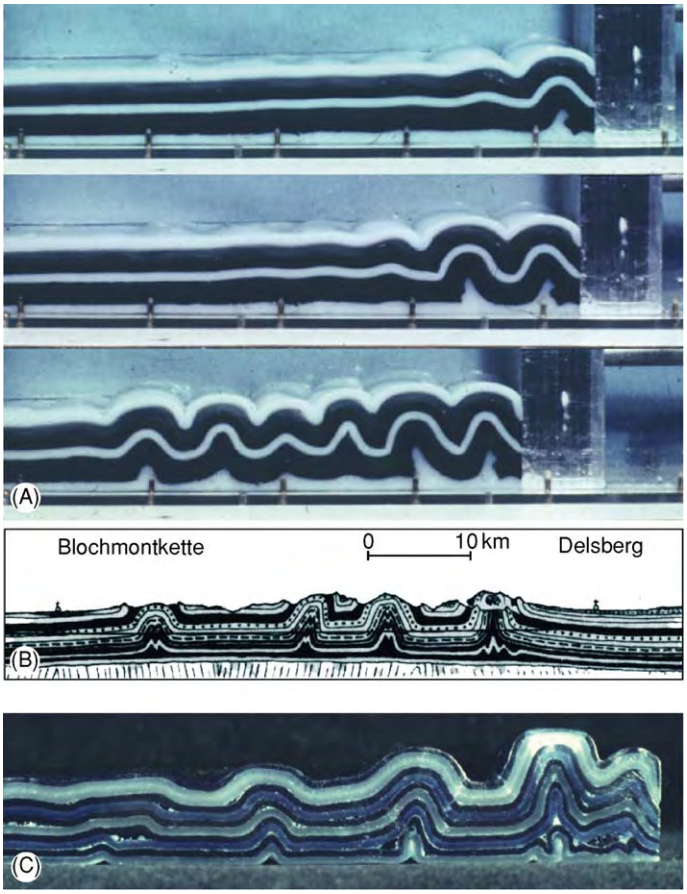

Figure 11 (A) The serial development of folds in a lubricated gelatine multilayer caused by a piston moving from right to left. (B) Isolated folds in the Jura mountains Switzerland. (C) Isolated folds in a lubricated wax multilayer.

Figure 12 Harmonic and disharmonic folding in a specimen of the Castile and Todilto evaporites, New Mexico, USA (c.f. layers 1 and 2). Some of the folding (layers 1 and 2), can be described by the theory of single layer buckling, some by the theory of multilayer buckling, (3) and some (4) by the theory of buckling of an anisotropic material.

Three-Dimensional Geometry of Buckle Folds

The three-dimensional geometry and spatial organization of buckle folds has been studied primarily by field observations and analogue modelling. These studies show that buckle folds have a periclinal geometry, i.e., have the form of an elongate dome, basin, or saddle (Figure 20A). The geometry of a pericline is often given in terms of the ratio of its half wavelength and its hinge length. This is termed the aspect ratio and although it will increase as the fold amplifies, it

is found that the majority of buckle folds in the upper crust have ratios of between 1:5 and 1:10. Typical geometries of geological folds are shown in Figure 13.

Bending

Bending is the term used to describe the flexuring of a layer induced by a compression acting at a high angle to the layering (Figure 1B). Geological flexures that are the result of bending are known as drape folds or forced folds and are frequently formed when sediments, which cover a more rigid basement, flex in response to components of vertical movement along basement faults (Figure 14). This may be normal movement, in which case the flexing of the layering involves layer parallel extension (Figure 14A), or reverse movement, in which case the folds that result will involve an element of buckling (Figure 14D).

A forced fold is defined as a fold in which the final overall shape and trend are dominated by the shape of some forcing member below. These are frequently fault blocks, movements of which produce linear fault scarps which in turn produce linear forced folds with an aspect ratio much higher that that associated with buckle folds and with different spatial organizations.

The two types of basement faults linked to the formation of forced folds are dip-slip faults (either normal or reverse Figure 14A and D respectively). These faults produce fault scarps at the basement–cover interface over which the forced folds form. When the third type of faulting, i.e., strike-slip or wrench faulting occurs in the basement, no fault scarp is produced and consequently no forced folds are produced in the overlying strata. However, movement on basement strike-slip faults can give rise to

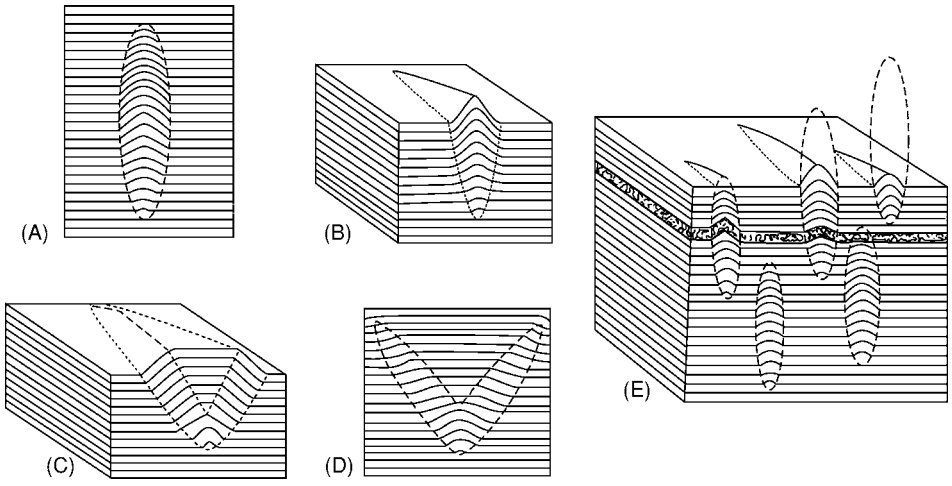

Figure 13 (A) Typical profile geometry of a fold in a multilayer. (B) Block diagram showing a fold dying out in both profile and plan view. (C) Block diagram and (D) profile geometry of a box fold. (E) The spatial organization of folds within a multilayer.

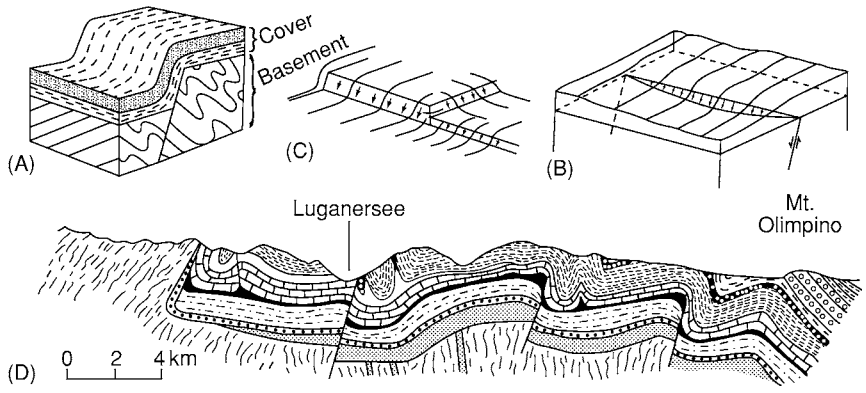

Figure 14 (A) and (B) block diagrams of drape or forced folds, the result of normal faulting in the basement. (C) shows the type of fold geometry which may be associated with block faulting in the basement. (D) Forced folds probably formed over reverse faults in the basement.

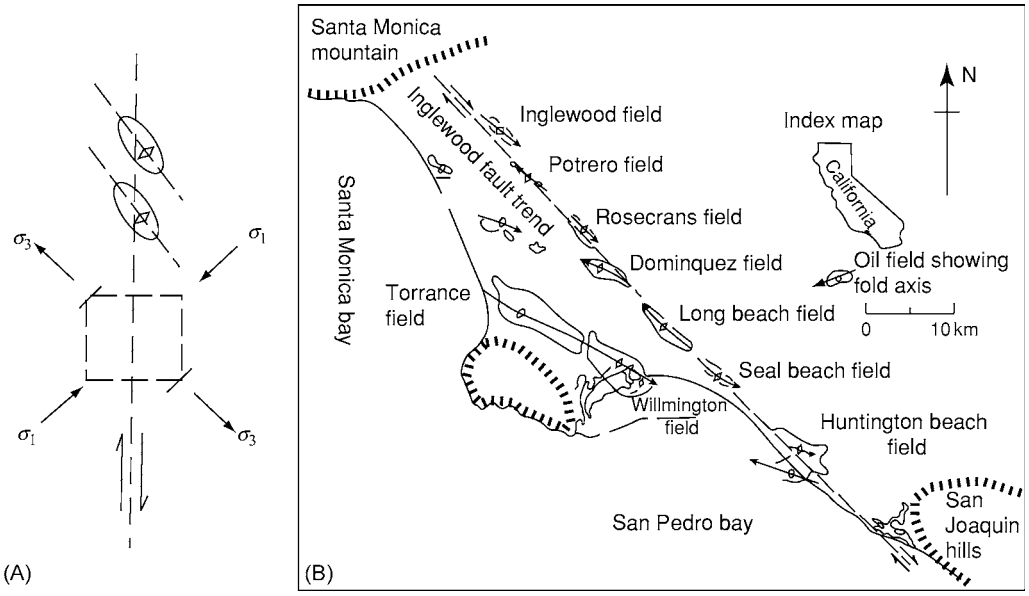

Figure 15 (A) Movement along a wrench fault in the basement produces horizontal compression in the cover rocks and the formation of a linear train of offset folds above the fault. (B) Such en echelon folds above the Inglewood fault, California.

folding in the overlying cover rocks. The stress generated in the cover rocks above a basement strikeslip fault is shown in Figure 15A. A local horizontal compression, inclined at 45° to the basement fault, is developed in the cover and this can give rise to a variety of structures, depending on the rheological condition of the cover rocks. If they behave in a ductile manner, then a series of folds may develop. They will form with their axial planes at right angles to the local maximum compression (σ_1) and will be arranged in an offset manner along the trace of the basement fault (Figure 15A). Natural examples of these linear arrays of buckle folds (see, for example, Figure 15B, which shows folding induced in the cover rocks above the San Andreas wrench fault) are excellent markers for locating major hidden faults.

Fault-Bend Folds

The forced folds shown in Figure 14 occur in cover rocks which respond in a ductile manner in response to movement on faults in a relatively rigid basement. Other well-documented relationships between faults and folds are known, one of the most familiar being fault-bend folding (Figure 16). In this type of forced folding, the folding is not the result of the movement of rigid fault blocks in the basement but rather the result of fault movement within the cover rocks. As can be seen from Figure 16, faults are not perfectly planar surfaces of slip. They generally have gentle undulations and may display substantial curvature or sharp bends. For example, the thrust fault shown in Figure 16 is made up of two horizontal portions (flats) linked by an inclined portion (ramp). As the two fault blocks slip past one another there must be deformation in at least one of them because rocks are not strong enough to support large voids. For this reason, many major folds within layered rock exist within the hanging-wall fault blocks, formed by bending the fault blocks as they slip over non-planar fault surfaces. This mechanism of folding is termed Fault-bend folding.

Flow Folding

In addition to the mechanisms of buckling and bending, folds can also be produced by flow. Impressive examples occur during the outpouring of lavas and during the slower flow of ice and salt. Salt is less dense than most rocks and therefore tends to rise diapirically though overlying strata. The resulting salt domes often emerge at the Earth's surface (Figure 17) where they can form salt glaciers (Namakiers). Figure 18 shows large flat lying flow folds formed as a result of flow within a salt glacier.

Implications of Folds Regarding the Properties of the Rock

The Earth's crust is characterized by an upper seismically active zone where brittle failure dominates, resulting in the formation of fractures and loss of continuity of the rocks, and a lower aseismic zone associated with ductile deformation, i.e., deformation that

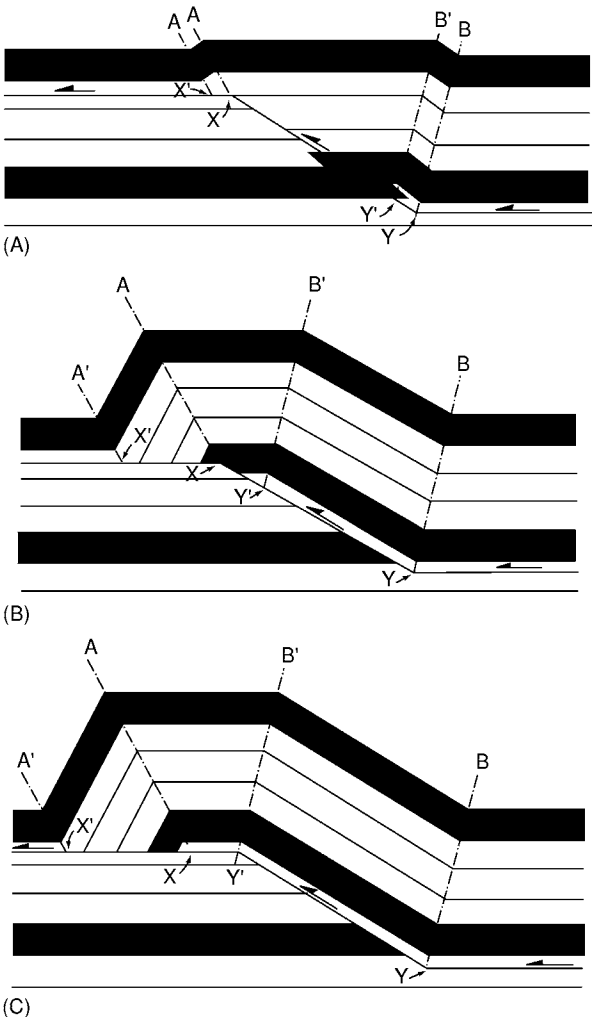

Figure 16 The development of a fault bend fold as a thrust sheet rides over a ramp in the detachment horizon. (After Suppe (1983).)

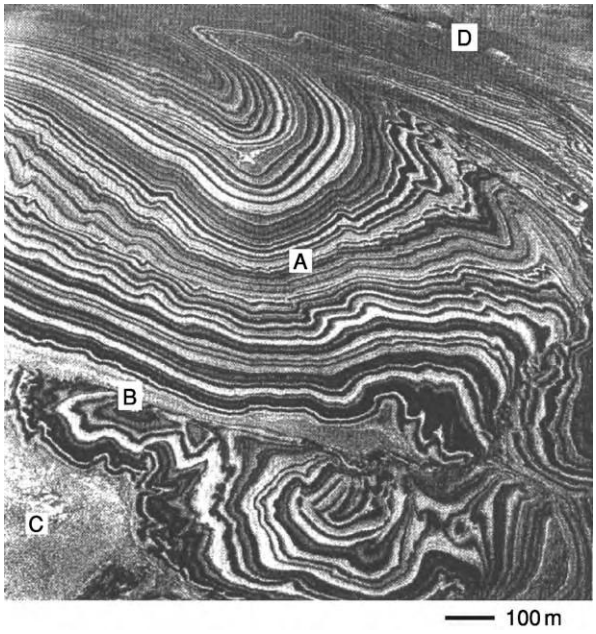

Figure 17 Oblique aerial view of a salt dome from the Great Kavir, Iran, showing the agate like regularity of bedding in the younger salt (A) and a fault contact (B) with the more massive older salt (C).

occurs without the loss of continuity of the material. Folding tends to occur within this ductile zone although, as noted earlier, folds can form at all depths in the crust. In addition, fractures can form in association with folding and the orientation of the fractures indicates clearly that they are formed by the same stress field that operated during folding (Figure 19).

Strain Within a Folded Layer and Associated Fracturing

The strain distribution (and therefore the fracture pattern) within a folded layer is dependant on the layer properties. In a homogenous isotropic layer, such as a uniform sandstone or limestone bed, the strain distribution is likely to be similar to that shown in Figure 20B, in which a layer parallel extensional field associated with the outer arc is separated from a layer parallel compression field associated with the inner arc by a neutral surface along which there is no strain. This model of strain distribution is termed Tangential Longitudinal strain folding. In contrast, a homogeneous anisotropic layer, such as a well-bedded shale, may fold by bedding parallel slip which results in the strain distribution shown in Figure 20C. This is known as flexural flow folding if the shear strain parallel to the layer boundary is uniformly distributed across the layer, and flexural slip folding if it is concentrated along distinct bedding planes. It is interesting to note that both models of folding (Figure 20B and C) produce parallel folds, i.e., folds with a constant orthogonal thickness. This illustrates the fact that the strain state within a fold cannot be deduced from the geometry of its profile section. However, the different strain patterns within the two models reflect the fact that they have very different stress fields within them which may lead to the formation of characteristic fracture patterns which enable the two fold types to be recognized in the field. For example, the extensional fractures in the outer arc of the pericline shown in Figure 20A and the shear fractures in the inner arc, indicate outer arc extension and inner arc contraction, respectively, i.e., a pattern compatible with the deformation associated with the Tangential Longitudinal Strain fold (Figure 20B).

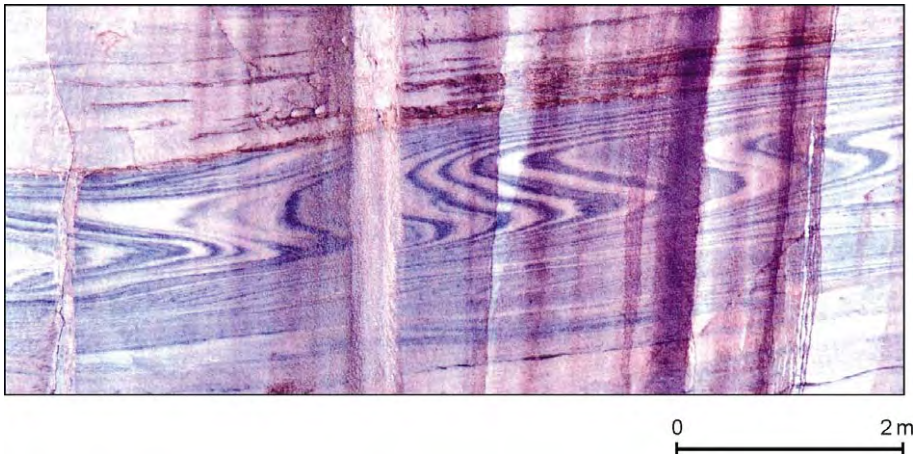

Figure 18 Large flat lying flow folds formed as a result of flow within a salt glacier, Iran.

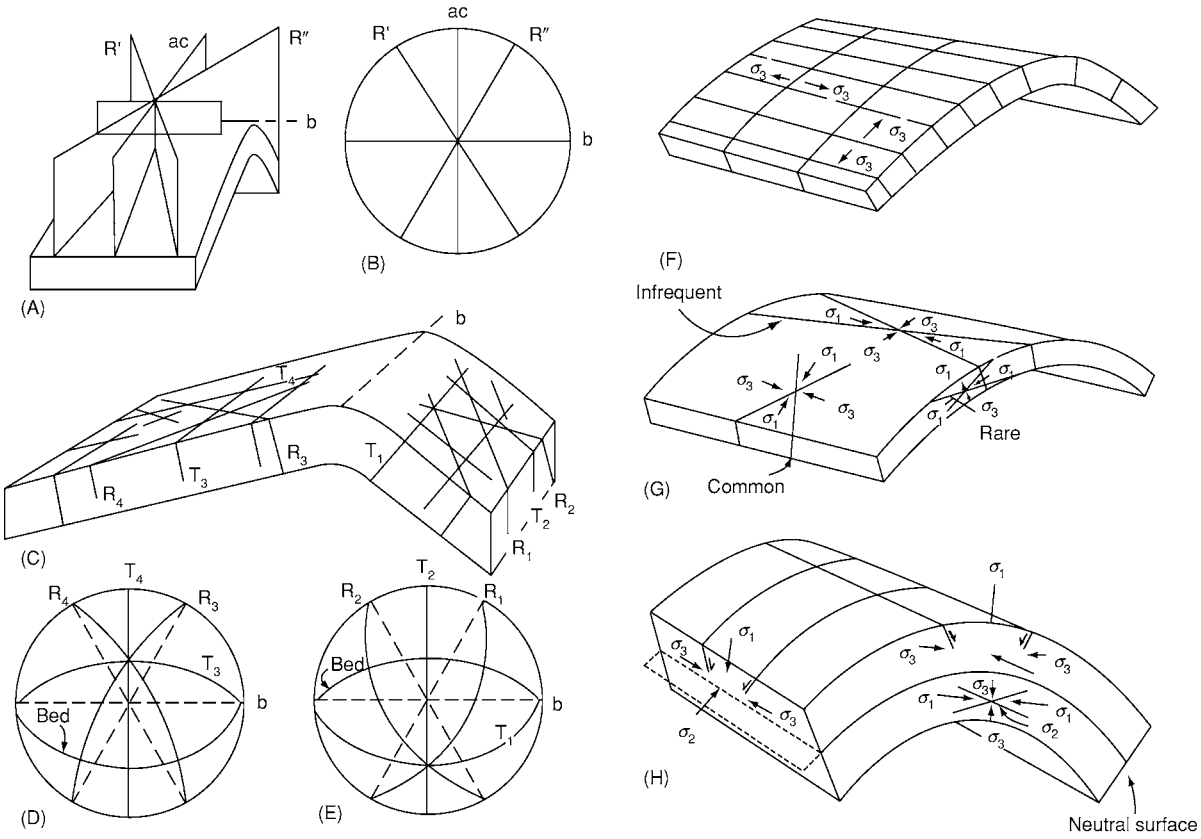

Figure 19 (A) Ideal relationship of master joints to a relatively small fold. (B) Stereographic plot of fractures shown in (A). (C) Trend of minor fractures in a folded competent unit. (D) and (E) Stereographic plots of fractures in the two limbs. R and T are shear and extension fractures, respectively. (F) Typical relationship of extensional fractures to a fold. The orientation of the least principal stress associated with each set (which are of different ages) is shown. (G) Typical orientation of shear fractures in a thin bedded layer, with associated stress systems. (H) Typical orientation of normal faults and thrusts which may develop in a thick flexed unit.

Thus, fractures formed in association with buckle folds may be the result of the local stresses generated as a result of buckling. Alternatively, they may be caused by the regional stress field. The existence of a buckle is likely to disturb the regional stress field. For example, folds are often accompanied by bedding plane slip, implying that the bedding planes cannot sustain a large shear stress. It follows, therefore, that

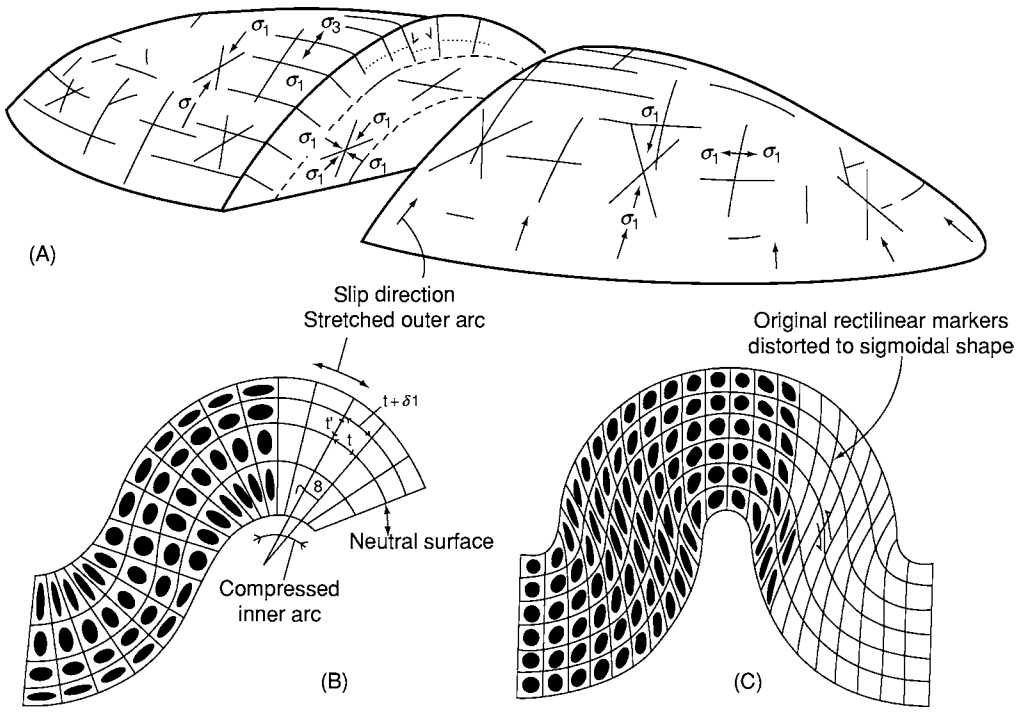

Figure 20 (A) Various fractures associated with a pericline. (After Stearns (1978).) (B) Strain distribution in a tangential longitudinal strain fold and (C) a flexural flow fold. (After Ramsay (1967).)

the principal stresses must be constrained to being either subparallel or subnormal to the folding layers. As a result of this stress deflection, the fractures also form normal to bedding. This is illustrated in Figure 19, which shows the predicted orientation of the shear and extensional fractures that would form in response to the regional compression generating the fold (Figure 19A), together with their projection on a stereographic plot (Figure 19B), and the frequently observed orientation of these fractures on the limbs of the fold which occurs as a result of the principal compressive stress following the layering (Figure 19C–E). The types and orientations of fracture found in association with buckle folds, which form as a result of both the regional and local stresses, are summarized in Figure 19F–H.

Fractures (Including Joints)

J W Cosgrove, Imperial College London, London, UK

Introduction

Fractures are the result of brittle failure which is the general term given to failure during which continuity of the material is lost. Deformation that does not involve loss of continuity is termed ductile. Two modes of brittle failure have been recognized, namely Shear failure and Tensile failure and these can be distinguished from each other on the basis of: (i) the orientation of the fractures with respect to the principal stresses that caused them; and (ii) the relative motion of the rock on each side of the fractures (Figure 1).

If the rock moves parallel to the fracture (Figure 1A) the fracture is a shear fracture and if it only moves normal to the fracture (Figure 1B) it is a tensile fracture.

Shear fractures in rocks are called faults and tensile fractures joints.

Mechanism of Formation of Fractures

The current understanding of brittle failure in rocks is the result of a combination of field observation, experimental work, and theoretical study. Field observations show the two types of fractures, and experimental work reveals that shear fracture occurs when the principal stresses are all compressive, and tensile failure when the least principal stress is tensile and equal to or greater than the tensile strength of the rock.

Shear Failure

Experiments have been performed in which cylindrical rock samples, surrounded by a hollow jacket into which a fluid can be injected to provide a confining stress (σ_3), are subjected to an axial loading (σ_1) until they fail. This results in a body of data recording the principal stress necessary for the rock to fail under a wide range of confining stress. These data can be represented graphically in two ways. The first is to plot the axial load against the confining stress (Figure 2A). For many rocks this plot produces a straight line whose intersection with the axial stress axis gives the uniaxial strength, i.e., the stress a rock can sustain with no confining stress. The graph

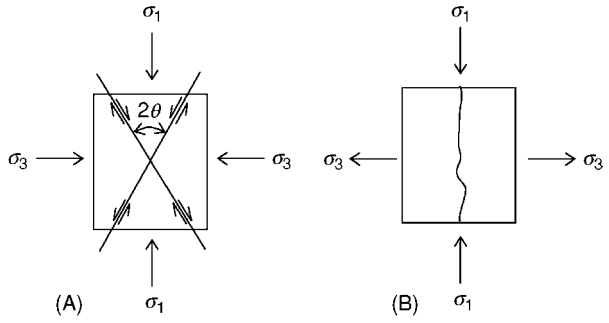

Figure 1 The two modes of brittle failure (A) Shear failure and (B) Tensile failure. They can be distinguished from each other on the basis of: (i) the orientation of the fractures with respect to the principal stresses that caused them; and (ii) the relative motion of the rock on each side of the fracture.

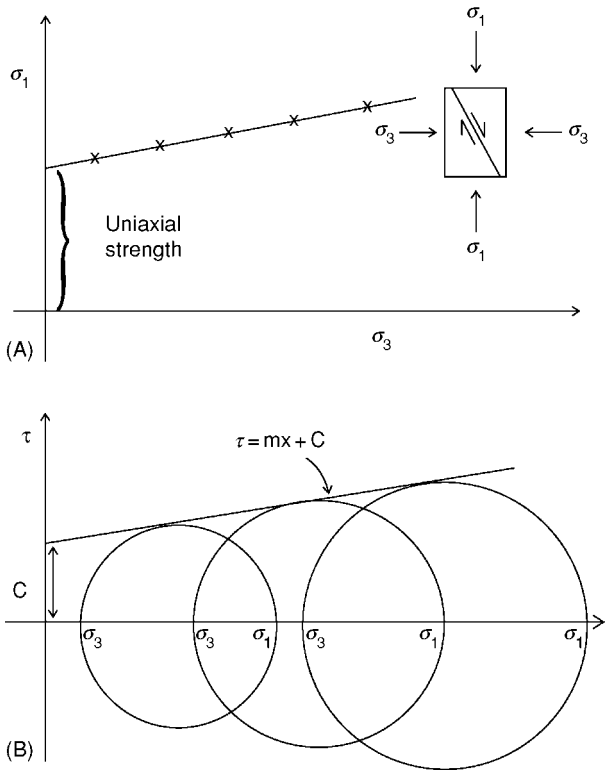

Figure 2 The graphical expression of the experimental data on shear failure. These data can be represented graphically in two ways. (A) is a plot the axial load against the confining stress at failure, (B) shows the same data plotted as a series of Mohr stress circles. The tangent to these circles represents the failure envelope for shear failure.

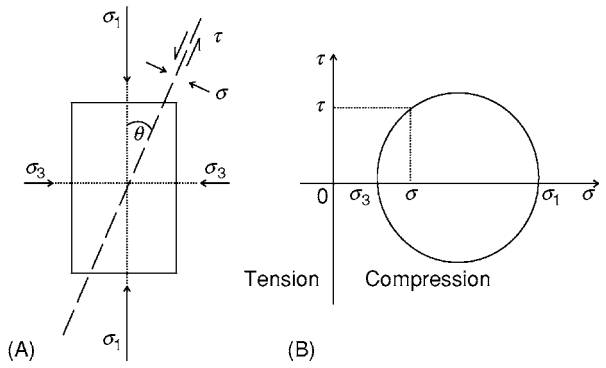

Figure 3 (A) The state of stress (σ and τ) on a plane inclined at θ° to the maximum principal compression, is given by the biaxial stress equations. (eqns [1] and [2]). The graph of σ against τ for values of θ between 0° and 180°; (B) defines a circle, the Mohr stress circle, which defines the state of stress.

indicates clearly that the strength of a rock (i.e., its ability to sustain a load without permanent deformation) is not a fixed value but depends (amongst other things) on the confining stress. The higher the confining stress, σ_3, the greater the axial load needed to cause failure. A rock's strength will, therefore, increase with increasing depth in the crust.

The second method of plotting the experimental data is to plot the stress state for each experiment (i.e., a stress state that caused the rock to fail) as a Mohr circle. The state of stress on any plane inclined at θ° to the maximum principal compression (Figure 3) is given by the biaxial stress equations:

$$\sigma = \sigma_1 \cos^2\theta + \sigma_3 \sin^2\theta \qquad [1]$$

$$\tau = (\sigma_1 - \sigma_3)\cos^2\theta \sin^2\theta \qquad [2]$$

These equations can be represented graphically by calculating σ and τ for values of θ between 0° and 180° and plotting the results on a graph of σ against τ. The resulting points define a circle, the Mohr stress circle (Figure 3B), which defines the state of stress. The diameter of the circle, which is a measure of the differential stress, $(\sigma_1 - \sigma_3)$, is determined by the values of the principal stresses, σ_1 and σ_3. As the experimental data represented in Figure 2A consists of values of the principal stresses that caused the rock to fail, these data can be plotted as a series of Mohr circles (Figure 2B). The tangent to these circles represents the failure criterion for shear failure.

For many rocks, this tangent is a straight line whose equation is:

$$\tau = m\sigma + C \qquad [3]$$

where m is the slope of the line and C its intersection with the shear stress axis.

Having established the shear failure criterion experimentally, it is important to compare it with the theoretically derived criterion. This was developed independently by Navier and Colomb, who argued that in order for a shear fracture to develop, the shear stress τ acting along the potential fracture plane (Figure 3A) must be sufficiently large to overcome the cohesion along that plane, C_0, plus the resistance to shear along the plane once it had formed. The resistance to slip is given by Amonton's law of frictional sliding which states:

$$\tau = \mu\sigma \qquad [4]$$

where τ and σ are the shear and normal stresses, respectively acting on the fracture plane and μ the coefficient of sliding friction. μ is defined as the tangent of the angle of sliding friction φ. Hence the complete criterion can be expressed in the form:

$$\tau = \sigma \tan\varphi + C_0 \qquad [5]$$

This is known as the Navier–Colomb criterion of shear failure and is identical to the criterion established experimentally (eqn [3]). The orientation of the planes where this condition is first met can be determined by substituting the biaxial stress equations (eqns [1] and [2]) into the shear failure criterion (eqn [5]) and solving for the minimum. The optimum orientations for the shear fractures are:

$$\theta = + \text{ or } - [45^\circ - \varphi/2] \qquad [6]$$

where θ is the angle between the maximum compressive stress (σ_1) and the shear fracture (Figure 1A). Note that two fracture orientations are predicted, inclined at $45^\circ - \varphi/2$ each side of σ_1. They are termed conjugate shear planes and although the magnitude of the shear stress along them is the same, the sense of shear is different. Faults are the geological expression of shear failure, and conjugate small-scale faults in a sequence of alternating sandstones and shales are shown in Figure 4.

Classification of Faults

As can be seen from Figure 1A, the orientation of a fault is controlled by the orientation of the principal stresses that generate them. Field observations reveal that faults fall into three classes, normal faults, wrench (or strike slip) faults, and thrust (or reverse) faults which, as can be seen from Figure 5, correspond to stress states where σ_1, σ_2, and σ_3 are vertical.

Figure 4 Conjugate normal faults in Carboniferous turbidites from Bude, Cornwall, England.

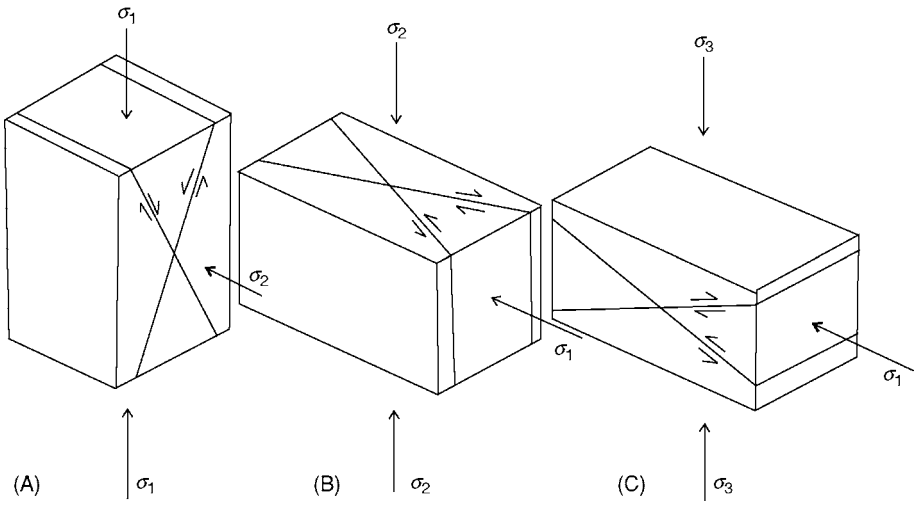

Figure 5 The orientation of shear fractures that form when (A) σ_1, (B) σ_2 and (C) σ_3 are vertical. The resulting faults are termed, normal faults, wrench (or strike slip) faults, and thrust (or reverse) faults, respectively.

This observation implies that the principal stresses tend to be oriented in one of these three orientations. In 1951, Anderson argued that this was because the Earth's surface is a free surface which cannot sustain a shear stress. Thus, in order not to generate a shear stress parallel to this surface, the principal stresses are constrained to remain either parallel or normal to it. As is discussed later, the three classes of faults characterize three different tectonic regimes.

Tensile Failure

Joints and veins are the most common geological expression of tensile failure. Experiments show that this type of failure generates fractures normal to σ_3 (Figure 1B). The theory of tensile failure was developed by Griffith (1925) who argued that in an ideal material the tensile strength of a material would be determined by the strength of the

inter-atomic bonds. However, experiments revealed that the measured tensile strength of a material is usually several orders of magnitude lower than that calculated on the basis of their inter-atomic bond strength. Griffith argued that this was because the materials contain small flaws or microfractures and that these resulted in a local stress magnification at the crack tips. This is illustrated diagrammatically in Figure 6, which shows the stress configuration of a plate subjected to a horizontal extension. In the first plate (Figure 6A), the stress is evenly distributed through the plate. In the second plate, which contains a flaw represented by an elliptical crack (Figure 6B), the tensile stress is locally magnified at the fracture tips. The amount of magnification depends primarily on the orientation and eccentricity of the crack. The greater the eccentricity, the greater the magnification. Griffith argued that by this means, a relatively low applied stress could be locally amplified at fracture tips within the material to the point where it reached the stress required to break the atomic bonds within the material causing the material to fail. He developed the following failure criterion (the Griffith criterion of tensile failure) based on this model:

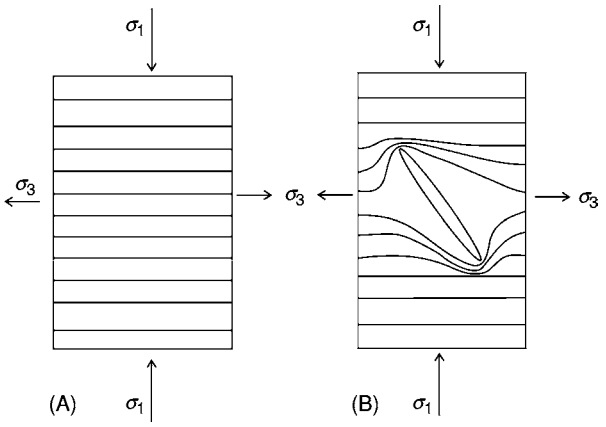

Figure 6 (A) A uniform stress field represented by uniformly spaced stress trajectories in a stretched layer. (B) The concentration of tensile stress at crack tips in a uniformly extended layer.

$$\tau^2 + 4T\sigma - 4T^2 = 0 \qquad [7]$$

where τ is the shear stress, σ the normal stress, and T the tensile strength of the material. The graphical expression of this failure criterion is shown in Figure 7A. It has the form of a parabola whose intersection with the normal stress axis gives the tensile strength and with the shear stress axis the cohesion.

The complete criteria for brittle failure, (the Griffith, Navier–Colomb criteria), is obtained by linking the two criterion (eqns [5] and [7]) at the point where their slopes are identical (Figure 7B). Any stress state can be represented on this graph as

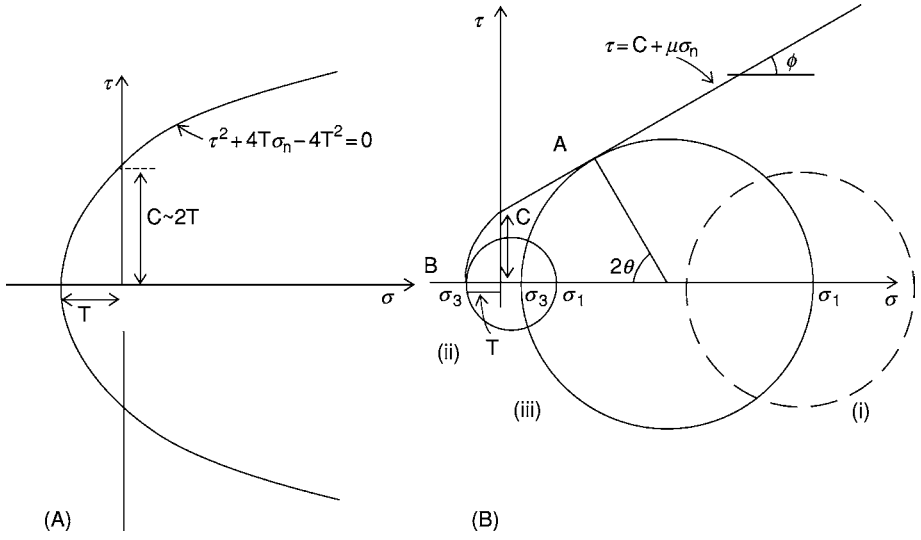

Figure 7 (A) The graphical expression of the Griffith criterion of tensile failure (eqn [7]). It has the form of a parabola whose intersection with the normal stress axis gives the tensile strength of the material and with the shear stress axis the cohesion. (B) The complete criteria for brittle failure, (the Griffith, Navier Colomb criteria), is obtained by linking the two criteria (eqns [5] and [7]) at the point where their slopes are identical.

a Mohr circle whose position is determined by the values of the principal stresses (σ_1 and σ_3). If a stress state, when plotted on the graph, does not touch or intersect the failure envelope, the stress state is stable, i.e., will not cause the rock to fail, e.g., stress field (i) Figure 7B. If, however, it does touch the envelope, failure will occur, either by tensile fracturing if the contact is with the tensile part of the envelope (Figure 7B (ii)), or shear fracturing if it is with the shear part (Figure 7B (iii)).

What Determines Whether Tensile or Shear Fractures Form?

It can be seen from Figure 7B that shear failure is associated with a large differential stress ($\sigma_1 - \sigma_3$) i.e., the Mohr's stress circle must be large in order to intersect the shear failure envelope, and that tensile failure is associated with a low differential stress, i.e., the Mohr's stress circle must be small in order to intersect the tensile failure envelope. The precise conditions necessary for the formation of the two types of fractures are:

$$\text{For tensile failure to occur} \quad (\sigma_1 - \sigma_3) < 4T \qquad [8a]$$

$$\text{For shear failure to occur} \quad (\sigma_1 - \sigma_3) > 4T \qquad [8b]$$

where T is the tensile strength of the material.

The geometrical relationships between the principal stresses and the fractures they produce (i.e., a conjugate set of shear fractures symmetrically about σ_1 and a single set of tensile fractures at right angles to σ_3) is shown in Figure 1 and, as noted below, the understanding of these relationships provides a powerful tool in fracture analysis.

It follows therefore that the orientation of the fractures that form in response to a stress field is determined by the orientation of the principal stresses (Figure 1), and the type of fracture (shear or tensile) by the magnitude of the differential stress.

The Effect of a Fluid Pressure on Fracturing

Fluid-Induced Failure

The state of stress in the crust is dominantly compressional. For example, in a nontectonic environment, the stress at any depth is generated by the overburden which produces a compressive vertical stress which induces a compressive horizontal stress. Thus, at any depth the Mohr stress circle will plot in the compressive regime in Figure 7B and there will be no possibility of tensile failure. Geologists were, therefore, perplexed to find that large numbers of tensional fractures occur in the crust. This paradox was resolved when the importance of fluid pressures within a rock was understood. Pore fluid pressure within a rock increases as the rock is buried. (*see* **Tectonics:** Hydrothermal Activity). The stress state within the pores is hydrostatic and the pressure acts so as to appose the lithostatic stress caused by the overburden. This effect can be shown diagrammatically by representing the lithostatic stress as an ellipse with the stress acting compressively and the fluid pressure as a circle with the pressure acting outwards (Figure 8A). The fluid pressure reduces all the lithostatic stresses by an amount P_{fluid} to give an effective stress. Thus, the principal stresses σ_1 and σ_3 become $(\sigma_1 - P_{fluid})$ and $(\sigma_3 - P_{fluid})$. This new stress field can be plotted as a Mohr stress circle (Figure 8B). It can be seen that the original lithostatic stress circle is moved towards the tensile regime but that the diameter of the circle, i.e., the differential stress, remains unchanged.

The amount of migration of the stress circle is determined by the magnitude of the fluid pressure. Thus, as the fluid pressure gradually increases during burial, the stress circle is pushed inexorably towards the failure envelope. When it hits the envelope, failure occurs. Such failure is termed fluid induced or hydraulic fracturing. In this way an originally compressional stress regime can be changed so that one or more of the principal stresses becomes effectively tensile and the conditions for tensile failure can be satisfied.

The Expression of Fluid-Induced Failure

In the example shown in Figure 8B the lithostatic stress had a small differential stress (i.e., less that 4T (see eqn [8]) and as a result the induced hydraulic fractures were tensile fractures. If it had been greater than 4T, shear fractures would have formed.

The Organization of Tensile Fractures

The Mohr circles shown on Figure 9 all intersect the failure envelope in the tensile regime, i.e., the differential stresses are all less than 4T and will all therefore result in tensile failure. Their differential stresses vary from just less than 4T (circle (i) Figure 9), to zero (circle (iv), Figure 9). Note that when the stress state is hydrostatic, the Mohr circle is reduced to a point.

As noted above, tensile fractures form normal to the minimum principal compressive stress σ_3 (Figure 1B), i.e., they open against the minimum compressive stress. The stress state represented by Mohr circle (i) in Figure 9, has a relatively large differential stress and there is, therefore, a definite direction of easy opening for the fractures. The fractures would

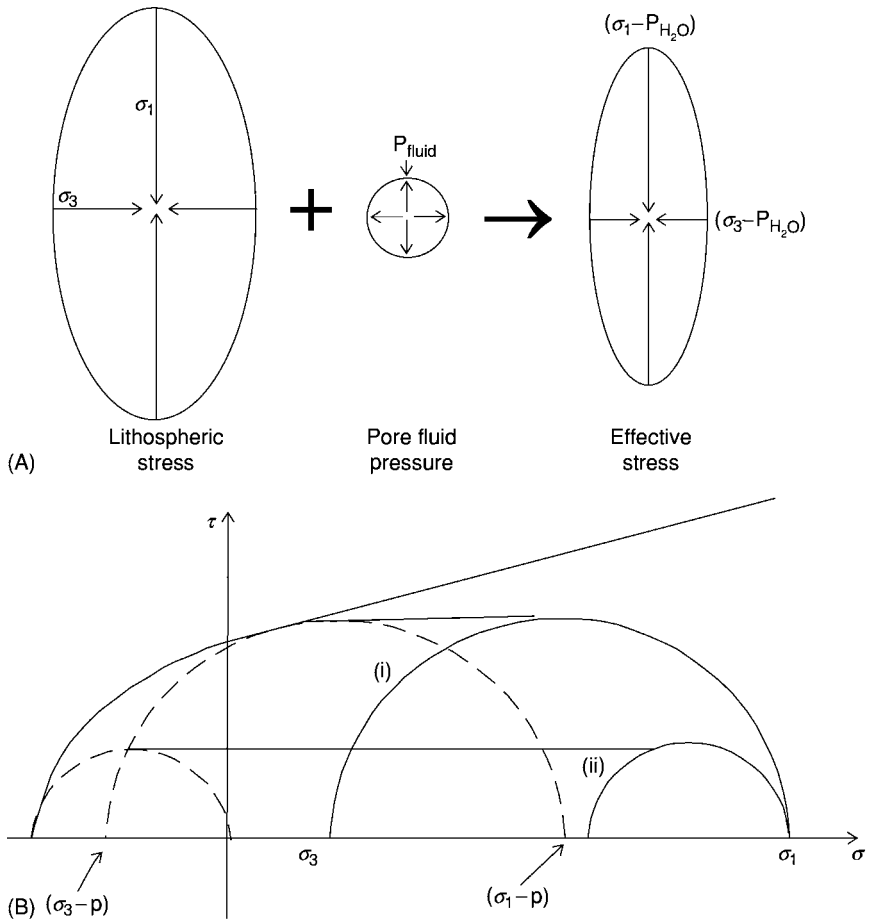

Figure 8 (A) Diagramatic representation of the effect of a fluid pressure (the circle with the outwardly acting stress) on the stress state in a rock (the ellipse with the inwardly acting stresses). All normal stresses are reduced to an effective stress (σ p_{fluid}) but the differential stress (σ_1 σ_3) remains unchanged. The effect is to cause the Mohr stress circle to move to the left by an amount equal to the fluid pressure; (B). Thus depending on the magnitude of the differential stress the induced fractures will be either shear (stress state (i)) or tensile (stress state (B)) (*see* **Tectonics:** Folding).

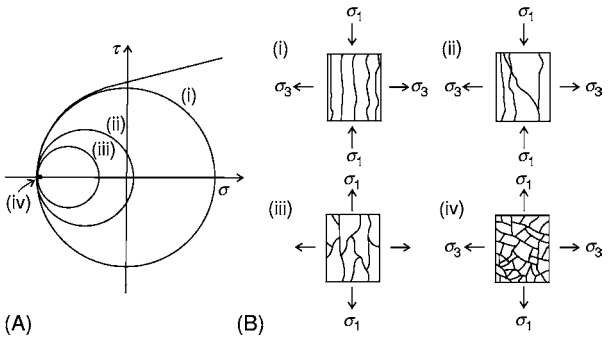

Figure 9 (A) Mohr stress circles (i) (iv) representing a range of stress states, all of which will lead to tensile failure. NB the Mohr circle (iv), that represents hydrostatic stress is a point. (B) Pat terns of tensile failure generated by the corresponding stress states shown in (A).

therefore exhibit a marked alignment normal to this direction (Figure 9B (i)). However, for the stress states represented by the Mohr circles (ii–iv), the differential stress becomes progressively smaller until, for the hydrostatic stress represented by circle (iv), the differential stress is zero. In a hydrostatic stress field the normal stress across all planes is the same and there is, therefore, no direction of relatively easy opening for the fractures. Thus, they will show no preferred orientation and, if they are sufficiently closely spaced and well developed, will produce a brecciation of the rock (Figure 9B (iv)). It can be seen that as the differential stress becomes progressively lower so the tendency for the resulting tensile fractures to form a regular array normal to σ_3 decreases. Tensile fracture systems ranging from well-aligned fractures to randomly

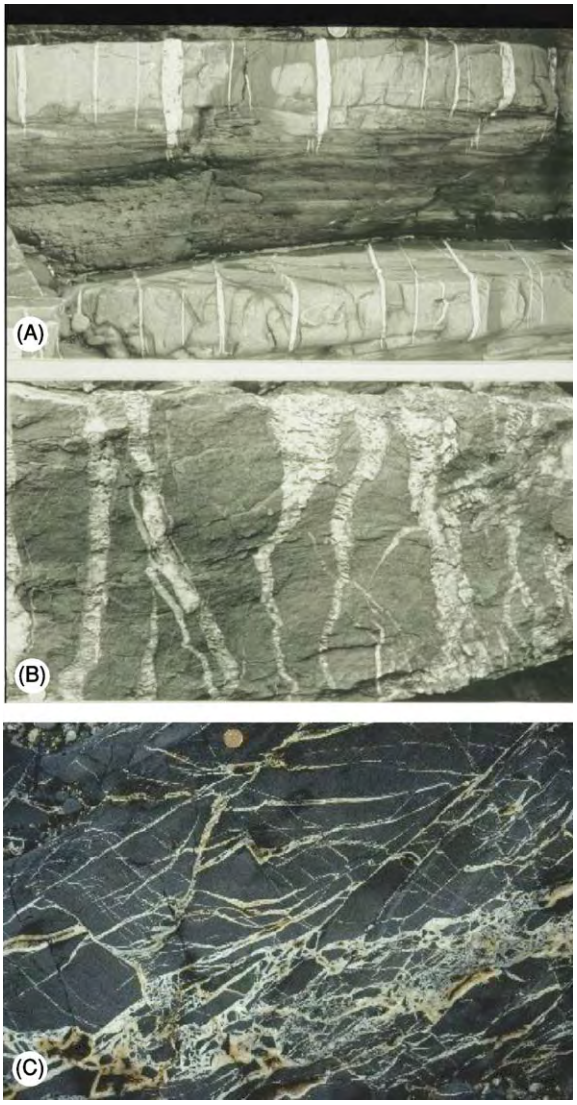

Figure 10 (A) A regular array of tensile fractures exposed on a bedding plane in Carboniferous sandstone, Millook, Cornwall, England. (B) Less well organized tensile fractures cutting Devonian sandstones, St. Anne's Head, South Wales. (C) Carboniferous sandstone cut by randomly oriented tension fractures.

Figure 11 Polygonal arrays of tensile fractures cause by the desiccation of a silt layer.

Figure 12 Polygonal arrays of tensile fractures cause by the cooling of a lava flow. (Giant's Causeway Northern Ireland).

oriented fractures are to be expected in rocks, and field observations support this idea, Figure 10.

As noted above, the problem of forming tensile fractures in the compressive stress field that generally characterizes the Earth's crust can be solved by appealing to high fluid pressures. However, tensile failure can occur in rocks without the aid of a high internal fluid pressure, for example, during the contraction of a layer as a result of desiccation of a sediment (Figure 11) or the cooling of an igneous body (Figure 12).

In both these examples, the fractures are organized into polygonal arrays showing that the tensile stresses generated were the same in all directions.

Fracture Sets

Generally, the state of stress in the Earth's crust is not hydrostatic. Consequently a single episode of deformation is likely to generate a set of fractures with the same orientation. However, most rocks experience several different stress regimes during their history with the result that several fracture sets are frequently found superimposed on each other to produce a fracture network (Figure 13). The interaction of late fractures with early fractures is illustrated in Figure 14.

The effect of early fractures on later ones is to arrest their propagation and to modify their orientation. It can be seen from Figures 14A and B that one

fracture often ends abruptly against another. This abutting relationship gives the relative age of the fractures, i.e., the later fracture abuts against the earlier fracture. If an early fracture is an open fracture then it will represent a free surface within the rock and, as discussed in the above section on classification of faults, will be unable to support a shear stress. Consequently, the principal stresses will reorient as they approach it into a position either normal or parallel to the fracture. This effect can be clearly seen in Figure 14, where later fractures curve into an orientation at right angles to the earlier fracture as they approach it.

Figure 13 A fracture network in a Liassic limestone bed from Lilstock, North Somerset, England. It was produced by the super position of individual fracture sets.

Fracture Networks

Structural geologists study the cross-cutting relationships of different fracture sets in order to determine their relative age. A variety of rules have been established to help in this task. It is found that early fractures tend to be long and relatively continuous and, as noted above, later fractures abut against these and are consequently shorter. Some of these features can be seen in Figure 15, which shows a fractured limestone pavement containing several fracture sets. The

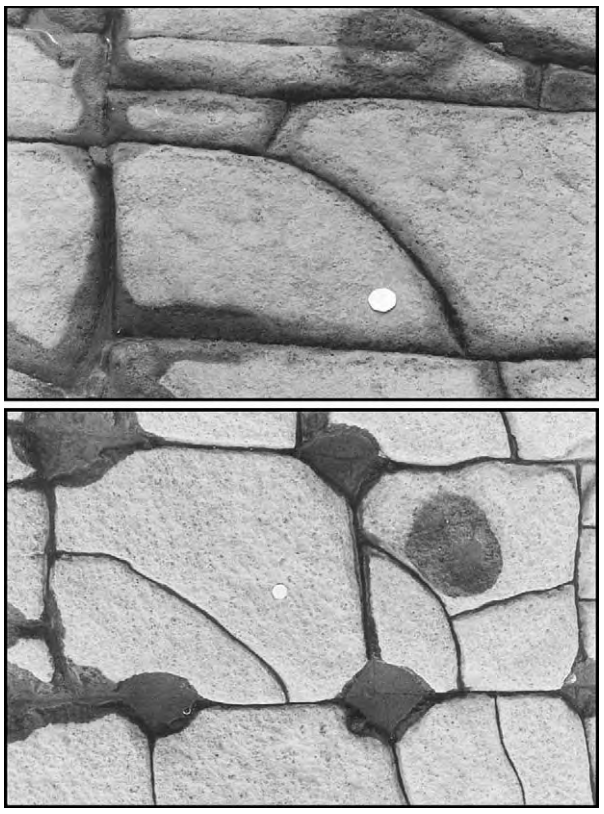

Figure 14 Details of the limestone pavement shown in Figure 13 illustrating the interaction of late fractures with early fractures. The effect of early fractures on later ones is to arrest their propagation and to modify their orientation. It can be seen that the later fractures are deflected by and abut against the earlier fractures.

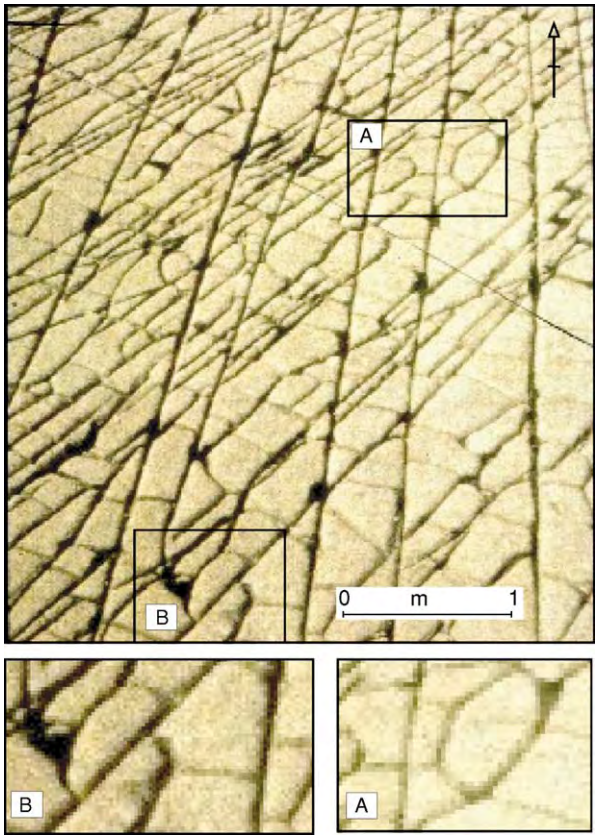

Figure 15 Fracture patterns in a limestone pavement at Lilstock, North Somerset, SW England. The older fracture sets are the most continuous and, as the sets become progressively younger, they become less continuous and less well oriented.

longest and most continuous runs approximately N–S. These are the oldest fractures and are crosscut by several younger sets which become progressively less continuous and less aligned as the regional stress fields responsible for their formation becomes progressively modified by the pre-existing fractures. The fracture set trending approximately NW–SE, the second set to form, shows a remarkable degree of continuity, being only affected by the N–S fractures; its orientation is related directly to the regional stress field.

However, as more fracture sets develop in the rock mass, modification of the stress orientation by the pre-existing fractures may result in there being a poor correlation between the fracture orientation and the regional stress field responsible for its formation. This is well illustrated in subarea A in Figure 15 which has been enlarged in the bottom left-hand corner of the figure. The influence of the pre-existing fractures on the orientation of the late fracturing is so marked that the later fractures display a polygonal organization and cannot be linked directly to the regional stress field responsible for their formation.

Fracture Analysis

A fracture analysis is the study of a fractured rock mass in order to: (i) establish the detailed geometry of the fracture network; (ii) determine the sequence of superposition of the different fracture sets that make up the fracture network; and (iii) deduce the stress regime associated with the formation of each fracture set. The reason why a detailed knowledge of the geometry of the fracture network is so important is that the bulk properties (e.g., strength, permeability) of a fractured rock mass (and most natural rocks are fractured) are generally determined by the fractures they contain rather than by the intrinsic rock properties.

Stages (ii) and (iii) of a fracture analysis are carried out using the principals outlined above relating to the interaction of fractures and the relationship between the stress field and fracture orientation (Figure 1).

Types of Faults a Plate Margins

The 'type' of plate margin is controlled by the relative motion of the two adjacent plates. They can be subdivided into three classes, convergent, divergent, and strike-slip. Convergent margins lead to compressional regimes at the plate margins which results in the formation of mountain belts. The stress regime is that appropriate for thrusts to form, namely a horizontal maximum principal compressive stress and a vertical minimum stress (Figure 5C). Divergent plate margins result in the formation of oceans and the separation of plates. The initial stage of this process is the fracturing of the lithosphere and the formation in the upper crust of major rift systems such as the East African Rift (*see* **Tectonics:** Rift Valleys). The stress regime of a horizontal minimum principal compressive stress and a vertical maximum stress is appropriate for the formation of normal faults (Figure 5A). When plates move parallel to each other at different velocities, conditions are appropriate for the formation of major wrench (strike-slip) faults (Figure 5B) such as the San Andreas Fault zone of California which separates the Pacific and North American plates.

Thus it can be seen that each of the three types of plate margins is characterized by a different types of fault.

Scale of Fracturing

Fractures occur on all scales within the Earth's crust, ranging from major faults that define plate margins, through faults that can be seen on seismic sections (*see* **Tectonics:** Seismic Structure At Mid-Ocean Ridges), down to faults that can be observed directly in the field, e.g, Figure 4, to microscopic fractures only visible under the microscope. Detailed studies of the microfractures in rocks at different stages of the evolution of tensile fractures show, as predicted by Griffith's theory of stress magnification (1925) outlined above, that the microfractures grow by tensile failure at the crack tips and that suitably located microfractures link to form larger fractures oriented normal to σ_3, the minimum compressive stress (*see* **Tectonics:** Faults).

More remarkably, when the growth of shear fractures are studied in the same way, it is found that

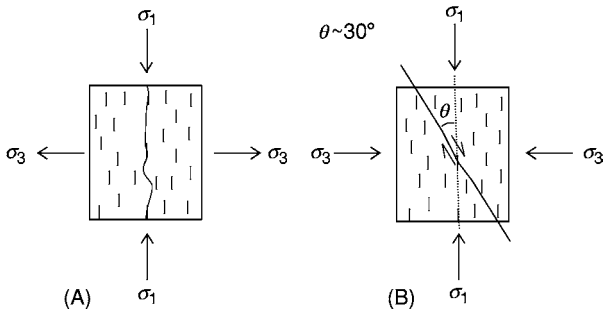

Figure 16 Randomly oriented micro fractures within a material and their growth by tensile failure and subsequent linkage to form (A) macroscopic tensile fractures and (B) macroscopic shear fractures.

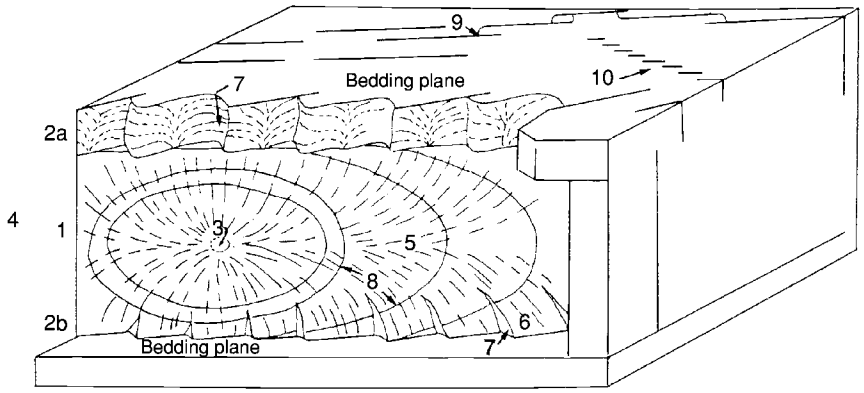

Figure 17 A block diagram illustrating the different types of surface structures (patterns) and fracture trace architecture. (Based on Kullander *et al.*, 1990.) (1) Main joint face, (2a) abrupt twist hackle fringe, (2b) Gradual twist hackle fringe, (3) Origin of fracture, (4) Hackle plume, (5) Plume axis, (6) Twist hackle face, (7) Twist hackle step, (8) Rig marks (front line of the fracture), (9) hooking, (10) En echelon fractures.

initially fracturing occurs by the growth of microfractures at their tips and in an orientation normal to σ_3. However, the macroscopic shear fractures are formed by the linking of offset microfractures, as shown in Figure 16. Thus, it can be seen that despite the two types of fractures having independent failure criteria and different orientations with respect to the principal stresses, they are nevertheless fundamentally linked on a microscopic scale. They are both the result of the growth of microfractures by tensile failure and differ only in the way in which these fractures are linked to a macroscopic fracture.

Surface Features of Fractures

Fractures display a variety of surface features and Figure 17 is a summary diagram showing some of these. Fractography is the science which deals with the description, analysis, and interpretation of fracture surface morphologies and links them to the causative stresses, mechanisms, and subsequent evolution of the fractures. It has been demonstrated that the diverging rays of the plumose structures (Figures 17 and 5) always remain parallel to the direction of propagation of the fracture. Thus, by constructing lines at right angles to these rays, the position and shape of the fracture front at different times of its evolution can be determined (Figures 17 and 8). When the exposures are sufficiently good, it is found that the fracture fronts form a series of concentric 'ellipses', the centre of which marks the site of fracture initiation.

Hydrothermal Activity

R P Lowell, Georgia Institute of Technology, Atlanta, GA, USA
P A Rona, Rutgers University, New Brunswick, NJ, USA

Introduction

Hydrothermal activity results from the complex interplay of heat transfer, fluid–rock chemical reactions, and fluid circulation within Earth's continental and oceanic crust. Hydrothermal circulation redistributes heat energy in the crust, often giving rise to regions of concentrated thermal output that lead to the emplacement of economically important mineral deposits and that serve as geothermal energy resources. Hydrothermal activity is thus an important component of Earth's global heat engine whereby heat transferred to the lithosphere by mantle convection is transferred to Earth's surface by thermal conduction, volcanic extrusion, and hydrothermal venting. Lithospheric plate motions, volcanic and tectonic activity, and earthquakes are manifestations of Earth's global heat engine. There is a close connection between tectonic plate boundaries and sites of hydrothermal activity (Figure 1). In the following sections of this article we compare some aspects of terrestrial and submarine hydrothermal activity, describe the basic physics and chemistry of hydrothermal circulation, briefly discuss the importance of two-phase flow, and suggest some directions for future study.

Comparison between Terrestrial and Submarine Activity

Although hydrothermal activity in terrestrial and submarine settings has many similarities there are significant distinctions. Part of the reason for this distinction stems from the manner in which heat is transported in continental and oceanic lithosphere, respectively (Table 1). In terrestrial settings, nearly 40% of the heat flux stems from radiogenic heat production in the crust, and 60% is conducted from the underlying mantle. Terrestrial hydrothermal activity accounts for less than 1% of Earth's thermal budget. On the other hand, the process of plate creation and seafloor spreading along the roughly 60 000-km ocean ridge system dominates the thermal regime of the oceanic lithosphere. Conductive heat flux from the spreading lithosphere decreases as $\tau^{-1/2}$, where τ is the lithospheric age. Hydrothermal circulation transports a significant fraction of the lithospheric heat advectively, leading to lower than expected conductive heat flow in young lithosphere (Figure 2). Nearly 25% of Earth's global heat loss and 33% of the heat loss from oceanic lithosphere result from hydrothermal activity. Most seafloor hydrothermal heat loss occurs at low temperature. High-temperature hydrothermal activity, which accounts for less than 10% of the total seafloor hydrothermal heat loss (Table 1), appears to occur only in lithosphere less than 1 My old.

Another interesting distinction between terrestrial and submarine hydrothermal activity has been their role in human endeavours. Warm and hot springs on the continents have been used for bathing and medicinal purposes since antiquity. Thermal springs were utilized throughout the Roman empire, and early descriptions of springs in Europe appear in seventeenth-century writings. Terrestrial hydrothermal systems have also long been used as an energy resource. Geothermal waters in Iceland have been used for heating for centuries, and by the 1930s a centralized heating system was established for Reykjavik. Geothermal steam has been produced at Lardarello, Italy, since the latter half of the nineteenth century, and the Geysers geothermal field in California was first exploited in the 1920s. It is remarkable that commercial development of geothermal resources occurred long before measurements of geothermal heat flux and without detailed geophysical exploration.

On the other hand, direct detection of submarine hydrothermal activity did not occur until the 1960s (Red Sea) and the 1970s at mid-ocean ridges of the Atlantic and Pacific. As a result of these discoveries the understanding of biogeochemical processes on Earth was revolutionized. It became clear that submarine hydrothermal circulation significantly impacts global geochemical cycles of both the lithosphere and the ocean. Chemical transport of certain major and trace elements to the ocean by hydrothermal discharge equals or exceeds river inputs. Moreover, hydrothermal fluids also serve as an energy resource for complex chemosynthetic biological ecosystems. The discovery of chemosynthetic ecosystems at seafloor hydrothermal vents has led to a new awareness of life in extreme environments and has stimulated the discussion of the origin of life on Earth and other planetary bodies in the solar system.

Physics and Chemistry

The fundamental components of hydrothermal activity are a heat source and a fluid circulation system

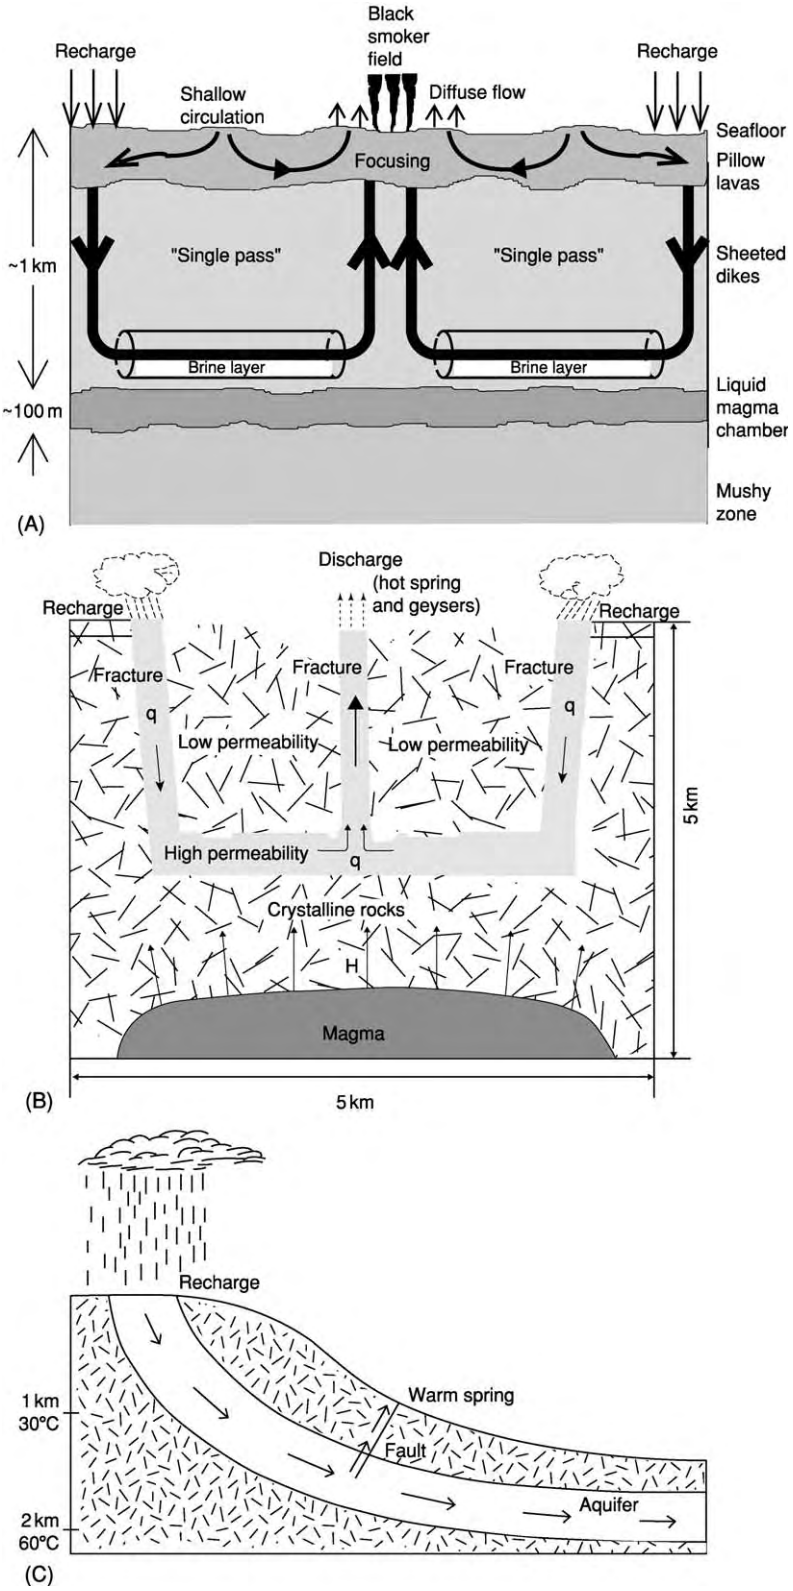

Figure 3 (A) Cartoon of single pass hydrothermal circulation model at an ocean ridge crest. The major single pass segment refers to a deep circulation cell in which seawater recharge penetrates through sheeted dykes to near the top of a magma body, takes up heat and undergoes water rock chemical reactions while flowing quasihorizontally, and ascends through faults or fractures to the seafloor as high temperature focussed black smoker flow. Mixing of the deep circulation with shallow cooler circulation in the basaltic pillow lavas may result in diffuse discharge. Reproduced from Germanovich LN, Lowell RP, and Astakhou DK (2000) Stress dependent

(*see* **Geysers and Hot Springs**). It is the nature of the heat source that generally determines whether hydrothermal activity occurs at high (>150°C) or low temperature. The circulation system consists of a recharge zone through which fluids enter the crust, a region in which the fluid takes up heat from its surroundings, and a discharge zone, through which the heated hydrothermal fluid emerges at the surface as a hot spring or hydrothermal vent. Although fluid may sometimes recirculate several times before exiting the system, it is often convenient to describe circulation in terms of a simple single-pass circulation model. Figure 3 shows cartoons of single-pass models envisioned for high-temperature terrestrial and submarine systems and a low-temperature warm spring system. In addition, all hydrothermal activity exhibits temporal variability, and chemical reactions between the circulating fluid and rock are often important.

Heat

Geothermal gradient Conductive heat flux, H, is related to the geothermal gradient by $H = \lambda\ dT/dz$, where λ is the thermal conductivity. For rocks, λ ranges from approximately 1.8 to 5 W $(m\,^{\circ}C)^{-1}$, with most igneous and metamorphic rocks falling into a narrower range between 2.0 and 2.5 W $(m\,^{\circ}C)^{-1}$. In older, stable continental cratons, the geothermal gradient may be as low as $10^{\circ}C\,km^{-1}$, whereas in active volcanic regions it may be more than $100^{\circ}C\,km^{-1}$. A typical geothermal gradient of $\approx 25^{\circ}C\,km^{-1}$ gives a conductive heat flux of $\approx 60\,mW\,m^{-2}$.

In terrestrial low-temperature hydrothermal activity, fluids driven by a topographic head circulate to a depth of ~1–3 km in the crust where they are heated by the geothermal gradient. The fluids emerge through faults at the surface as warm or hot springs with temperatures ranging from a few tens of degrees above ambient to the local surface boiling temperature (Figure 3C). Such springs are found worldwide in areas of both normal and elevated heat flow.

Low-temperature hydrothermal circulation in oceanic crust occurs from ridge axes to a lithospheric age of ~60 My. This circulation is partially controlled seafloor topography in combination with the geothermal gradient, with discharge occurring at highs and recharge occurring at topographic lows. Type and thickness of sediment cover also influences this circulation. More than 90% of all hydrothermal heat loss from the seafloor occurs at low temperature. This circulation impacts geochemical cycles as the equivalent of an ocean volume approximately evens 10^6 years.

Magmatic heat High-temperature hydrothermal activity (typically classified as > 150°C) is associated with active volcanism. In these settings, shallow magmatic intrusions provide the heat source. Part of this heat comes from the latent heat of crystallization and part of the heat is derived from the cooling pluton. Thermal buoyancy differences between the colder and hotter parts of the system drive convective fluid motions. As volcanism is associated with ocean ridges, hot spots, and island arc systems (fore-arc, arc, and back-arc settings) at subduction zones, it is not surprising that essentially all high-temperature hydrothermal activity occurs in these regions (Figure 1).

In terrestrial settings, boiling hot springs and geysers provide the surface expressions high-temperature hydrothermal activity. Reservoir temperatures of these systems typically lie between 200 and 350°C. In oceanic settings vigorous high-temperature hydrothermal activity is exhibited as "black smoker" venting at temperatures between 300 and 400°C (Figure 4). Lower temperature "white smokers" with temperatures ~150–200°C are also common. Because of the high pressure (~250 bars) at the seafloor, these high-temperature vents lie below the boiling temperature. As discussed later, however, boiling and phase separation appear to occur in the subsurface of both terrestrial and submarine high-temperature hydrothermal systems.

Chemical heat It has long been recognized that hydration of peridotite is an exothermic reaction that produces heat, that alters the chemistry of the rocks and hydrating solutions involved, and that expands the volume of the rocks (~40%). It is only now emerging how widespread this process called the "serpentinization reaction" may be beneath ocean basins and possibly continents. The reaction involves peridotite, the characteristic ultramafic rock type of the Earth's upper mantle, and either seawater or meteoric water. Serpentinization is commonly observed in ultramafic rocks recovered from the seafloor and in slices of ancient oceanic mantle exposed on land as ophiolites. This reaction yields distinctive chemical solutions characterized by high alkalinity, high ratios of Ca to Mn and other metals, and abiogenic

permeability and the formation of seafloor event plumes. *Journal of Geophysical Research* 105: 8341 8354. generation of methane (CH_4) and hydrogen (H_2) gas. The heat released, depending on the volume and rate of serpentinization, may be sufficient to drive hydrothermal circulation over a range of fluid temperatures, typically low to intermediate (degrees to tens of degrees Celsius), and possibly up to several hundred degrees Celsius.

Serpentinization is favoured by conditions that facilitate access of water to large volumes of the upper mantle. In ocean basins the conditions include a low magma budget, which produces thin ocean crust, and tectonic extension and volume expansion that creates permeability through fractures and faults and that exposes rocks of the upper mantle on the seafloor. Such conditions generally occur at sections of slow-spreading ocean ridges in the Atlantic, Indian, and Arctic oceans. For example, fluids with the chemical signatures of serpentinization reactions are common along the mid-Atlantic ridge where several high-temperature (to 360°C) seafloor hydrothermal fields (Logatchev at 14°45′ N, 44°58′ W and Rainbow, 36°14′ N, 33°54′ W) at least partially situated in serpentinized ultramafic rocks of the upper mantle have been found. Only one of these fields appears to be an end member of a hydrothermal system entirely driven by serpentinization reactions (Lost City field, near 30° N, 42° W) located about 15 km west of the eastern intersection of the rift valley with the Atlantis Fracture Zone, where the field is apparently isolated from magmatic heat sources. There serpentinization-derived fluids are discharging at temperatures up to 75°C and precipitating calcium carbonate and magnesium hydroxide chimneys, which have grown up to 60 m high. Thermal and chemical fluxes from such serpentinization-driven seafloor hydrothermal systems have yet to be determined, but may be a significant fraction of global hydrothermal mass and heat budgets. Seawater and upper mantle rocks are ubiquitous in ocean basins, although the sites of serpentinization may be localized.

Fluid Sources

The aqueous fluid involved in hydrothermal activity can, in principle, have several different origins. Meteoric waters are the predominant fluid, but metamorphic or magmatic fluids may also contribute. The origin of the fluid is generally determined by examining their oxygen and hydrogen isotopic ratios (Figure 5). Meteoric waters are defined by a characteristic linear relationship between δD and δ^{18}O (MWL), whereas metamorphic and magmatic rocks and waters tend to be enriched in δ^{18}O relative to the MWL, and hence lie to the right of the curve. Ocean waters occupy a small range of δD–δ^{18}O space near the MWL (denoted by SMOW). Hydrothermal source waters are typically meteoric (or seawater) and hence lie somewhere along the MWL. At temperatures greater than 200°C, hydrothermal waters may be enriched in δ^{18}O as a result of isotopic exchange during water–rock reactions. The presence of a magmatic or metamorphic component may also move the

isotopic signature of the fluid to the right of the MWL (Figure 5). Isotopic evidence of a magmatic component in active hydrothermal systems is generally inconclusive, but the presence of CO_2 in some hydrothermal fluids points to the presence of magmatic volatiles. Seawater is by far the predominant fluid in submarine hydrothermal systems.

The Circulation System

Heat transport by fluid flow through the rock requires interconnected fluid pathways and a driving force for fluid flow. The relationship between the driving force, the gradient of hydraulic head $\partial\hat{H}/\partial x_j$, and volumetric flow rate per unit area per unit time, or specific discharge q_i, is generally given by the empirical relationship called Darcy's Law.

$$q_i = (gk_{ij}/v)(\partial\hat{H}/\partial x_j) \qquad [1]$$

where g is the acceleration due to gravity, v is the kinematic viscosity of the fluid, and k_{ij} is the intrinsic rock permeability tensor, respectively. Subscripts, i, j refer to the Cartesian coordinate directions. In many applications k_{ij} is treated as a scalar k; the units of k_{ij} are m^2.

Rock permeability is the single most important physical parameter that affects hydrothermal circulation. This parameter is a measure of the interconnectivity of pore spaces and fractures; however, these features and their interconnectivity may depend upon physical and chemical processes related to the flow itself. Consequently, in any given hydrothermal environment, rock permeability may be a complex function of time and space that is difficult to determine *in situ* at the field scale. Moreover, permeability is often heterogeneous and anisotropic; it is a scale-dependent parameter that may vary over several orders of magnitude on relatively small spatial scales. Considerable research effort has been devoted to the determination of permeability and its temporal evolution during hydrothermal activity. In the following subsections we discuss some approaches to describing permeability in hydrothermal systems and its temporal evolution.

Porous medium permeability The percentage of rock volume that may be occupied by fluid is termed the porosity. To the extent that this porosity is interconnected it may give rise to permeable pathways for fluid flow. Such porosity-related permeability is termed primary permeability. There have been several mathematical models attempting to relate effective, or interconnected, porosity, ϕ, with permeability, but these have had limited success. A mathematical relationship between porosity and permeability is highly desirable for two reasons. First, porosity is scale independent and therefore laboratory-based measurements of porosity are meaningful; secondly, *in situ* porosity can be estimated from both electrical and seismic data.

Mathematical models relating effective porosity ϕ to a scalar bulk permeability k are generally of the form

$$k = Cb^2\phi^n \qquad [2]$$

where b is the average grain size of the medium and C is a numerical constant, respectively. The exponent n ranges between 2 and 3 in most formulations. The well-known Carmen-Kozeny relation is similar to eqn [2]. Equations of the form [2] often fail in practice because in most systems, even those that have significant primary permeability, field-scale permeability is controlled by fractures.

Fracture- and fault-related permeability Permeability in essentially all hydrothermally active regions is controlled by fractures and faults. Such permeability is termed secondary. In igneous and metamorphic rocks, which host most high-temperature hydrothermal activity, cracks must provide the main permeability because porosity and, hence, primary permeability is low. When permeability is controlled by fractures, large permeability can exist in the presence of very low interconnected porosity. In fracture-controlled systems, permeability is related to crack density, the abundance of crack intersections and the cube of the crack aperture.

A generalized formulation can be written as

$$k = C'\frac{l^3}{h}Na^2 \qquad [3]$$

where C' is a dimensionless coefficient describing the degree of crack interconnectivity, l is the mean crack aperture, h is the crack spacing, a is the crack length, and N is the number of cracks per unit area. As special case of [3], one may consider a set of planar parallel cracks of aperture l and spacing h. In this case the permeability is

$$k = \frac{l^3}{12h} = \frac{h^2}{12}\phi^3 \qquad [4]$$

where the porosity $\phi = l/h$. Figure 6 depicts k vs ϕ for selected values of h; the results show that large values of crack permeability can exist for $\phi \leq 1\%$. These values are several orders of magnitude greater than 10^{-18}–$10^{-20}\,m^2$, which are typical laboratory values for unfractured granite.

Estimates of permeability for hydrothermally active regions have been determined from borehole

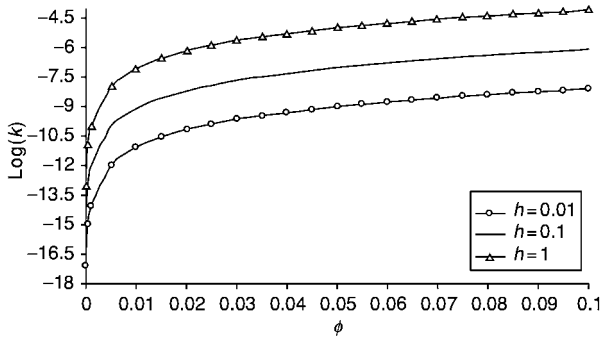

Figure 6 Graph of permeability versus porosity at a number of given fracture spacings for rock permeability resulting from planar parallel fractures. The curves show that high fracture permeability can occur in low porosity rocks.

measurements and from field measurements of crack distributions in fossil systems. Field-scale permeability has also been estimated from mathematical modelling of hydrothermal heat output. Measurements made in Deep Sea Drilling Project and Ocean Drillng Project boreholes give permeability values ranging from 10^{-18} m^2 in sheeted dykes to as high as 10^{-10} m^2 in pillows. Values in continental hydrothermal systems often fall between 10^{-12} and 10^{-15} m^2. Crack spacing and apertures in ophiolites yield permeability values ranging between 10^{-13} and 10^{-8} m^2. Mathematical modelling studies of high-temperature venting at ocean ridge crests give a similar range. The high values of permeability and the broad range of values estimated from field and modelling studies further indicate that permeability in hydrothermal regions is fracture-controlled.

Fracture-controlled permeability is typically heterogeneous and possibly anisotropic. Fracture concentration and orientation may result from tectonic stresses as well as processes related to magma emplacement and volcanic eruptions and thermal stresses. Zones of high fracture-controlled permeability are associated with dikes. In both continental and submarine hydrothermal systems discharge zones are often focussed along tectonic faults. Recharge zones are more problematical, but faulting could be important there as well.

Although fractures and faults control hydrothermal circulation patterns, one does not often consider flow in discrete fractures. Mathematical models usually treat flow in fractured rock as an equivalent porous medium and apply Darcy's Law. It is important in this regard, however, to recognize that fracture permeability can exist on several spatial scales and that the permeability may depend on time.

Temporal variations in permeability Temporal changes in permeability can result from several mechanisms. In addition to changes in response to tectonic and magmatic processes, both thermal and chemical processes can be significant. Because the processes have not been quantified in great detail, their relative importance is uncertain.

As circulating aqueous fluids encounter different pressure and temperature environments dissolution and precipitation of chemical constituents may occur. During water–rock reactions, hydrothermal fluids reach thermodynamic equilibrium with quartz. At pressures of a few hundred bars, the solubility of quartz reaches a maximum between 350 and 400°C. Thus if the hydrothermal solution is heated above 400°C quartz will precipitate and clog fractures and pore spaces. Similarly as the hydrothermal solution ascends towards the surface, both lower pressures and temperatures in the environment will foster quartz precipitation. Both quartz and amorphous silica are common vein minerals in hydrothermal systems, and precipitation of these phases may exert a strong influence on hydrothermal circulation over time. The development of a low permeability barrier as a result of quartz precipitation is likely an important factor in the evolution of vapour-dominated hydrothermal systems.

In submarine hydrothermal systems precipitation of anhydrite may be important in both recharge and discharge zones. Because the solubility of anhydrite decreases with increasing temperature, heating of seawater during hydrothermal recharge to $T \geq 150$°C results in precipitation of anhydrite in recharge zones (**Figure 3A**). Sulphate is removed from seawater by precipitation of anhydrite and reaction with crustal rocks; however, upon ascent, mixing of sulphate-poor, hot hydrothermal fluid with cold sulphate-rich seawater may again result in the precipitation of anhydrite. Mixing in the subsurface may contribute to focussing seafloor venting into black smokers; whereas mixing above the seafloor contributes to the formation of chimney structures.

Thermoelastic stresses result from the passage of either cold fluids through initially hotter rock or hot fluid through cooler rocks. In the former case, cooling of rock surfaces leads to thermal contraction and the enhancement of permeability. In the latter case, heating of the rock leads to thermal expansion and reduction of permeability. The dependence of permeability on temperature can be expressed as

$$k = k_0[1 - \gamma(T - T_0)]^3 + k_{\text{res}} \qquad [5]$$

where k_0 is the permeability of the main crack network, k_{res} is a finer-scale residual permeability, and γ is factor expressing the strength of the thermoelastic effect.

At temperatures exceeding 350–400°C, rocks begin to exhibit ductile behaviour. Although this behaviour depends upon the rate which stresses are applied, ductile behaviour will tend to seal cracks. Thus permeable pathways that may initially be opened by stresses resulting in brittle failure may gradually close. This process may limit the depth to which cracks remain open in the crust and the extent to which hydrothermal circulation may approach magma bodies.

Water–Rock Chemical Reactions

As aqueous fluids pass through hot subsurface rocks, chemical reactions occur. Some chemical constituents may be removed from the fluid, others may be extracted from the rock. The reactions may also involve isotopic exchange between the fluid and rock. These reactions are complex functions of temperature, pressure, lithology, permeability structure, duration of activity, and other factors. A detailed discussion of this topic is beyond the scope of this article; however, the use of geochemical thermometers and the formation of hydrothermal ore deposits are discussed briefly.

Geochemical thermometers The strong temperature dependence of solubility of certain chemical constituents in hydrothermal fluids, the temperature dependence of elemental partitioning between rock and solution, and the temperature dependence of isotopic partitioning between mineral and fluid phases have led to the development of a variety of geochemical thermometers to deduce subsurface conditions from surface samples. The quartz geothermometer utilizes the strong temperature dependence of quartz solubility and the slow kinetics of quartz precipitation at low temperature. As hydrothermal solutions in equilibrium with quartz at high temperature rise to the surface and cool, the high degree of disequilibrium in the measured quartz concentration permits a calculation of the equilibrium temperature at depth Other common geothermometers include:

1. Na/K, which makes use of the temperature dependence of partitioning of these elements between aluminosilicate rocks and hydrothermal fluid;
2. Na–K–Ca, which includes the effect of Ca in the partitioning; and
3. ratios of stable isotopes such as $\delta^{13}C$, $\delta^{18}O$, δD, and $\delta^{34}S$.

Various factors affect the resolution and reliability of each of these geothermometers, so often many independent ones are used.

Ore deposits–fossil hydrothermal systems As a result of water–rock chemical reactions at intermediate to high temperature, trace metallic ore-forming metals such as Fe, Cu, Zn, Sb, Au, Ag, and Pb are transferred from the rock to the hydrothermal solution. Because most of these metals form metallic sulphides that are highly insoluble in water, solubility is achieved by the formation of bisulphide or chloride ion complexes. Various mechanisms may cause local precipitation of these metal–ion complexes, resulting in a concentrated accumulation of metallic ore. A rapid drop in the solution temperature because of thermal conduction or mixing with cooler fluids, a change in solution pH, and boiling can all lead to ore deposition.

Many types of ore deposits in the geological record, such as porphyry ore deposits associated with silicic volcanism, Mississippi Valley-type lead-zinc deposits, and volcanically hosted massive sulphide deposits are linked to hydrothermal activity. Such ore deposits thus present an integrated fossil record of hydrothermal activity, and provide a window into subsurface heat transfer and fluid flow processes. By coupling this integrated fossil record with studies of active ore-forming processes on the seafloor and in other active hydrothermal environments, one can obtain a more complete picture of hydrothermal activity (*see* **Mining Geology:** Hydrothermal Ores).

Temporal Variability in Hydrothermal Activity

Temporal variability on a range of time-scales is a fundamental characteristic of hydrothermal activity (Table 2). Some of this variability is linked to episodicity in magmatic and tectonic activity, or climate changes. The occurrence of these processes ranges from scales of plate reorganization of $\sim 10^6$–10^7 years to magma replacement times of $\sim 10^1$–10^4 years at fast and slow spreading ridges, respectively. Temporal variability related to the fluid circulation system, mainly resulting from changes in crustal permeability, occurs on time-scales ~ 1–10^2 years. Seafloor hydrothermal activity is known to change on time-scales of hours to months following earthquakes, igneous intrusions (e.g., dykes), or volcanic eruptions. Climate changes may alter precipitation patterns, and hence fluid recharge, on time-scales of 10–10^3 years; ice ages and glaciation may affect high-altitude systems on similar time-scale.

Two-Phase Flow

Boiling and phase separation commonly occur in high-temperature hydrothermal systems. For pure water, boiling is defined by the boiling point curve as a function of pressure. Liquid phase occurs below

Table 2 Time scale of events and processes related to hydrothermal activity[a]

Time scale	*Activity or process*
10^6 10^7 years	Plate reorganization
10^6 10^7 years	Episodes of seafloor spreading
10^5 years	Magnetic polarity interval
10^1 10^6 years	Duration of ore formation processes
10^3 10^4 years	Eruption cycle on slow spreading ridges
10^1 10^3 years	Eruption cycle on fast spreading ridges
10^3 10^4 years	Glacial episodes
10^3 10^6 years	Duration of hydrothermal activity
10^1 10^3 years	Episodes of climate change
10^0 10^2 years	Duration of individual seafloor hydrothermal vent
10^0 10^1 years (hours to decade)	Duration of volcanic eruption
10^0 10^1 years	Residence time of hydrothermal fluid in oceanic crust
10^4 10^7 s	Transit time of upwelling hydrothermal fluid
10^5 10^7 s	Duration of earthquake swarms
10^5 10^7 s	Duration of dyke emplacement event
10^5 10^6 s	Duration of seafloor event plume
10^3 10^6 s	Period of tidal signals
0.1 3 s	Precipitation of sulphide particles during mixing of high *T* hydrothermal fluid with ambient seawater

[a]Modified from Lowell RP, Rona PA, and Von Herzen RP (1995) and Rona (1988).

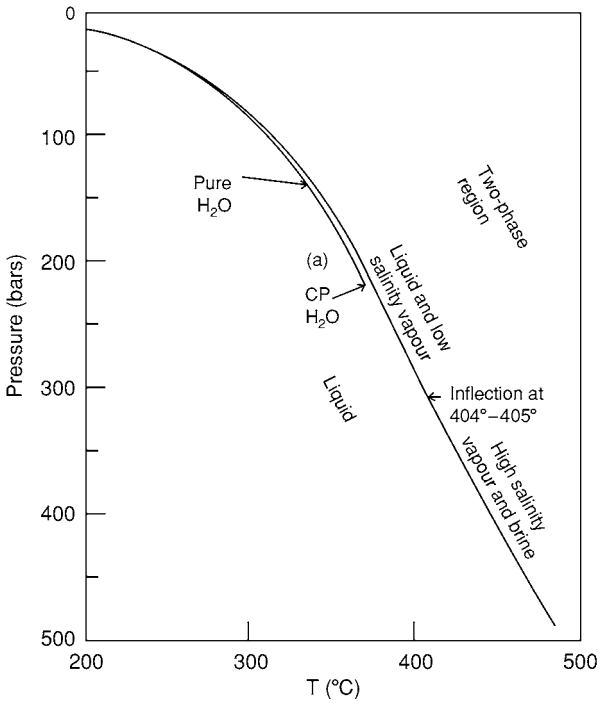

Figure 7 Boiling point curve for pure water compared with that for seawater. Note that the pure water curve ends at the critical point. The region above the pure water curve is pure vapour and the two phases only exist along the boiling curve. Reproduced from Bischoff and Rosenbauer (1984) The critical point and two phase boundary of seawater, 200 500°C. *Earth and Planetary Sci ence Letters* 68: 172 180.

the boiling point and the vapour phase occurs above it. The two phases are in equilibrium along the curve, and the volume fractions of each phase along the curve depend upon the enthalpy of the system. The phase diagram for water (Figure 7) most readily shows these relations. A key feature of the pure water phase diagram is the critical point defined by $P_c = 218$ bars, $T_c = 374°C$. Above the critical point only a single-phase "water substance" exists.

Most hydrothermal aqueous fluids contain some amount of dissolved salts; however, the presence of these dramatically alters the two-phase behaviour of water. First of all, both P_c and T_c increase as the salt content increases. For seawater, which can be represented by salinity $x \approx 3.2\%$ NaCl solution, $P_c \approx 300$ bars, $T_c \approx 405°C$. Secondly, two-phase flow is defined by a region of *P-T-x* space rather than a curve. Thirdly, because fluid density is a function of salinity, the fractionation of salt between the liquid and vapour phases affects the dynamics of the phases. Figure 8 depicts part of the phase diagram for NaCl–water solution.

In terrestrial systems subsurface boiling results in either liquid- or vapour-dominated systems. In liquid-dominated systems, fluid pressures are near hydrostatic. Hot spring fluids are generally neutral to alkaline pH and chloride rich. Liquid and vapour phases are intermingled within the two-phase zone, and the two-phase zone overlies a single-phase fluid. By contrast, in vapour-dominated systems low, nearly uniform, vapour-static fluid pressure occurs over a considerable thickness. Fluid discharge occurs at low pH and low chloride. The presence of a region of underpressure implies a permeable barrier between the vapour-dominated zone and the surrounding cold recharge. Vapour-dominated systems act as a heat pipe with near zero net mass flux; heat is carried upwards by high enthalpy vapour while small amounts of low-enthalpy liquid flow downwards. Most systems are liquid-dominated, including the geyser basins of Yellowstone National Park, USA, Wairakei and Broadlands, NZ, and Ahuachapan, MX; vapour-dominated systems include Geysers, USA, Lardarello, IT, Kamodjang, IND, and Matsukawa, JP (Figure 1).

In submarine systems venting black smoker fluids are mostly in the liquid phase; however, the chlorinity of vent fluids seldom corresponds to seawater (≈540 mmol kg). Rather it ranges from ≈30 to ≈1200 mmol kg (Table 3). The departure of vent salinity from that of seawater is attributed to phase separation. The lowest chlorinity values often occur shortly after magmatic eruptions or diking events and thus are indicative of active phase separation.

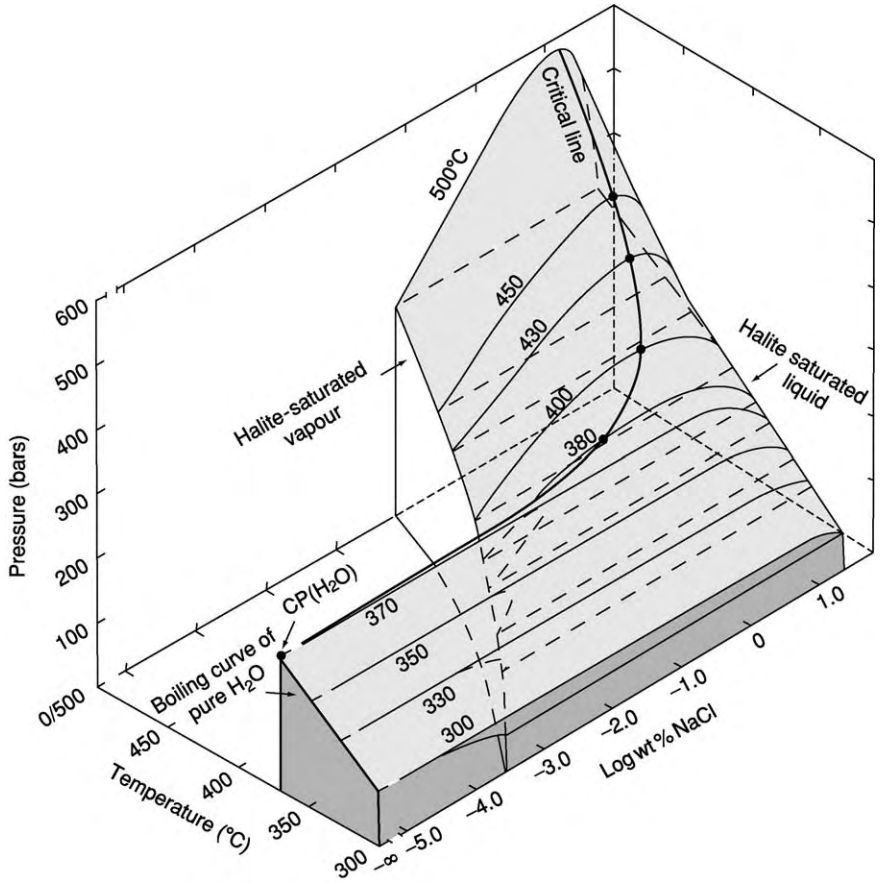

Figure 8 Three dimensional perspective of the NaCl H_2O phase diagram between 300 and 500°C. Reproduced from Bischoff and Pitzer (1989) Liquid vapor relations for the system NACL H_2O: Summary of the P T x surface from 300° to 500°C. *American Journal of Science* 289: 217 248.

Table 3 Chlorinity of selected high temperature seafloor hydrothermal Vents[a]

Vent site	*Year(s) sampled*	*Value (mmol kg ^{1})*[b]
East Pacific rise

MARK	1986	559
Lau basin	1989	650 800

[a]Modified from Von Damm (1985).
[b]Normal seawater chlorinity 540 mmol kg ^{1}.

Phase separation also results in the formation of saline brines that, because of their high density, sink towards the base of the system. Later mixing of these saline brines with seawater may result in vent chlorinity greater than seawater. The formation of a brine layer at the base of a hydrothermal system may act as a thermal conductive barrier between the overlying hydrothermal circulation and the magma body (Figure 3A) and be a salinity source for saline vent fluids.

Future Directions

Hydrothermal activity represents an exciting dynamic area for future research. This is particularly true for submarine systems because of their links to studies of the origin of life, life in extreme environments, and the continued discovery of novel types of hydrothermal activity. The detailed sampling and data analysis and continued exploration for serpentinization-driven hydrothermal activity will likely grow during the next decade. At ridge crest and volcanic island arc systems, advances in ocean drilling technology, remote and autonomous sensing devices, long-term monitoring, integrated interdisciplinary experiments at various well-characterized seafloor

sites, and improvements in mathematical modelling techniques will stimulate the science over the next decade. Finally, we believe that analysis of seafloor hydrothermal activity over geological time, and attempts to discern the importance of hydrothermal activity elsewhere in the solar system will emerge as an important endeavour. Such studies are necessary to understand the links between hydrothermal activity and life.

In terrestrial systems continued exploitation as an energy resource will be important. Moreover, climatically induced precipitation changes, because of the link to hydrothermal recharge, may alter warm spring and geyser behaviour. Utilization of hydrothermal activity as a climate monitor has yet to receive attention.

Mid-Ocean Ridges

K C Macdonald, University of California–Santa Barbara, Santa Barbara, CA, USA

Introduction

The mid-ocean ridge system is the largest mountain chain and the most active system of volcanoes in the solar system. In plate-tectonic theory, the ridge is located between plates of the Earth's rigid outer shell that are separating at speeds of approximately 10–170 mm year ^{1} (up to 220 mm year ^{1} in the past). The ascent of molten rock from deep within the Earth (*ca*. 30–60 km) to fill the void between the plates creates new seafloor and a volcanically active ridge. This ridge system wraps around the globe like the seam of a baseball and is approximately 70 000 km long (including the lengths of ridge offsets, such

as transform faults). Yet the ridge itself is only about 5–30 km wide, very small compared with the plates, which can be thousands of kilometres across (Figure 1).

Early exploration showed that the gross morphology of spreading centres varies with the rate of plate separation. At slow spreading rates (10–40 mm year ^{1}) a rift valley 1–3 km deep marks the axis, while for fast spreading rates (more than 90 mm year ^{1}) the axis is characterized by an elevation of the seafloor of several hundred metres called an axial high (Figure 2). The rate of magma supply is a second factor that may influence the morphology of mid-ocean ridges. For example, a very high rate of magma supply can produce an axial high even where the spreading rate is slow; the Reykjanes Ridge south of Iceland is a good example. Also, for intermediate spreading rates (40–90 mm year ^{1}) the ridge crest may have either an axial high or a rift valley depending on the rate of magma supply. The depth to the seafloor increases from a global average of approximately 2600 m at the spreading centre to more than 5000 m beyond the ridge flanks. The rate of deepening is proportional to the square root of the age of the seafloor because it is caused by the thermal contraction of the lithosphere. Early mapping efforts also showed that the mid-ocean ridge is a discontinuous structure, which is offset at right angles to its length by numerous transform faults that are tens to hundreds of kilometres long.

Maps are powerful: they inform, excite, and stimulate. Just as the earliest maps of the world in the sixteenth century ushered in a vigorous age of exploration, so the first high-resolution continuous-coverage maps of the mid-ocean ridge system stimulated investigators from a wide range of fields, including petrologists, geochemists, volcanologists, seismologists, tectonicists, and practitioners of marine magnetics and gravity, as well as researchers outside the Earth sciences, including marine ecologists, chemists, and biochemists. Marine geologists have found that many of the most revealing variations are observed by exploring along the axis of the active ridge. This along-strike perspective has revealed the architecture of the global rift system. The ridge axis undulates up and down in a systematic way, defining a fundamental partitioning of the ridge into segments bounded by a variety of discontinuities. These segments behave like giant cracks in the seafloor, which can lengthen or shorten and have episodes of increased volcanic and tectonic activity. In fact, elementary fracture mechanics can be used to explain the interaction between neighbouring ridge segments.

Another important change in perspective came from the discovery of hydrothermal vents by marine geologists and geophysicists. It became clear that,

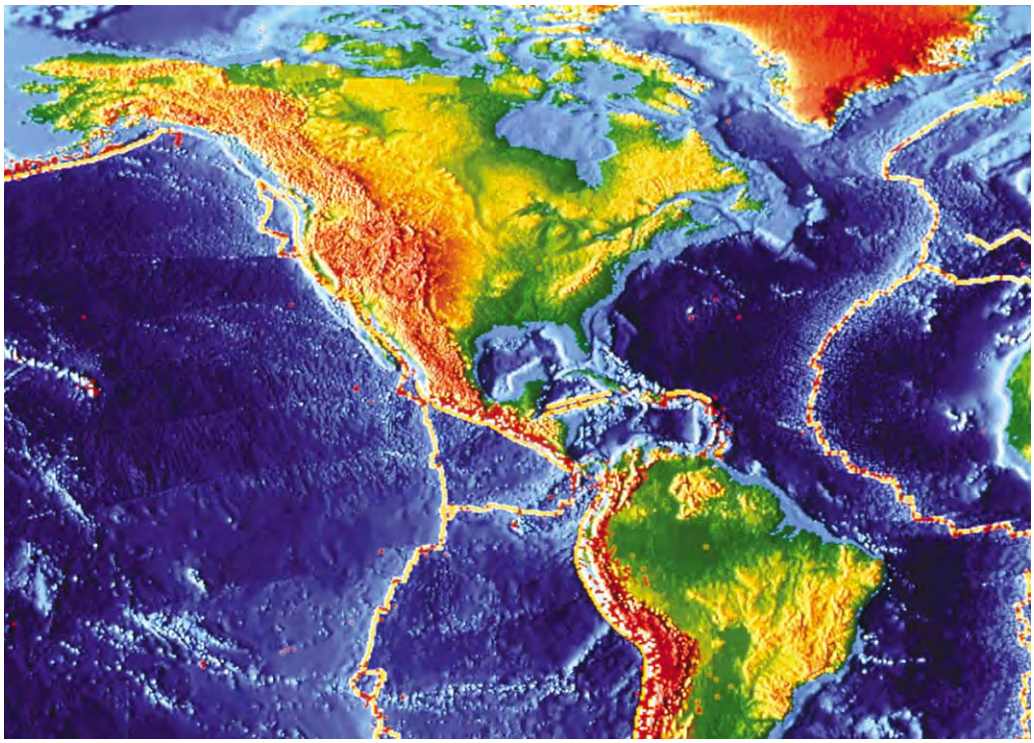

Figure 1 Shaded relief map of the seafloor showing parts of the East Pacific Rise, a fast spreading centre, and the Mid Atlantic Ridge, a slow spreading centre (courtesy of the National Geophysical Data Centre).

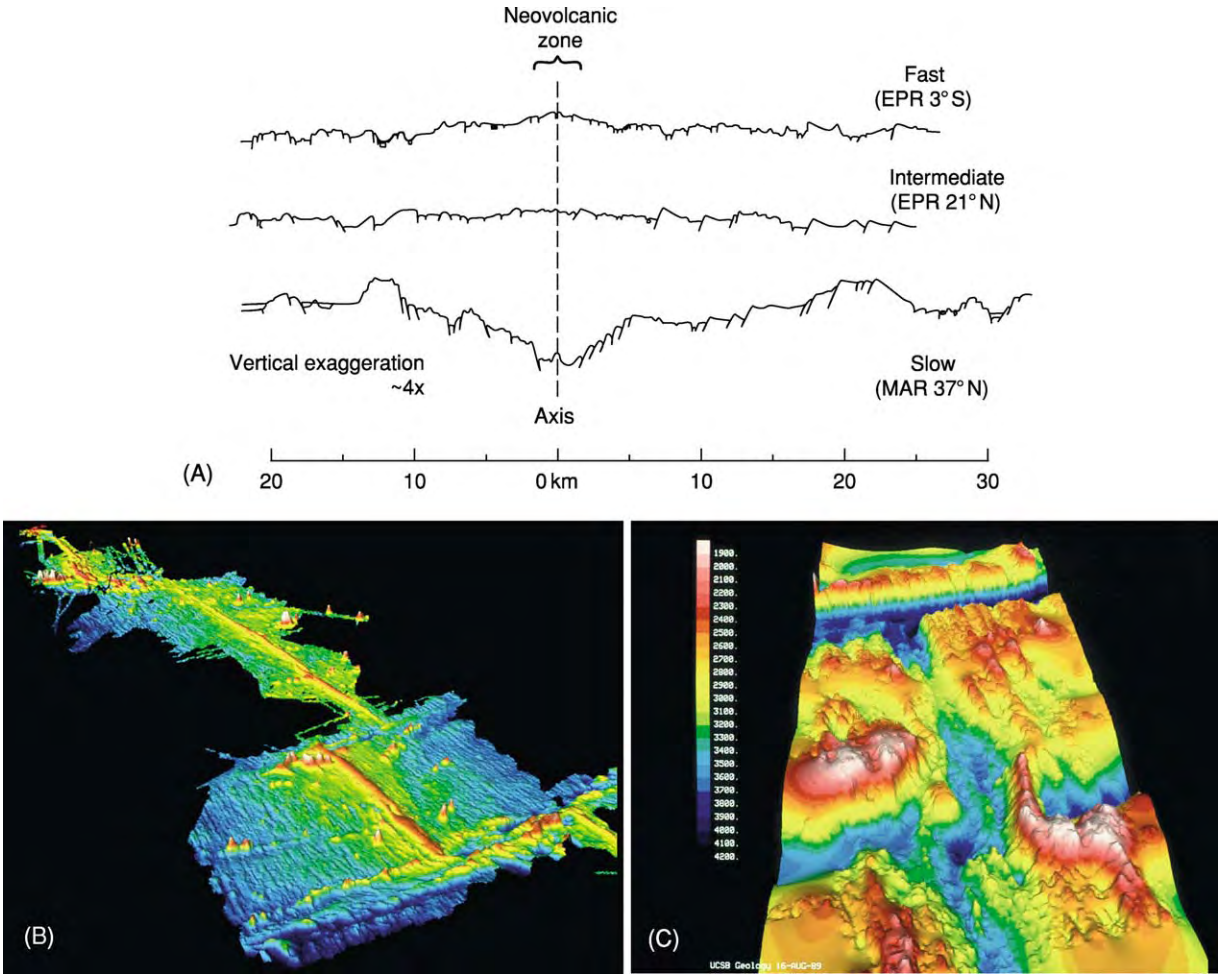

Figure 2 Topography of spreading centres. (A) Cross sections of typical fast intermediate and slow spreading ridges based on high resolution deep tow profiles. The neovolcanic zone (the zone of active volcanism) is indicated and is several kilometres wide; the zone of active faulting extends to the edge of the profiles and is several tens of kilometres wide. (Reproduced from Macdonald KC (1982) Mid ocean ridges: fine scale tectonic, volcanic and hydrothermal processes within the plate boundary zone. *Annual Review of Earth and Planetary Sciences* 10: 155 190.) EPR, East Pacific Rise; MAR, Mid Atlantic Ridge. (B) Shaded relief map of a 1000 km stretch of the East Pacific Rise extending from 8° N to 17° N. Here, the East Pacific Rise is the boundary between the Pacific and Cocos plates, which are separating at a 'fast' rate of 120 mm year ^{1}. The map reveals two kinds of discontinuity: large offsets, about 100 km long, known as transform faults, and smaller offsets, about 10 km long, called overlapping spreading centres. Colours indicate depths of 2400 m (pink) to 3500 m (dark blue). (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.) (C) Shaded relief map of the Mid Atlantic Ridge. Here, the ridge is the plate boundary between the South American and African plates, which are spreading apart at the slow rate of approximately 35 mm year ^{1}. The axis of the ridge is marked by a 2 km deep rift valley, which is typical of most slow spreading ridges. The map reveals a 12 km jog of the rift valley, a second order discontinuity, and also shows a first order discontinuity called the Cox transform fault. Colours indicate depths of 1900 m (pink) to 4200 m (dark blue). (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

in studies of mid-ocean ridge tectonics, volcanism, and hydrothermal activity, the greatest excitement is in the linkages between these different fields. For example, geophysicists searched for hydrothermal activity at mid-ocean ridges for many years by towing arrays of thermistors near the seafloor. However, hydrothermal activity was eventually documented more effectively by photographing the distribution of exotic vent animals. Even now, the best indicators of the recency of volcanic eruptions and the duration of hydrothermal activity are found by studying the characteristics of benthic faunal communities. For example, during the first deep-sea mid-ocean-ridge eruption witnessed from a submersible, divers did not see a slow lumbering cascade of pillow lavas, as observed by divers off the coast of Hawaii. What they

saw was completely unexpected: white bacterial matting billowing out of the seafloor, creating a scene much like a mid-winter blizzard in Iceland, covering the freshly erupted glassy black lava with a thick blanket of white bacterial 'snow'.

Ridge Segmentation

The most recognizable segmentation of mid-ocean ridges is that defined by transform faults. These plate boundaries are usually perpendicular to the ridge segments they offset and are tens to hundreds of kilometres long, although some exceed 1000 km in length (e.g. the Romanche and San Andreas faults). In plate tectonics, a transform fault traces a small circle about the Euler pole of opening between any pair of plates. Thus the transform fault and its off-axis fracture zone traces may be used to determine the pole of opening as well as changes in the pole of opening. At a ridge–transform intersection, normal spreading processes are truncated. Normal faulting predominates on mid-ocean ridges, while strike-slip faulting dominates along transform faults. The transition can be very complex, with normal faults and strike-slip faults occurring along trends that are affected by shear stresses on the transform fault. Crustal accretionary processes are also affected by the juxtaposition of thick cold lithosphere against the end of a spreading segment. This effect increases with the age and thickness of the lithosphere that is sliding past the ridge–transform intersection. Transverse ridges occur along the length of some of the largest transform faults; some of these ridges have been elevated above sea-level for part of their history.

Between major transform faults, the axial depth profile of mid-ocean ridges undulates up and down with a wavelength of tens of kilometres and an amplitude of tens to hundreds of metres at fast-spreading and intermediate-spreading ridges. This pattern is also observed for slow-spreading ridges, but the wavelength of undulation is shorter and the amplitude is larger (Figure 3). In most cases, ridge-axis discontinuities occur at local maxima of the axial depth profile. These discontinuities include transform faults, as discussed above (first order), overlapping spreading centres (second order), and higher order (third and fourth order) discontinuities, which are increasingly short-lived, mobile, and associated with smaller offsets of the ridge (see Table 1 and Figure 4).

A much-debated hypothesis is that the axial depth profile (Figures 3 and 5) reflects the magma supply along a ridge segment. According to this idea, the magma supply is enhanced along shallow portions of ridge segments and is relatively starved at segment ends (discontinuities). In support of this hypothesis

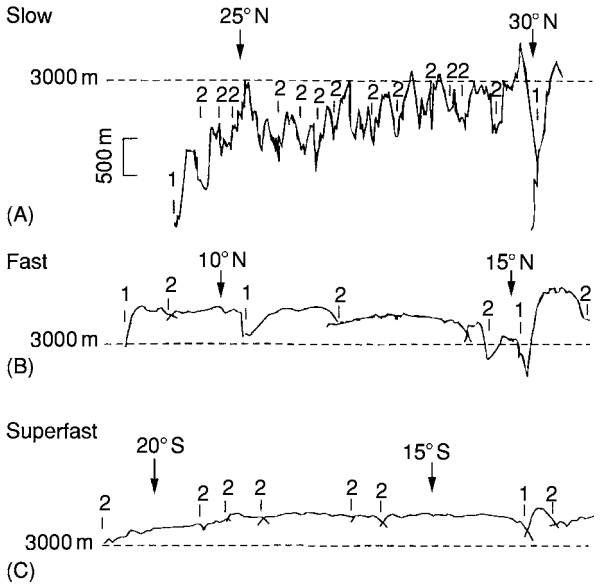

Figure 3 Axial depth profiles for (A) slow spreading, (B) fast spreading, and (C) superfast spreading ridges. Discontinuities of orders 1 and 2 typically occur at local depth maxima (discontinuities of orders 3 and 4 are not labelled here). The segments at faster spreading ridges are longer and have smoother lower amplitude axial depth profiles. These depth variations may reflect the pattern of mantle upwelling. (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

is the observation at ridges with an axial high (fast-spreading ridges) that the cross-sectional area or axial volume varies directly with depth (Figure 6). Maxima in the cross-sectional area (more than 2.5 km^2) occur at minima along the axial depth profile (generally not near ridge-axis discontinuities) and are thought to correlate with regions where magma supply is robust. Conversely, small cross-sectional areas (less than 1.5 km^2) occur at local depth maxima and are interpreted to reflect minima in the magma-supply rate along a given ridge segment. On slow-spreading ridges characterized by an axial rift valley, the cross-sectional area of the valley is at a minimum in the mid-segment regions, where the depth is at a minimum. In addition, there are more volcanoes in the shallow mid-segment area, and fewer volcanoes near the segment ends. Studies of crustal magnetization show that very highly magnetized zones occur near segment ends; these are most easily explained by a local restriction of magma supply resulting in the eruption of highly fractionated lavas that are rich in iron.

Multichannel seismic and gravity data support the axial volume–magma supply–segmentation hypothesis (Figure 6). A bright reflector, which is phase-reversed in many places, occurs commonly (>60%

Table 1 Characteristics of segmentation, updated from Macdonald KC, Scheirer DS, and Carbotte SM (1991) Mid ocean ridges: discontinuities, segments and giant cracks. *Science* 253: 986 994 (see references therein). This four tiered hierarchy of segmentation probably represents a continuum in segmentation

	Order 1	*Order 2*	*Order 3*	*Order 4*
Segments				
Segment length (km)	600 ± 300[a] (400 ± 200)[b]	140 ± 90 (50 ± 30)	20 ± 10 $(15 \pm 10?)$	7 ± 5 $(7 \pm 5?)$

[c]Offset age refers to the age of the seafloor that is juxtaposed to the spreading axis at a discontinuity.
NA, not applicable; ?, not presently known as poorly constrained; OSC, overlapping spreading centre.

of ridge length) beneath the axial regions of both the northern and southern portions of the fast-spreading and ultra-fast-spreading East Pacific Rise. This reflector has been interpreted as a thin lens of magma residing at the top of a broader axial magma reservoir. The amount of melt is highly variable along strike, varying from a lens that is primarily crystal mush to one that is close to 100% melt. This 'axial magma chamber' reflector is observed where the ridge is shallow and where the axial high has a broad cross-sectional area. Conversely, it is rare where the ridge is deep and narrow, especially near ridge-axis discontinuities. A reflector may occur beneath ridge-axis discontinuities during propagation and ridge-axis realignment, as may be occurring now on the East Pacific Rise near 9° N (*see* **Tectonics:** Seismic Structure At Mid-Ocean Ridges; Propagating Rifts and Microplates At Mid-Ocean Ridges).

There is evidence that major-element geochemistry correlates with axial cross-sectional area (**Figure 7**). On the East Pacific Rise between 13° S and 21° S there is a good correlation between MgO wt% and cross-sectional area (higher MgO indicates a higher eruption temperature and perhaps a greater local magmatic budget). The abundance of hydrothermal venting (as measured by light transmission and backscatter in the water column and geochemical tracers) also varies directly with the cross-sectional area of the East Pacific Rise. It is not often that one sees a correlation between two such different kinds of measurement. It is all the more remarkable considering that the measurements of hydrothermal activity are sensitive to changes on a time-scale of days to months, while the cross-sectional area probably reflects a time-scale of change measured in tens of thousands of years.

On slow-spreading centres, such as the Mid-Atlantic Ridge, the picture is less clear. Seismic and gravity data indicate that the oceanic crust thins significantly near many of the transform faults, even

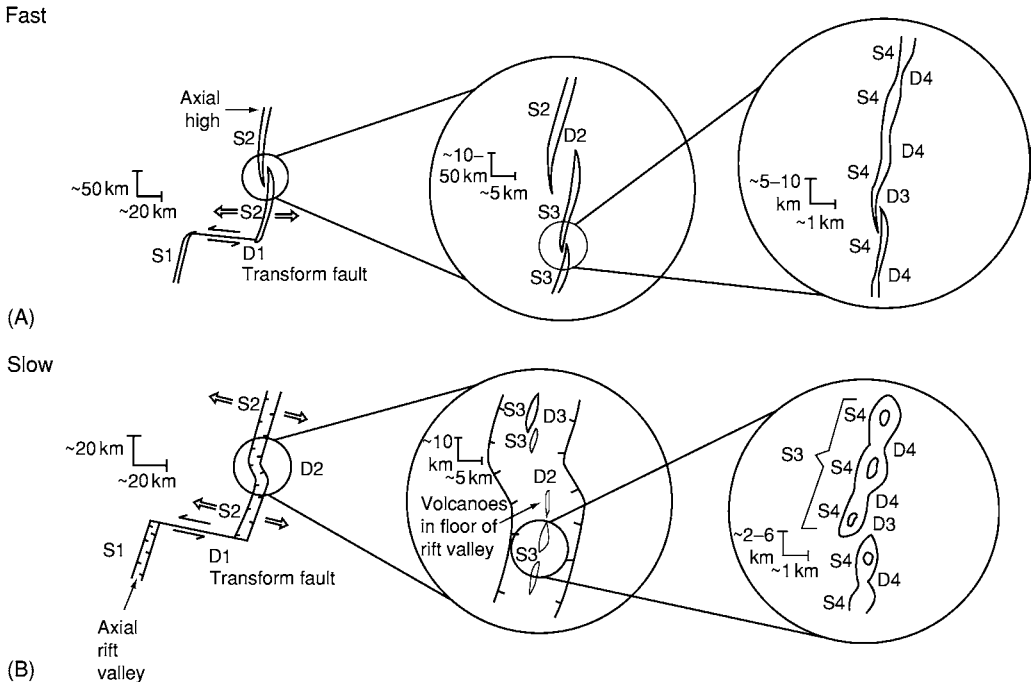

Figure 4 A possible hierarchy of ridge segmentation for (A) fast spreading and (B) slow spreading ridges. S1 S4 are ridge segments of orders 1 4, and D1 D4 are ridge axis discontinuities of orders 1 4. At both fast spreading and slow spreading centres, first order discontinuities are transform faults. Examples of second order discontinuities are overlapping spreading centres on fast spreading ridges and oblique shear zones on slow spreading ridges. Third order discontinuities are small overlapping spreading centres on fast spreading ridges. Fourth order discontinuities are slight bends or lateral offsets of the axis of less than 1 km on fast spreading ridges. This four tiered hierarchy of segmentation probably represents a continuum; it has been established, for example, that fourth order segments and discontinuities can grow to become third , second , and even first order features and vice versa at both slow spreading and fast spreading centres. (Reproduced from Macdonald KC, Scheirer DS, and Carbotte SM (1991) Mid ocean ridges: discontinuities, segments and giant cracks. *Science* 253: 986 994.)

those with small offsets. This is thought to be the result of highly focused mantle upwelling near the mid-segment regions, with very little along-axis flow of magma away from the upwelling region. Focused upwelling is inferred from 'bulls-eye'-shaped residual gravity anomalies and variations in crustal thickness that have been documented by seismic refraction and studies of microearthquakes. At slow-spreading centres, melt probably resides in small, isolated, and very short-lived pockets beneath the median valley floor (Figure 5) and beneath elongate axial volcanic ridges. An alternative view is that the observed along-strike variations in topography and crustal thickness can be accounted for by along-strike variations in mechanical thinning of the crust by faulting. There is no conflict between these models, so both focused upwelling and mechanical thinning may occur along each segment.

One might expect the same to hold at fast-spreading centres, i.e. crustal thinning adjacent to overlapping spreading centres. This does not appear to be the case at 9° N on the East Pacific Rise, where seismic data suggest a thickening of the crust towards the overlapping spreading centres and a widening of the axial magma chamber reflector. There is no indication of crustal thinning near the Clipperton transform fault either. And yet, as one approaches the 9° N overlapping spreading centres from the north, the axial depth plunges, the axial cross-sectional area decreases, the axial magma chamber reflector deepens, the average lava age increases, the MgO content of dredged basalts decreases, hydrothermal activity decreases dramatically, crustal magnetization increases significantly (suggesting eruption of more fractionated basalts in a region of decreased magma supply), crustal fracturing and inferred depth of fracturing increase (indicating a greater ratio of extensional strain to magma supply), and the throw of off-axis normal faults increases (suggesting thicker lithosphere and greater strain) (Figure 8A). How can these parameters all correlate so well, indicating a decrease in the magmatic budget and an increase in amagmatic extension, yet the seismic data suggest crustal thickening off-axis from and a wider magma lens near the overlapping spreading centres?

One possibility is that mantle upwelling and the axial magmatic budget are enhanced away from ridge-axis discontinuities even at fast-spreading

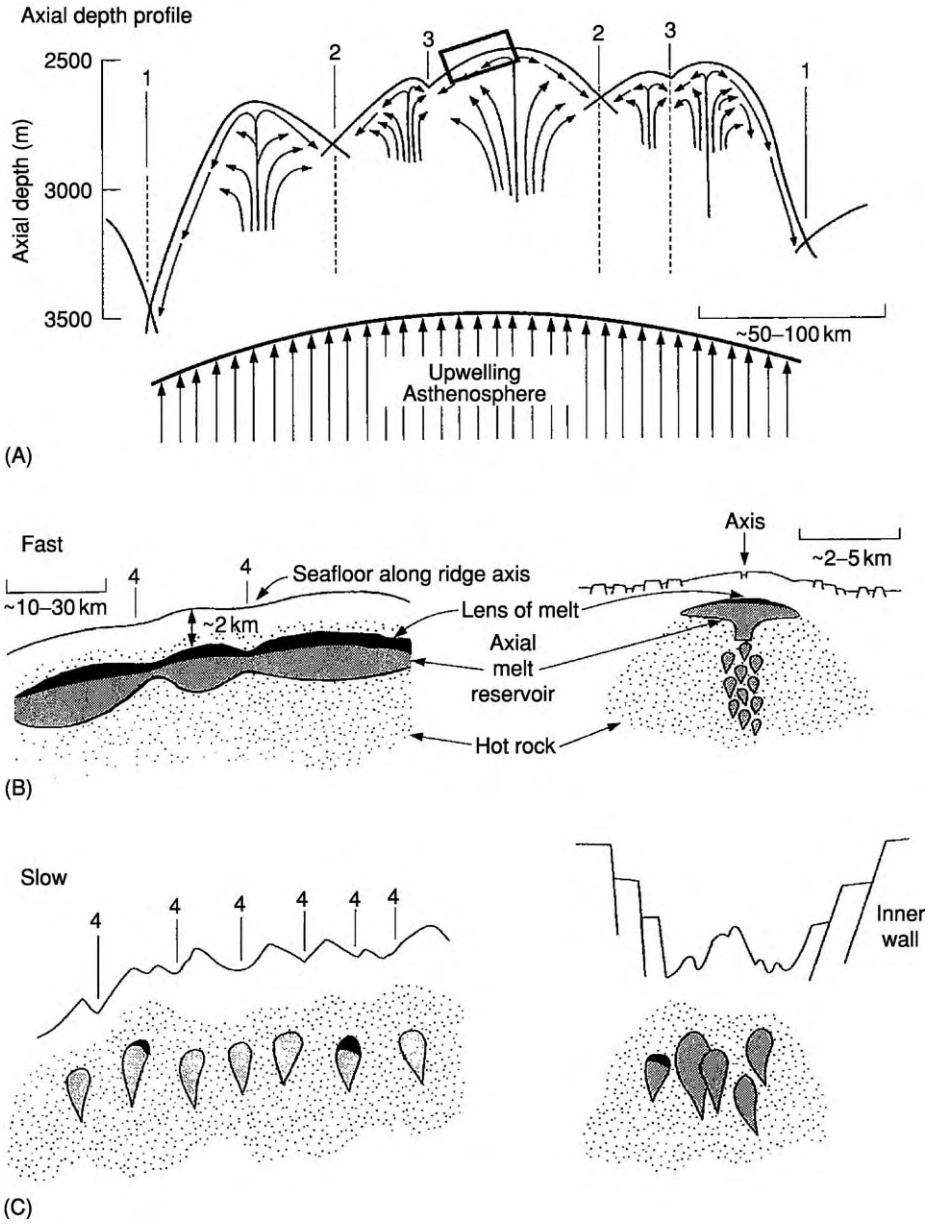

Figure 5 (A) How ridge segmentation may be related to mantle upwelling, and (B and C) the distribution of magma supply. In (A), the depth scale applies only to the axial depth profile; numbers denote discontinuities and segments of orders 1 3. Decompression partial melting in the upwelling asthenosphere occurs at depths of 30 60 km beneath the ridge. As the melt ascends through a more slowly rising solid residuum, it is partitioned at different levels to feed segments of orders 1 3. Mantle upwelling is hypothesized to be 'sheetlike' in the sense that melt is upwelling along the entire length of the ridge, but the supply of melt is thought to be enhanced beneath shallow parts of the ridge away from major discontinuities. The rectangle indicates the area enlarged to show fine scale segmentation for (B) a fast spreading example and (C) a slow spreading example. In (B) and (C) along strike cross sections showing the hypothesized partitioning of the magma supply relative to fourth order discontinuities (4s) and segments are shown on the left. Across strike cross sections for fast spreading and slow spreading ridges are shown on the right. (Reproduced from Macdonald KC, Scheirer DS, and Carbotte SM (1991) Mid ocean ridges: discontinuities, segments and giant cracks. *Science* 253: 986 994.)

centres, but subaxial flow of magma 'downhill' away from the injection region redistributes the magma episodically (Figure 5). This along-strike flow and redistribution of magma may be unique to spreading centres with an axial high, such as the East Pacific Rise or Reykjanes, where the axial region is sufficiently hot at shallow depths to facilitate subaxial flow. It is well-documented in Iceland and other volcanic areas analogous to mid-ocean ridges that magma can flow in subsurface chambers and dykes

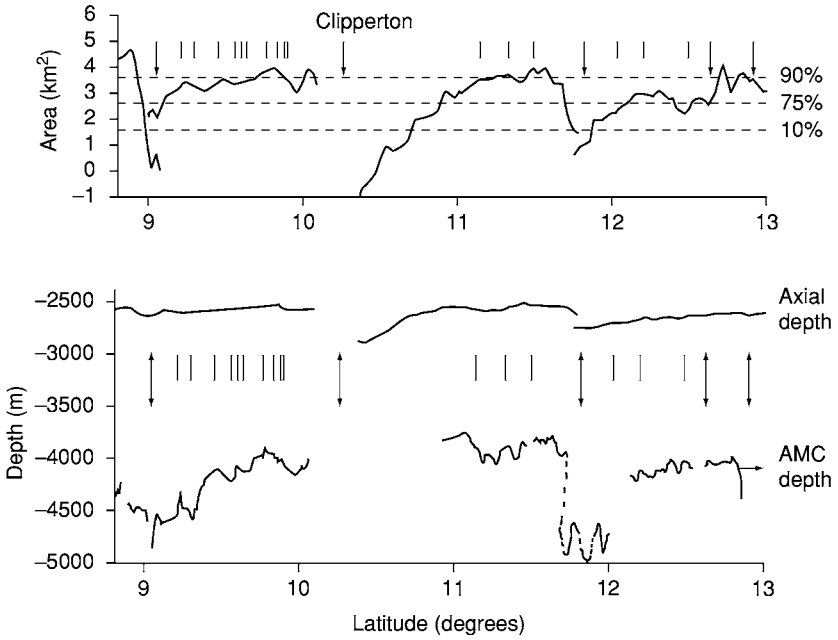

Figure 6 Profiles of the along axis cross sectional area, axial depth, and axial magma chamber (AMC) seismic reflector depth for the East Pacific Rise 9° 13° N. The locations of first and second order discontinuities are denoted by vertical arrows (first order discontinuities are named); each occurs at a local minimum of the ridge area profile and a local maximum of the ridge axis depth smaller discontinuities are denoted by vertical bars. There is an excellent correlation between ridge axis depth and cross sectional area; there is a good correlation between cross sectional area and the existence of an axial magma chamber, but detailed characteris tics of the axial magma chamber (depth, width) do not correlate. (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

for many tens of kilometres away from the source region before erupting. In this way, thicker crust may occur away from the mid-segment injection points, proximal to discontinuities such as overlapping spreading centres.

Based on studies of the fast-spreading East Pacific Rise, a 'magma supply' model has been proposed, which explains the intriguing correlation between over a dozen structural, geochemical, and geophysical variables within a first-, second-, or third-order segment (Figure 9). It also addresses the initially puzzling observation that the crust is sometimes thinner in the mid-segment region, where upwelling is supposedly enhanced. Intuitively, one might expect the crust to be thickest over the region where upwelling is enhanced, as is observed on the Mid-Atlantic Ridge. However, along-axis redistribution of melt may be the controlling factor on fast-spreading ridges, where the subaxial melt region may be well-connected for tens of kilometres. In this model, temporal variations in along-axis melt connectivity may result in thicker crust near the mid-segment when connectivity is low (most often at slow-spreading ridges) and thicker crust closer to the segment ends when connectivity is high (most often, but not always, at fast-spreading ridges).

The basic concepts of this magma-supply model also apply to slow-spreading ridges that are characterized by an axial rift valley. Mantle melting is enhanced beneath the mid-segment regions. However, the axial region is colder (averaged over time), and along-strike redistribution of melt is impeded. Thus, the crust tends to be thickest near the mid-segment regions and thinnest near ridge-axis discontinuities (Figures 8B and 9).

It is possible that the segmentation of mid-ocean ridges and the observations that correlate with segmentation (e.g. axial depth, geochemistry of lavas, lava morphology, etc.; Figure 8) are not related to the supply of magma to the ridge. This is still an area of active research and debate. For example, it has been suggested that the supply of melt is uniform along fast-spreading ridges and that along-strike variations are caused by differences in hydrothermal heat loss. If heat loss were enhanced near segment ends, this could cause many of the along-strike variations noted in Figure 8. So far, however, there is no indication that hydrothermal heat loss is greater near segment ends. On the contrary, hydrothermal heat loss is least evident at segment ends and is often enhanced near the shallow mid-sections of first-, second-, and third-order segments.

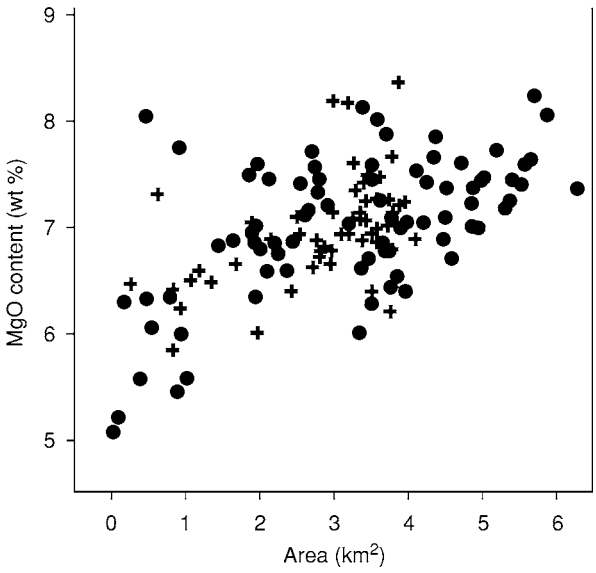

Figure 7 Cross sectional area of the East Pacific Rise plotted against the MgO content of basalt glass (crosses from 5 14° N; circles from 13 23° S). There is a tendency for high MgO contents (interpreted as higher eruption temperatures and perhaps a higher magmatic budget) to correlate with larger cross sectional areas. Smaller cross sectional areas are correlated with lower levels of MgO and a greater scatter in MgO content, suggesting magma chambers that are transient and changing. Thus shallow inflated areas of the ridge tend to erupt hotter lavas. Updated from Scheirer and Macdonald (1993) and references therein. (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, *Mid ocean ridge tectonics, volcanism and geomorphology*, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

Fine-Scale Variations in Ridge Morphology Within the Axial Neovolcanic Zone

The axial neovolcanic zone occurs on or near the axis of the axial high of fast-spreading centres and within the floor of the rift valley of slow-spreading centres (**Figures 2A**). Studies of the widths of the polarity transitions of magnetic anomalies, including *in situ* measurements from ALVIN, document that approximately 90% of the volcanism that creates the extrusive layer of oceanic crust occurs in a region 1–5 km wide at most spreading centres. Direct qualitative estimates of lava age at spreading centres using submersibles and remotely operated vehicles tend to confirm this, as do recent high-resolution seismic measurements that show that layer 2A (interpreted to be the volcanic layer) achieves its full thickness within 1–3 km of the rise axis (*see* **Tectonics:** Seismic Structure At Mid-Ocean Ridges). However, there are significant exceptions, including small-volume off-axis volcanic constructions and voluminous off-axis floods of basaltic sheet flows.

The axial high on fast-spreading and intermediate-spreading centres is usually bisected by an axial summit trough approximately 10–200 m deep, which is found along approximately 60–70% of the axis. Along the axial high of fast-spreading ridges, side-scan sonar records show that there is an excellent correlation between the presence of an axial summit trough and an axial magma chamber reflector as seen on multichannel seismic records (over more than 90% of the ridge length). Neither axial summit troughs nor axial magma chambers occur where the ridge has a very small cross-sectional area.

In rare cases, an axial summit trough is not observed where the cross-sectional area is large. In these locations, volcanic activity is presently occurring or has occurred within the last decade. For example, on the East Pacific Rise, near 9°45′–9°52′ N, a volcanic eruption documented from the submersible ALVIN was associated with a single major dyke intrusion, similar to the 1993 eruption on the Juan de Fuca Ridge. Side-scan sonar records showed that an axial trough was absent from 9°52′ N to 10°02′ N and, in subsequent dives, it was found that dyke intrusion had propagated into this area producing very recent lava flows and hydrothermal activity complete with bacterial 'snowstorms'. A similar situation has been thoroughly documented at 17°25′–17°30′ S on the East Pacific Rise, where the axial cross-sectional area is large but the axial summit trough is partly filled. Perhaps the axial summit trough has been flooded with lava so recently that magma withdrawal and summit collapse are still occurring. Thus, the presence of an axial summit trough along the axial high of a fast-spreading ridge is a good indicator of the presence of a subaxial lens of partial melt (axial magma chamber); where an axial summit trough is not present but the cross-sectional area is large, this is a good indicator of very recent or current volcanic eruptions; where an axial summit trough is not present and the cross-sectional area is small, this is a good indicator of the absence of a magma lens (axial magma chamber).

In contrast to the along-axis continuity of the axial neovolcanic zone of fast-spreading ridges, the neovolcanic zone of slower-spreading ridges is considerably less continuous and there is a great deal of variation from segment to segment. Volcanic constructions, called axial volcanic ridges, are most common along the shallow mid-segment regions of the axial rift valley. Near the ends of segments, where the rift valley deepens, widens, and is truncated by transform faults or oblique shear zones, the gaps between axial volcanic ridges become longer. The gaps between axial volcanic ridges are regions of older crust, characterized by faulting and a lack of recent volcanism.

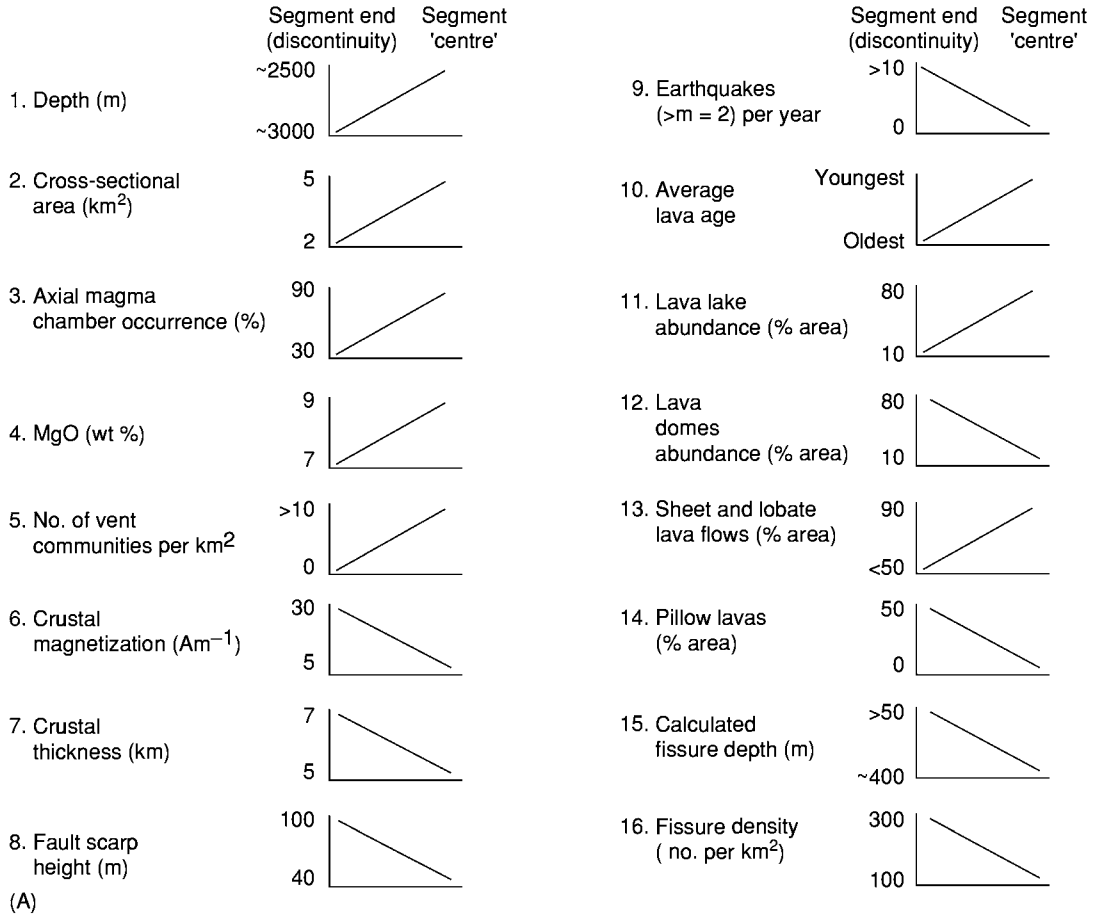

Figure 8 Summary of along axis variations in spreading centre properties from segment end (discontinuity of order 1, 2, or 3) to segment mid section areas for (A) fast spreading ridges with axial highs and (B) slow spreading ridges with axial rift valleys. A large number of parameters correlate well with location within a given segment, indicating that segments are distinct independent units of crustal accretion and deformation. These variations may reflect a fundamental segmentation of the supply of melt beneath the ridge.

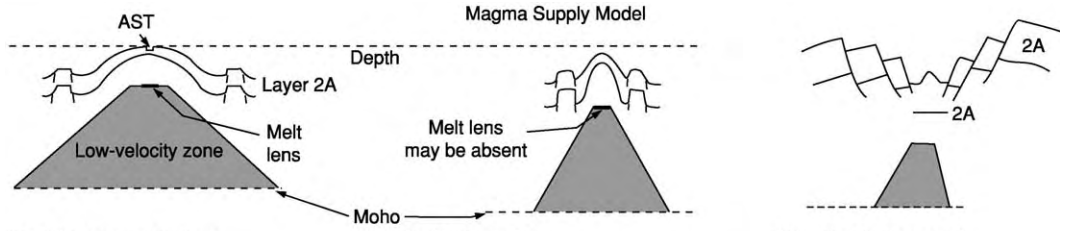
Continued

These gaps may correspond to fine-scale (third- and fourth-order) discontinuities of the ridge.

There is another important difference between volcanism on fast-spreading and slow-spreading ridges. Axial volcanic ridges represent a thickening of the volcanic layer atop a lithosphere that may be 5–10 km thick, even on the axis. In contrast, the volcanic layer is usually thinnest along the axis of the fast-spreading East Pacific Rise (*see* **Tectonics:** Seismic Structure At Mid-Ocean Ridges). Thus, the axial high of fast-spreading ridges is not a thickened accumulation of lava, while the discontinuous axial volcanic ridges of slow-spreading ridges are.

On both slow-spreading and fast-spreading ridges, pillow and lobate lavas are the most common lava morphologies. Based on laboratory studies and observations of terrestrial basaltic eruptions, this indicates that the lava effusion rates are slow to moderate on most mid-ocean ridges. High volcanic effusion rates, indicated by fossil lava lakes and extensive outcrops



(A) High magma budget	(B) Moderate to low magma budget	(C) Very low, sporadic magma supply
Shallow water depth	Deeper water depth	Deep rift valley floor
Broad cross-sectional area	Small cross-sectional area	Wide valley floor
Wide low-velocity zone High MgO content High temperature Low density	Narrow (except where 2 LVZ coalesce at an OSC)* Lower MgO content Lower temperature Higher density	Narrow low-velocity zone
Melt lens ubiquitous, depth and width variable*	Melt lens less common, highly variable width, depth where present, disrupted at RADs*	Melt lens very rare
Thinner crust (melt flows 'downhill' away from mantle upwelling zone)*	Thicker crust, but highly variable*	Highly variable crustal thickness
Axial summit trough present unless in eruptive phase*	Axial summit trough rare	
Hydrothermal venting abundant*	Hydrothermal venting rare*	Hydrothermal vents rare, fault controlled
Less crustal fissuring*	More crustal fissuring*	Extensive fissuring
Younger average lava age*	Older average lava age*	Highly variable but generally older lava age, mostly pillows
Lower crustal magnetization*	Higher crustal magnetization*	
Smaller throw on flanking fault scarps	Larger throw on flanking fault scarps	Large fault scarps, especially at inside corner highs
Layer 2A thinnest along axis	Layer 2A thinnest along axis	Layer 2A thick beneath axial volcanic ridges

Figure 9 Magma supply model for mid ocean ridges. (A) A segment with a robust magmatic budget, generally a fast spreading ridge away from discontinuities or a hotspot dominated ridge with an axial high. (B) A segment with a moderate magma budget, generally a fast spreading ridge near a discontinuity or a non rifted intermediate rate ridge. (C) A ridge with a sporadic and diminished magma supply, generally a rifted intermediate to slow spreading centre (for along strike variations at a slow ridge, see **Figure 8B**). AST, axial summit trough; LVZ, low velocity zone; OSC, overlapping spreading centres; RAD, ridge axis discontinuity. (Less than 1% of the ridge has been studied in sufficient detail to create this summary.) (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

of sheet-flow lavas, are very rare on slow-spreading ridges. High-effusion-rate eruptions are more common on fast-spreading ridges and are more likely to occur along the shallow inflated mid-segment regions of the rise, in keeping with the magma-supply model for ridges discussed earlier (Figure 9A).

Very little is known about eruption frequency. It has been estimated based on some indirect observations that, at any given place on a fast-spreading ridge, eruptions occur approximately every 50–100 years, and that on slow-spreading ridges eruptions occur approximately every 5000–10 000 years. If this is true, then the eruption frequency varies inversely with the square of the spreading rate. On intermediate- to fast-spreading centres, if one assumes a typical dyke width of around 50 cm and a spreading rate of 5–10 cm year ^{1}, then an eruption could occur approximately every 5–10 years. This estimate is in reasonable agreement with the occurrence of megaplumes and eruptions on the well-monitored Juan de Fuca Ridge. However, observations of sheeted-dyke sequences in Iceland and of ophiolites indicate that only a small percentage of the dykes reach the surface to produce eruptions.

On fast-spreading centres, the axial summit trough is so narrow (30–1000 m) and well-defined in most places that tiny offsets and discontinuities of the rise axis can be detected (Table 1 and Figure 2). This finest scale of segmentation (fourth-order segments and discontinuities) probably corresponds to individual fissure eruption events similar to the Krafla eruptions in Iceland and the Kilauea east rift zone eruptions in Hawaii. Given a magma chamber depth of 1–2 km, an average dyke ascent rate of approximately 0.1 km h ^{1}, and an average lengthening rate of approximately 1 km h ^{1}, typical diking events would give rise to segments 10–20 km long. This agrees with observations of fourth-order segmentation and the scale of recent diking events on the Juan de Fuca Ridge and in other volcanic rift zones. The duration of such segments is thought to be very short, of the order of 100–1000 years (too brief in any case to leave even the smallest detectable trace off-axis; Table 1). Yet, even at this very fine scale, excellent correlations can be seen between average lava age, density of fissuring, the average widths of fissures, and the abundance of hydrothermal vents within individual segments. In fact, there is even an excellent correlation between ridge cross-sectional area and the abundance of benthic hydrothermal communities (Figure 8).

A curious observation on the East Pacific Rise is that the widest fissures occur in the youngest lava fields. If fissures widen over time with increasing extension, one would expect the opposite: the widest fissures should be in the oldest areas. The widest fissures are approximately 5 m wide. Using simple fracture mechanics, it can be concluded that these fissures probably extend all the way through layer 2A and into the sheeted-dyke sequence. These have been interpreted as eruptive fissures, and this is where high-temperature vents (more than 300 °C) are concentrated. In contrast to the magma-rich dyke-controlled hydrothermal systems that are common on fast-spreading centres, magma-starved hydrothermal systems on slow-spreading ridges tend to be controlled more by the penetration of seawater along faults near the ridge axis.

Faulting

Extension at mid-ocean ridges causes fissuring and normal faulting. The lithosphere is sufficiently thick and strong on slow-spreading centres to support shear failure on the axis, so normal faulting along dipping fault planes can occur on or very close to the axis. These faults produce grabens that are 1–3 km deep. In contrast, normal faulting is not common on fast-spreading centres within 2 km of the axis, probably because the lithosphere is too thin and weak to support normal faulting. Instead, the new thin crust fails by simple tensional cracking.

Fault strikes tend to be perpendicular to the direction of least compressive stress; thus, they also tend to be perpendicular to the spreading direction. While there is some 'noise' in the fault trends, most of this noise can be accounted for by perturbations in the direction of least compressive stress due to shearing in the vicinity of active or fossil ridge-axis discontinuities. Once this is accounted for, fault trends faithfully record changes in the direction of opening to within $\pm 3^{\circ}$ and can be used to study plate-motion changes on a finer scale than that provided by the study of seafloor magnetic anomalies. Studies of the cumulative throw of normal faults, seismicity, and fault spacing suggest that most faulting occurs within 20–40 km of the axis irrespective of spreading rate.

The occurrence of inward- and outward-dipping faults depends on the spreading rate. Most faults (*ca*. 80%) dip towards the axis on slow-spreading centres, but there is a monotonic increase in the frequency of outward-dipping faults with spreading rate (Figure 10). Inward- and outward-facing faults are approximately equally abundant at very fast spreading rates. This can be explained by the smaller mean normal stress across a fault plane that dips towards the axis, cutting through thin lithosphere, than across a fault plane that dips away from the axis, cutting through a much thicker section of lithosphere. Given reasonable thermal models, the difference in the

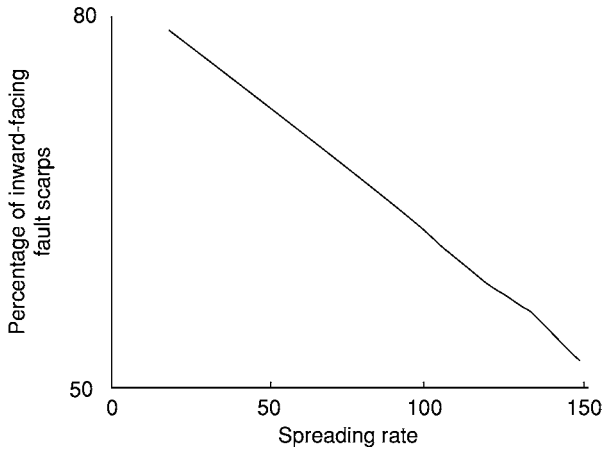

Figure 10 The effect of spreading rate on the percentage of fault scarps that are inward facing (facing towards the spreading axis rather than away from the spreading axis). A significant increase in the percentage of inward facing scarps occurs at slower spreading rates (mm yr). (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, Mid ocean ridge tectonics, volcanism and geomorphology, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

thickness of the lithosphere cut by planes dipping towards and away from the axis (and the mean normal stresses across those planes) decreases significantly with spreading rate, making outward-dipping faults more likely at fast spreading rates.

At all spreading rates, important along-strike variations in faulting occur within major (first-order and second-order) spreading segments. Fault throws (inferred from scarp heights) decrease in the mid-segment regions away from discontinuities (Figures 8 and 11). This may be caused by a combination of thicker crust, thinner lithosphere, greater magma supply, and less amagmatic extension away from ridge-axis discontinuities in the mid-segment region (Figure 11). Another possible explanation for along-strike variations in fault throw is along-strike variation in the degree of coupling between the mantle and crust. A ductile lower crust will tend to decouple the upper crust from extensional stresses in the mantle, and the existence of a ductile lower crust will depend on spreading rate, the supply of magma to the ridge, and proximity to major discontinuities.

Estimates of crustal strain due to normal faulting vary from 10–20% on the slow-spreading Mid-Atlantic Ridge to *ca*. 3–5% on the fast-spreading East Pacific Rise. This difference may be explained as follows. The rate of magma supply to slow-spreading ridges is relatively low compared with the rate of crustal extension and faulting, while extension and magma-supply rates are in closer balance on fast-spreading ridges. The resulting seismicity is different too. In contrast to faulting on slow-spreading ridges, where teleseismically detected earthquakes are common, faulting on fast-spreading ridges rarely produces earthquakes with magnitudes of more than 5. Nearly all of these events are associated with ridge-axis discontinuities. The level of seismicity measured at fast-spreading ridges accounts for only a very small percentage of the observed strain due to faulting, whereas fault strain at slow-spreading ridges is comparable to the observed seismic moment release. It has been suggested that faults in fast-spreading environments accumulate slip largely by stable sliding (aseismically) owing to the warm temperatures and associated thin brittle layer. At slower spreading rates, faults will extend beyond a frictional stability transition into a field where fault slip occurs unstably (seismically) because of a thicker brittle layer.

Disruption of oceanic crust by faulting may be particularly extreme on slow-spreading ridges near transform faults (Figure 12). Unusually shallow topography occurs on the active transform slip side of ridge–transform intersections; this is called the inside corner high. These highs are not volcanoes. Instead they are caused by normal faults that cut deeply into and perhaps all the way through the oceanic crust. It is thought that crustal extension may occur for 1–2 Ma on detachment faults with little magmatic activity. This results in extraordinary extension of the crust and exposure of large sections of the deep crust and upper mantle on the seafloor. Corrugated slip surfaces indicating the direction of fault slip are also evident and are called 'megamullions' by some investigators.

Disruption of oceanic crust by faulting may also reach extremes at the slowest known spreading rates of 0.5–1.0 cm year ^{1}, for example on the Gakkel Ridge in the Arctic Ocean and along parts of the Southwest Indian Ocean Ridge. There is evidence that crustal extension due to faulting exceeds 20% and that there are prolonged periods with no basaltic volcanism along the rift valley. Instead, upper-mantle peridotites upwell to fill the gap between the separating plates during the intervals between infrequent, but sometimes very large, basaltic eruptions.

At distances of several tens of kilometres from the axis, topography generated near the spreading centre is preserved on the seafloor with little subsequent change, except for the gradual accumulation of pelagic sediments at rates of approximately 0.5–20 cm per thousand years, until it is subducted. The preserved topographic highs and lows are called abyssal hills. At slow-spreading centres characterized by an axial rift valley, back-tilted fault blocks and half-grabens may be the dominant origins of abyssal hills (Figure 13),

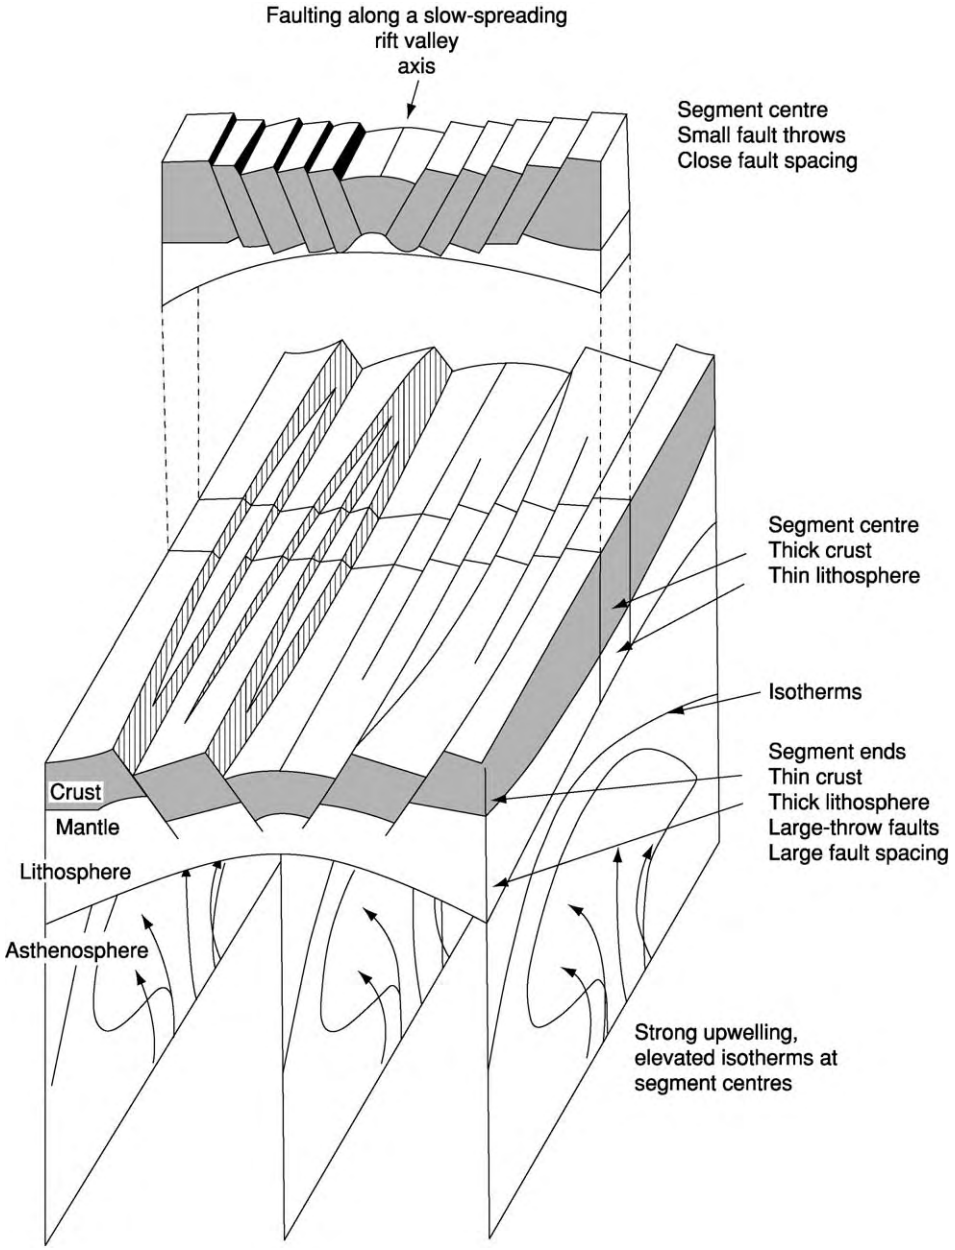

Figure 11 A geological interpretation of along axis variations in scarp height and the occurrence of more closely spaced scarps near mid segments on a slow spreading ridge. The cross section through the segment centre (top) shows more closely spaced smaller throw faults than at the segment ends (bottom). Focused mantle upwelling near the segment centre causes this region to be hotter: the lithosphere will be thinner, while increased melt supply will create a thicker crust. In contrast to observations at fast spreading centres, there may be very little melt redistribution along strike. Near the segment ends, the lithosphere will be thicker and magma supply will be less, creating thinner crust. Along axis variations in scarp height and spacing reflect these along axis variations in lithospheric thickness. Amagmatic extension across the larger faults near segment ends may also thin the crust, especially at inside corner highs. (Reproduced from Shaw PR (1992) Ridge segmentation, faulting and crustal thickness in the Atlantic Ocean. *Nature* 358: 490 493.)

although there is continued controversy over the roles of high-versus low-angle faults and listric faulting versus planar faulting and the possible role of punctuated episodes of volcanism versus amagmatic extension. At intermediate-rate spreading centres, abyssal-hill structure may vary with the local magmatic budget. Where the budget is starved and the axis is characterized by a rift valley, abyssal hills are

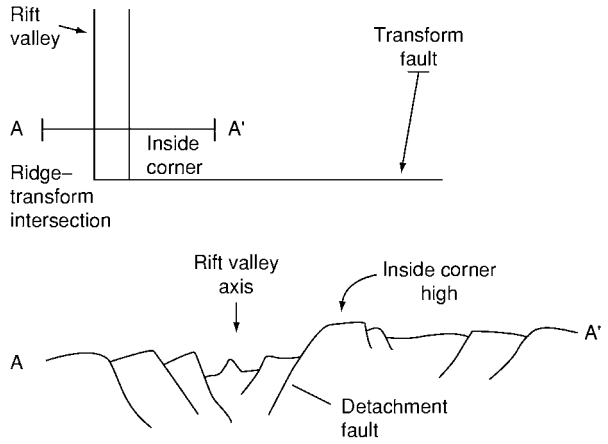

Figure 12 Inside corner high at a slow spreading ridge transform intersection. Extension is concentrated along a detach ment fault for up to 1 2 Ma, exposing deep sections of oceanic crust and mantle. The oceanic crust is thinned by this extreme extension; crustal accretion and magmatic activity may also be diminished. Figure 13 Five models for the development of abyssal hills on the flanks of mid ocean ridges. (A) Back tilted fault blocks (episodic inward dipping normal faulting off axis). (B) Horst and graben (epi sodic inward and outward dipping faulting off axis). (C) Whole volcanoes (episodic volcanism on axis). (D) Split volcanoes (epi sodic volcanism and splitt ng on axis). (E) Horsts bounded by inward dipping normal faults and outward dipping volcanic growth faults (episodic faulting off axis and episodic volcanism on axis or near axis). (Reprinted from *Encyclopedia of Ocean Sciences*, Steele J, Thorpe S, and Turekian K (eds.), Macdonald KC, *Mid ocean ridge tectonics, volcanism and geomorphology*, pp. 1798 1813, Copyright (2001), with permission from Elsevier.)

generally back-tilted fault blocks. Where the magmatic budget is robust and an axial high is present, the axial lithosphere is episodically thick enough to support a volcanic construction, which may then be rafted away intact or split in two by the spreading axis, resulting in whole-volcano and split-volcano abyssal hills, respectively.

Based on observations made from the submersible ALVIN on the flanks of the East Pacific Rise, it would appear that the outward-facing slopes of the hills are neither simple outward-dipping normal faults, as would be predicted by the horst-and-graben model, nor entirely of volcanic construction, as would be predicted by the split-volcano model. Instead, the outward-facing slopes are 'volcanic growth faults' (Figure 14). Outward-facing scarps produced by episodes of normal faulting are buried near the axis by syntectonic lava flows originating along the axial high. Repeated episodes of dip-slip faulting and volcanic burial result in structures resembling growth faults, except that the faults are episodically buried by lava flows rather than being continuously buried by sediment deposition. In contrast, the inward-dipping faults act as tectonic dams to lava flows. Thus, the abyssal hills are horsts and the intervening troughs are grabens, with the important modification to the horst-and-graben model that the outward-facing slopes are created by volcanic growth faulting rather than traditional normal faulting. Thus, on fast-spreading centres, abyssal hills are asymmetric, being bounded by steeply dipping normal faults

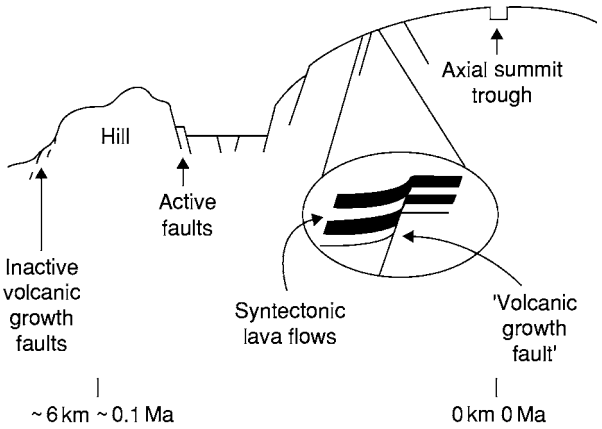

Figure 14 Cross sectional depiction of the development of volcanic growth faults. Volcanic growth faults are common on fast spreading centres and explain some of the differences between inward and outward facing scarps as well as the mor phology and origin of most abyssal hills on fast spreading cen tres. facing the spreading axis and volcanic growth faults on the opposing side. These faults lengthen at a rate of 20–60 Km/Ma reaching total lengths of 10–70 km to form abyssal hills and intervening grabens (Figure 15).

Hydrothermal Vents At Mid-Ocean Ridges

R M Haymon, University of California–Santa Barbara, Santa Barbara, CA, USA

Introduction

On the Galapagos Rift in 1977, ~2600 m beneath the sunlit surface of the sea, scientists exploring the lightless, frigid seafloor were astonished to discover springs of warm water teeming with life (Figure 1A). It was quickly realized these remarkable ecosystems in the deep sea are supported by microbes capable of metabolizing chemicals dissolved in hydrothermal spring waters. In 1979, submersible divers exploring the crest of the East Pacific Rise came on superheated ($380 \pm 30°C$) hot springs, where plumes of scalding fluid, blackened by minuscule mineral particles, billowed into the ocean through tall mineral conduits (Figure 1B). The minerals formed at these 'black smoker' hydrothermal vents proved to be rich in copper, iron, zinc, and other useful metals.

Hundreds of hydrothermal vents have now been located on the crest and flanks of the mid-ocean ridge, and more are found every year. The mid-ocean ridge is a globe-encircling rift where plates of ocean lithosphere are repeatedly ripped apart (*see* **Tectonics:** Mid-Ocean Ridges). New, hot seafloor freezes in the cracks between the plates and is cooled by hydrothermal circulation that entrains enormous volumes of seawater. The great magnitude of hydrothermal fluid flow through the mid-ocean ridge influences the chemistry, biology, and physical oceanography of the world ocean; the thermal structure, physical properties, and chemical composition of ocean crust; and the nature and diversity of subseafloor microbial environments. Many now believe that submarine hot springs may have been the biochemical crucibles for the origin of life in the solar system.

For thousands of years before mid-ocean ridge hot springs were discovered in the oceans, people mined copper from mineral deposits that were originally formed on oceanic spreading ridges. These fossil deposits are embedded in old fragments of seafloor, called 'ophiolites', that have been uplifted and emplaced onto land by fault movements. The copper-rich mineral deposits in the Troodos ophiolite of Cyprus are well-known examples of fossil ocean ridge deposits that have been mined for at least 2500 years; in fact, the word 'copper' is derived from the Latin word *cyprium*, which means 'from Cyprus'.

The mineral deposits accumulating today at hot springs along the mid-ocean ridge are habitats for a variety of remarkable organisms, ranging in size from tiny microbes to 2-m-long tubeworms. The properties of the mineral deposits are inextricably linked to the organisms that inhabit them. The mineral deposits contain important clues about the physical–chemical environments in which some of these organisms live, and also preserve fossils of some organisms, creating

a geological record of their existence. Hydrothermal vents thus help to balance the chemical composition of the oceans, and provide; sources of energy for deep-sea ecosystems; a renewable source of metals; and a depositional record of the physical, chemical, biological, and geological processes at modern and ancient submarine vents.

Where Deep-Sea Hydrothermal Vents and Deposits Form: Geological Controls

Less than 2% of the total area of the mid-ocean ridge crest has been studied at a resolution sufficient to reveal the spatial distribution of individual seafloor hydrothermal vents, mineral deposits, and other significant small-scale geological features. Nevertheless, because study areas have been carefully selected and strategically surveyed, and because methods for remotely mapping hydrothermal plumes have been developed, much has been learned about where vents and deposits form, and about the geological controls on their distribution. The basic requirements for hydrothermal systems include heat, to drive fluid circulation, and high-permeability pathways, to facilitate fluid flow through the seafloor. These requirements frequently are met at sites of seafloor volcanism and faulting on or near plate boundaries, or at 'mid-plate' seafloor volcanoes (for example, on Loihi Seamount near Hawaii). Along the mid-ocean ridge, vents and deposits are forming at sites where ascending magma intrusions introduce heat into the permeable shallow crust, and at sites where deep cracks provide permeability and fluid access to heat sources at depth.

Fast-Spreading Ridges

Near- and on-bottom studies along the fast-spreading East Pacific Rise suggest that most hydrothermal mineral deposits form at high-temperature vents ($\sim$100–400°C) concentrated along the summit of the ridge crest within a narrow 'axial zone' less than 500 m wide. Only a few active sites of mineral deposition have been located outside this zone. However, heat flow data indicate that $\sim$70% of the total hydrothermal heat loss from mid-ocean ridges occurs on ridge flanks, from lithosphere >1 million years old. Clearly, more exploration of the vast 'off-axis' region beyond the axial zone is needed to identify the nature and distribution of hydrothermal vents on ridge flanks.

Within the axial zone on fast-spreading ridges, the overall spatial distribution of hydrothermal vents and mineral deposits traces the segmented configuration of cracks and magma sources along the ridge axis. Active vents and mineral deposits are concentrated along the floors and walls of axial troughs created by volcanic collapse and/or faulting along the summit of the ridge crest. A majority of the deposits are located along fissures that have opened above magmatic dyke intrusions, and along collapsed lava ponds formed above these fissures by pooling and drainage of erupted lava. Where fault-bounded troughs have formed along the summit of the ridge crest, mineral deposition is focused along the bounding faults and also along fissures and collapsed lava ponds in the trough floor. Hydrothermal vents appear to be most abundant along magmatically inflated segments of fast-spreading ridges; however, the mineral deposits precipitated on the seafloor on magmatically active segments are often buried beneath frequent eruptions of new lava flows. The greatest number of deposits, therefore, can be observed on inflated ridge segments that are surfaced by somewhat older flows, i.e., along segments where much heat is available to power hydrothermal vents and mineral deposits have had time to develop but have not yet been buried by renewed eruptions.

Intermediate- and Slow-Spreading Ridges

Most hydrothermal deposits that have been found on intermediate- and slow-spreading ridge crests are focused along faults, fissures, and volcanic structures within large rift valleys that are several kilometres wide. The fault scarps along the margins of rift valleys are common sites for hydrothermal venting and mineral deposition. Some hydrothermal systems along rift valley bounding faults are known to have been episodically active over periods of thousands of years, and have produced large mineral deposits, several hundreds of metres in length and tens of metres thick. Fault intersections are thought to be particularly favorable sites for hydrothermal mineral deposition because they are zones of high permeability that can focus fluid flow. Vents and mineral deposits on rift valley floors also are observed above dike intrusions, along eruptive fissures and volcanic collapse troughs, or on top of volcanic mounds, cones, and other constructions. On the intermediate-rate Juan de Fuca Ridge, hydrothermal vents are located above seismically detectable magma lenses. Thus, both magmatic and tectonic controls on hydrothermal processes are observed at slow and intermediate spreading rates. In general, however, faults appear to play a greater role in controlling the distribution of hydrothermal vents and mineral deposits than they do at fast-spreading ridges, where magmatic fissures are clearly a dominant geological control on where vents and deposits are forming.

Spectacular fault-controlled hydrothermal mineral deposits have formed on older seafloor (approximately 1 million years old) on the west flank of the slow-spreading Mid-Atlantic Ridge, at the intersection of the Mid-Atlantic Ridge rift valley and the Atlantic Transform Fault near 30° N. This site, known as 'Lost City', is discharging warm hydrothermal fluids (<100°C) through more than 30 calcium carbonate mineral structures, the tallest of which is 60 m in height!

Structure, Morphology, and Size of Deposits

A typical hydrothermal mineral deposit on an unsedimented mid-ocean ridge accumulates directly on top of the volcanic flows covering the ridge crest. On sedimented ridges, minerals are deposited within and on top of the sediments. Beneath the seafloor are networks of feeder cracks through which fluids travel to the seafloor. Precipitation of hydrothermal minerals in these cracks and in the surrounding rocks or sediments creates a subseafloor zone of mineralization called a 'stockwork'. In hydrothermal systems in which fluid flow is weak or unfocused, or in which the fluids mix extensively with seawater beneath the seafloor, most of the minerals will precipitate in the stockwork rather than on the seafloor.

Hydrothermal deposits on mid-ocean ridges are composed of (1) vertical structures, including individual conduits known as 'chimneys' (Figure 2) and larger structures of coalesced conduits that are often called 'edifices', (2) horizontal 'flange' structures that extend outwards from chimneys and edifices, (3) mounds of accumulated mineral precipitates (Figure 2), and (4) horizontal layers of hydrothermal sediments, debris, and encrustations. Chimneys initially are built directly on top of the seabed around focused jets of high-temperature effluents. Chimneys and edifices are physically unstable and often break or collapse into pieces that accumulate into piles of debris. The debris piles are cemented into consolidated mounds by precipitation of minerals from solutions percolating through the piles. New chimneys are constructed on top of the mounds as the mounds grow in size. Hydrothermal plume particles and particulate debris from chimneys settle around the periphery of the mounds to form layers of hydrothermal sediment. Diffuse seepage of fluids also precipitates mineral encrustations on mound surfaces, on volcanic flows and sediments, and on biological substrates such as microbial mats or the shells and tubes of sessile macrofauna.

The morphology of chimneys is highly variable and evolves as the chimneys grow, becoming more complex with time. Black smoker chimneys often are colonized by organisms and evolve into 'white smokers' that emit diffuse, diluted vent fluids through a porous carapace of wormtubes (Figure 2). Fluid compositions and temperatures, flow dynamics, and biota are all factors that influence the development of chimney morphology. Both the complexity of the interactions between these factors and the high degree of spatial–temporal heterogeneity in the physical, chemical, biological, and geological conditions influencing chimney growth account for the diversity in

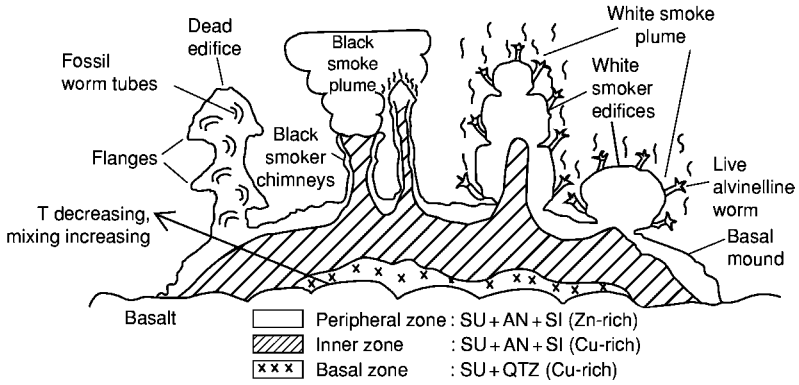

Figure 2 Composite sketch of the mineral structures and zones in hydrothermal mineral deposits on unsedimented ridge crests. Although mound interiors are seldom observed on the seafloor, the simplified sketch of m neral zoning within the mound is predicted by analogy with chimneys and massive sulphide deposits exposed in ophiolites. An outer peripheral zone of Zn rich sulphide (SU; dominantly $ZnS + FeS_2$), anhydrite (AN), and amorphous silica (SI) is replaced in the interior by an inner zone of Cu rich sulphide ($CuFeS_2 + FeS_2$), minor anhydrite, and amorphous silica. The inner zone may be replaced by a basal zone of Cu rich sulphide ($CuFeS_2 + FeS_2$) and quartz (QTZ). Zones migrate as thermochemical conditions within the mound evolve. Although not shown here, it is expected that zoning around individual fractures cutting through the mound will be superimposed on the simplified zone structure depicted in this sketch. T temperature. Modified with permission from Haymon RM (1989) Hydrothermal processes and products on the Galapagos Rift and East Pacific Rise. In: Winterer EL, Hussong DM, and Decker RW (eds.) *The Geology of North America: The Eastern Pacific Ocean and Hawaii*, vol. N, pp. 125 144. Boulder: Geological Society of America.

morphology exhibited by chimneys, and presents a challenge to researchers attempting to unravel the processes producing specific morphologic features.

The sizes of hydrothermal mineral deposits on ridges also vary widely. It has been suggested that the largest deposits are accumulating on sedimented ridges, where almost all of the metals in the fluids are deposited within the sediments rather than being dispersed into the oceans by hydrothermal plumes. On unsedimented ridges, the structures deposited on the seabed at fast spreading rates typically are relatively small in dimension (mounds are typically less than a few metres in thickness and less than tens of metres in length, and vertical structures are <15 m high). On intermediate- and slow-spreading ridges, mounds are sometimes much larger (up to tens of metres in thickness, and up to 300 m in length). On the Endeavour Segment of the Juan de Fuca Ridge, vertical structures reach heights of 45 m, and the edifices are even taller at the Lost City site on the Mid-Atlantic Ridge. The size of a deposit depends on many factors, including the magnitude of the heat source, which influences the duration of venting and mineral deposition; whether deposition recurs episodically at a particular site, which depends on the nature of the heat source and plumbing system and on the rate of seafloor spreading; the frequency with which deposits are buried beneath lava flows; and the chemical compositions of vent fluids and chimney minerals, which are affected by site-specific subseafloor rock composition and water–rock reactions. The large deposits found on slower spreading ridge crests are located on faults that have moved slowly away from the ridge axis and have experienced repeated episodes of venting and accumulated mineral deposition over thousands of years, without being buried by lava flows. The tall Endeavour Segment edifices are formed because ammonia-enriched fluid compositions favour precipitation of silica in the edifice walls. The silica is strong enough to stabilize these structures so that they do not collapse as they grow taller. At Lost City, precipitation of sturdy calcium carbonate permits very tall edifices to form.

How Do Chimneys Grow?

A relatively simple two-stage inorganic growth model has been advanced to explain the basic characteristics of black smoker chimneys (Figure 3). In this model, a chimney wall composed largely of anhydrite (calcium sulphate) precipitates initially from seawater that is heated around discharging jets of hydrothermal fluid. The anhydrite-rich chimney wall precipitated during Stage I contains only a small component of metal sulphide mineral particles that crystallize from rapid chilling of the hydrothermal fluids. In Stage II, the anhydrite-rich wall continues to grow upwards and to thicken radially, protecting the fluid flowing through the chimney from very rapid chilling and dilution by seawater. This allows metal sulphide minerals to precipitate into the central conduit of the chimney from the hydrothermal fluid. The hydrothermal fluid percolates outward through the chimney wall, gradually replacing anhydrite and filling voids with metal sulphide minerals. During Stage II, the chimney increases in height, girth, and wall thickness, and both the calcium sulphate/metal sulphide ratio and permeability of the walls decrease. Equilibration of minerals with pore fluid in the walls occurs continuously along steep, time-variant temperature and chemical gradients between fluids in the central conduit and seawater surrounding the chimney. This equilibration produces sequences of concentric mineral zones across chimney walls that evolve with changes in thermal and chemical gradients and wall permeability (Figure 4).

The model of chimney growth is accurate but incomplete, because it does not include the effects on chimney development of fluid-phase separation, biological activity, or variations in fluid composition. Augmented models that address these complexities are needed to characterize fully the processes governing chimney growth.

Elemental and Mineral Compositions of Deposits

Typical ridge crest hydrothermal deposits are dominantly composed of iron, copper, and zinc sulphide minerals (*see* **Minerals:** Sulphides); calcium and barium sulphate minerals (*see* **Minerals:** Sulphates); iron oxide and iron oxyhydroxide minerals; and silicate minerals (Table 1). These minerals precipitate from diverse processes, including heating of seawater; cooling of hydrothermal fluid; mixing between seawater and hydrothermal fluid; reaction of hydrothermal minerals with fluid, seawater, or fluid–seawater mixtures; reaction between hydrothermal fluid and seafloor rocks and sediments; and reactions that are biologically mediated or catalysed. This diversity in the processes and environments of mineral precipitation results in deposition of many different minerals and elements (Tables 1 and 2). High concentrations of strategic and precious metals are found in some deposits (Table 2). The deposits are potentially valuable, if economic and environmentally safe methods of mining them can be developed.

Chimneys can be classified broadly by composition into five groups: sulphate-rich, copper-rich, zinc-rich,

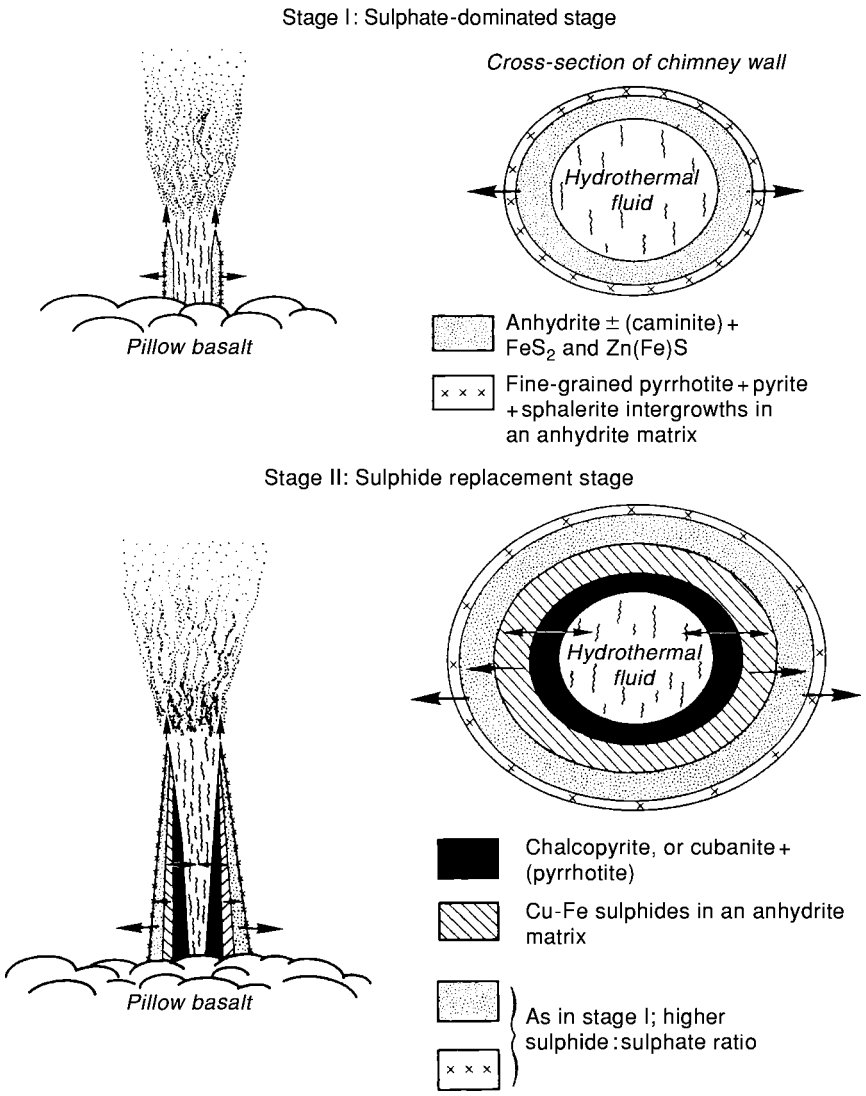

Figure 3 Two stage model of black smoker chimney growth. During Stage II, several different sulphide mineral zonation sequences develop, depending on permeability and thickness of chimney walls, hydrodynamic variables, and hydrothermal fluid composition. Arrows indicate directions of growth.

silica-rich, and carbonate-rich structures. Copper-rich chimney compositions are indicative of formation at temperatures above ~300°C. Sulphate-rich compositions are characteristic of active and immature chimneys formed at temperatures above ~150°C. Carbonate-rich chimneys are found in areas where discharging hydrothermal fluids have reacted with carbonate sediments or ultramafic igneous rocks, and may form at relatively low temperatures. Many chimneys are mineralogically zoned, with hot interior regions enriched in copper and cooler exterior zones enriched in iron, zinc, and sulphate (Figures 2–4). Mounds exhibit a similar gross mineral zoning, and those that are exposed by erosion in ophiolites often have silicified (quartz-rich) interiors (Figure 2). Seafloor weathering of deposits after active venting ceases results in dissolution of anhydrite and in oxidation and dissolution of metal sulphide minerals. Small deposits that are not sealed by silicification or buried by lava flows will not be well preserved in the geological record.

Chimneys as Habitats

Chimney and mound surfaces are substrates populated by microbial colonies and sessile organisms such as vestimentiferan worms (Figure 1), polychaete worms, limpets, mussels, and clams. It is likely that pore spaces in exterior regions of chimney walls and mounds also are inhabited by microbes. All of these chemosynthesis-dependent organisms benefit from the seepage of hydrothermal fluid through active

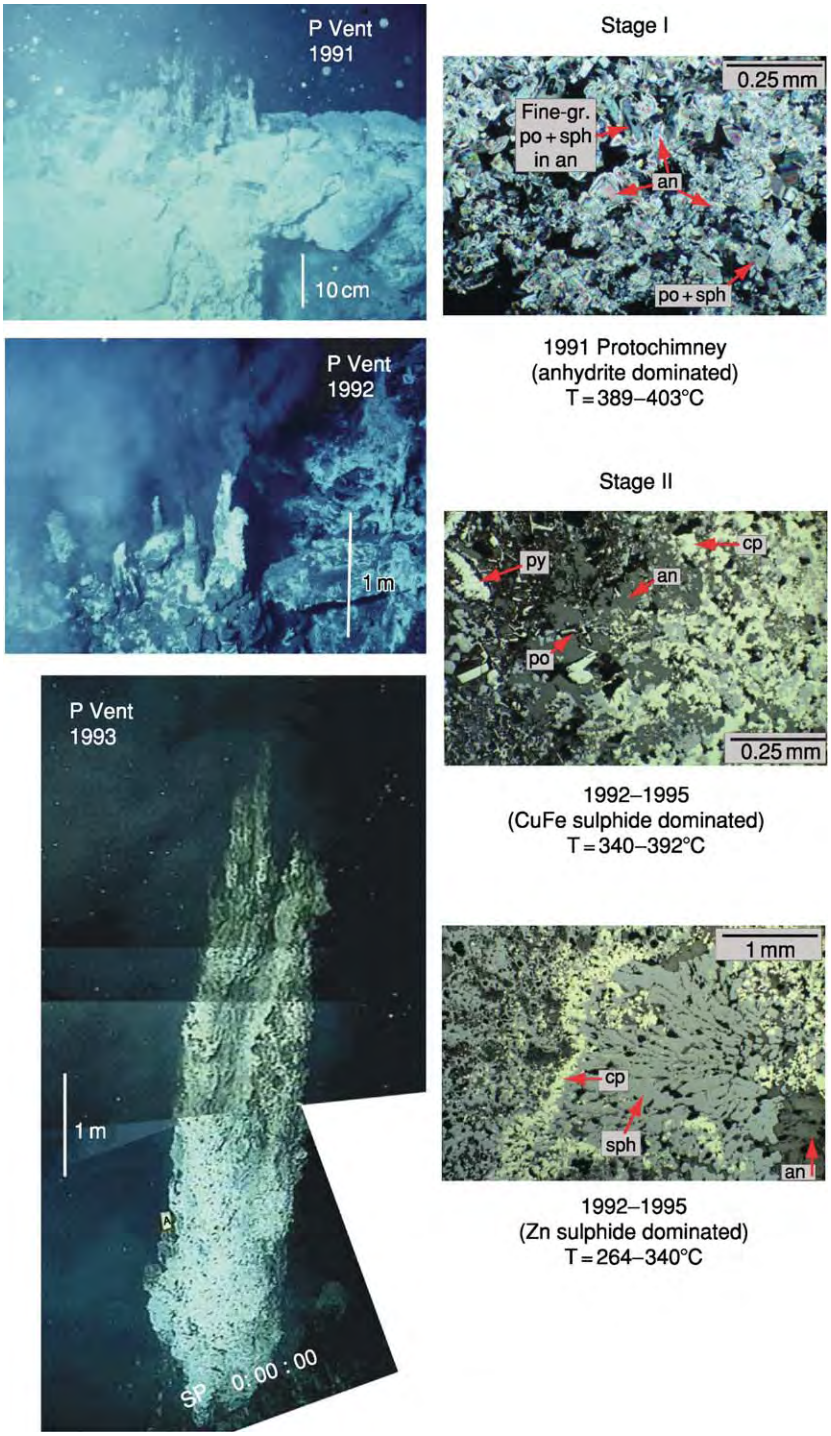

Figure 4 Morphological and mineralogical evolution of chimneys. (Left): A time series of seafloor photographs showing the morpho logical development of a chimney that grew on top of lava flows that erupted in 1991 on the crest of the East Pacific Rise near 9° 50.3′ N. Within a few days to weeks after the eruption, anhydrite rich Stage I 'protochimneys' a few centimetres high had formed where hot fluids emerged from volcanic outcrops that were covered with white microbial mats (top left). Eleven months later, the chimney consisted of cylindrical Stage II anhydrite sulphide mineral spires approximately 1 m in height, and as yet unpopulated by macrofauna (middle left). Three and a half years after the eruption, the cylindrical conduits had coalesced into a 7 m high chimney structure that was covered with inhabited Alvinelline wormtubes (bottom left). (Right): Photomicrographs of chimney samples from the eruption area that show how the chimneys evolved from Stage I (anhydrite dominated; top right) to Stage II (metal sulphide dominated) mineral compositions (see text). As the fluids passing through the chimneys cooled below ~330°C during Stage II, the CuFe sulphide minerals in the chimney walls (middle right) were replaced by Zn sulphide and Fe sulphide minerals (bottom right). Abbreviations: gr, grained; po, pyrrhotite; an, anhydrite; py, pyrite; cp, chalcopyrite. Photographs reproduced from Haymon R, Fornari D, Von Damm K, *et al.* (1993) Volcanic eruption of the mid ocean ridge along the East Pacific Rise at 9° 45 52′ N: direct submersible observation of seafloor phenomena associated with an eruption event in April, 1991. *Earth and Planetary Science Letters* 119: 85 101.

Table 1 Minerals occurring in ocean ridge hydrothermal mineral deposits

Mineral group/name	*Chemical formula*
Sulphides/sulphosalts	
Most abundant	
Sphalerite	Zn(Fe)S
Wurtzite	Zn(Fe)S
Pyrite	FeS_2
Chalcopyrite	$CuFeS_2$
Less abundant	
Iss (isocubanite)[a]	Variable ($CuFe_2S_3$)
Marcasite	FeS_2
Melnikovite	FeS_{2-x}
Pyrrhotite	$Fe_{1-x}S$
Bornite chalcocite	Cu_5FeS_4 Cu_2S
Covellite	CuS
Digenite	Cu_9S_5
Idaite	$Cu_{5\ 5}FeS_{6\ 5}$
Galena	PbS
Jordanite	$Pb_9As_4S_{15}$
Tennantite	$(Cu,Ag)_{10}(Fe,Zn,Cu)_2As_4S_{23}$
Valeriite	$2(Cu,Fe)_2S_23(Mg,Al)(OH)_2$
Sulphates	
Anhydrite	$CaSO_4$
Gypsum	$CaSO_4$ H_2O
Barite	$BaSO_4$
Caminite	$MgSO_4$ $x Mg(OH)_2$ (1 2x)H_2O
Jarosite natrojarosite	$(K,Na)Fe_3(SO_4)_2(OH)_6$
Chalcanthite	$CuSO_4$ $5H_2O$
Carbonates	
Magnesite	$MgCO_3$
Calcite	$CaCO_3$
Aragonite	$CaCO_3$
Elements	
Sulphur	S
Oxides/hydroxides	
Goethite	FeO(OH)
Lepidocrocite	FeO(OH)
Hematite	Fe_2O_3
Magnetite	Fe_3O_4
Brucite	$Mg(OH)_2$

Hannington MD, Jonasson IR, Herzig PM, and Petersen S (1995) In: Humphris SE, Zeirenberg RA, Mullineaux LS, and Thomason RE (eds), *Physical and chemical processes of seafloor mineralization at mid ocean ridges*, p. 115 157.

mineral structures and from the thermal and chemical gradients across mineral structures. The structures provide an interface between seawater and hydrothermal fluid that maintains tolerable temperatures for biota, and allows organisms simultaneous access to the chemical constituents in both seawater and hydrothermal fluid. However, organisms attached to active mineral structures must cope with changes in fluid flow across chimney walls (which sometimes occur rapidly) and with ongoing engulfment by mineral precipitation.

Some organisms actively participate in the precipitation and breakdown of minerals; for example, sulphide-oxidizing microbes mediate the crystallization of native sulphur crystals, and microbes are also thought to participate in the precipitation of marcasite and iron oxide minerals. Additionally, the surfaces of organisms provide favorable sites for nucleation and growth of amorphous silica, metal sulphide, and metal oxide crystals, and this facilitates mineral precipitation and fossilization of vent fauna.

Fossil Record of Hydrothermal Vent Organisms

Fossil moulds and casts of wormtubes, mollusc shells, and microbial filaments have been identified in both modern ridge hydrothermal deposits and in ancient deposits of Cretaceous, Jurassic, Devonian, and Silurian ages. This fossil record establishes the antiquity of vent communities and the long evolutionary history of specific faunal groups. The singular Jurassic fossil

assemblage preserved in a small ophiolite-hosted deposit in central California is particularly interesting because it contains fossils of vestimentiferan worms, gastropods, and brachiopods, but no clam or mussel fossils. In contrast, modern and Palaeozoic faunal assemblages described thus far include clams, mussels, and gastropods, but no brachiopods. Does this mean that brachiopods have competed with molluscs for ecological niches at vents, and have moved in and out of the hydrothermal vent environment over time? Fossilization of organisms is a selective process that does not preserve all of the fauna that are present at vents. Identification of fossils at the species level is often difficult, especially where microbes are concerned. Notwithstanding, it is important to search for more examples of ancient fossil assemblages and to trace the fossil record of life at hydrothermal vents back as far as possible, to shed light on questions about how vent communities have evolved and about whether life on Earth might have originated at submarine hydrothermal vents.

Summary

Hydrothermal activity is an integral aspect of seafloor accretion at mid-ocean ridges. The circulating fluids and plumes facilitate thermal and chemical exchange between the oceans and the lithosphere, support life above and below the seafloor, and affect current flow and biological activity at mid-water depths. The mineral deposits are valuable for their metals, for the role that they play in fostering hydrothermal vent ecosystems, for the clues that they hold to understanding spatial–temporal variability in hydrothermal vent systems, and as geological records of how life at hydrothermal vents has evolved. Vent organisms exhibit novel biochemistry, genetics, taxonomy, physiology, symbiosis, and community dynamics. From submarine hydrothermal systems, the insights gained about biogeochemical processes at high temperatures and pressures can be applied to biotechnology and to understanding life in inaccessible realms within Earth's crust, or the potential for life on other planetary bodies. As the complexities of hydrothermal systems on the mid-ocean ridge are unravelled through ongoing exploration and interdisciplinary studies, exciting applications of this knowledge are being discovered.

Propagating Rifts and Microplates At Mid-Ocean Ridges

R N Hey, University of Hawaii at Manoa, Honolulu, HI, USA

Introduction

Propagating rifts are extensional plate boundaries that gradually break through lithospheric plates, forming new plate boundaries and rearranging the geometries of old ones. If the rifting advances to the seafloor-spreading stage, propagating seafloor-spreading centres gradually extend through the rifted lithosphere. This evolution occurs rapidly ($\sim 10^5$ years) for oceanic propagators and much more slowly ($\sim 10^7$ years) for continental ones. The orthogonal combination of seafloor spreading and propagation produces a characteristic V-shaped wedge of lithosphere, with progressively younger and longer isochrons abutting the 'pseudofaults' that bound this wedge. Oceanic propagators generally replace pre-existing spreading centres, causing lithospheric transfer from one plate to another, and sequences of spreading-centre jumps, leaving failed rift systems in their wakes. This changes the classic plate tectonic geometry and results in asymmetric accretion of lithosphere to the plates. There is pervasive shear deformation in the overlap zone between the propagating and failing rifts, much of it accommodated by bookshelf faulting, in which, e.g., right-lateral plate motion shear produces high-angle left-lateral fault slip. When the scale or strength of the overlap zone becomes large enough, it stops deforming, and instead begins to rotate as a separate microplate between dual active spreading centres. Continental propagators break apart continents and can leave failed rifts (aulocogenes) along unsuccessful propagation paths, as well as predictable patterns of deformation ahead of the propagator tips. For continental rifting, the pseudofaults are the continental margins. Rift propagation appears to be the primary mechanism by which Earth's accretional plate boundary geometry is reorganized.

Oceanic Propagators

Figure 1 shows several variations of typical oceanic ridge propagation geometry, in which a pre-existing 'doomed rift' is replaced by the propagator. This always seems to result in at least slight spreading-centre reorientation. Whether this is because rifts propagate in response to changes in direction of seafloor spreading, or because the spreading direction changes while rifts propagate, rift propagation is the primary mechanism by which many seafloor-spreading systems have adjusted to changes in spreading direction. Propagation rates and local spreading rates are often similar in magnitude, although propagation rates as high as 1000 km My^{-1} have been discovered.

Figure 1A shows the discontinuous propagation model, in which periods of seafloor spreading alternate with periods of instantaneous propagation,

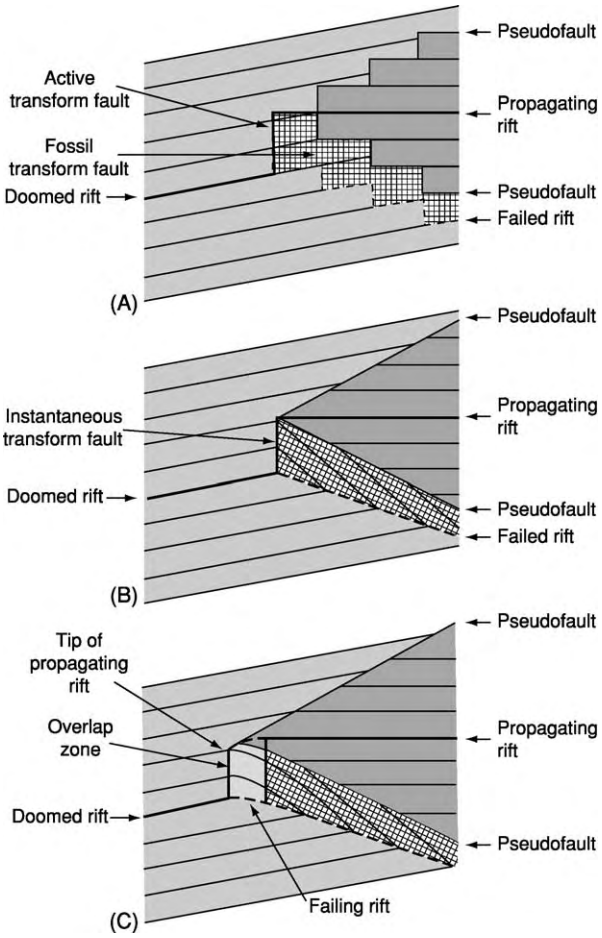

Figure 1 (A) Discontinuous, (B) continuous, and (C) non trans form zone oceanic propagating/failing rift models. Propagating rift lithosphere is marked by dark stipple, normal lithosphere created at the doomed rift is indicated by light stipple, and trans ferred lithosphere is cross hatched. Heavy lines show active plate boundaries. In the non transform zone model(C), active axes with full spreading rate are shown as heavy lines; active axes with transitional rates are shown as dashed lines. The overlap zone joins these transitional spreading axes. Reproduced with permission from Hey RN, Sinton JM, and Duennebier FK (1989) Propagating rifts and spreading centers. In: Winters EL, Hussong DM, and Decker RW (eds.) *Decade of North American Geology: The Eastern Pacific Ocean and Hawaii*, pp. 161 176. Boulder, CO: Geo logical Society of America.

producing *en echelon* failed rift segments, fossil transform faults, and fracture zones, and blocks of progressively younger transferred lithosphere. Figure 1B shows the pattern produced if propagation, rift failure, and lithospheric transferal are all continuous. In this idealized model, a transform fault migrates continuously with the propagator tip, never existing in one place long enough to form a fracture zone, and thus V-shaped pseudofaults are formed instead of fracture zones. Figure 1C shows a more geologically plausible model, in which the new spreading centre requires some finite time to accelerate from zero to the full rate, with concomitant decreases on the failing spreading centre, so that lithospheric transferal is not instantaneous. Instead of a transform fault, a migrating broad 'non-transform' zone of distributed shear deformation connects the overlapping propagating and failing ridges during the period of transitional spreading. Deformation occurring in this overlap zone is preserved in the zone of transferred lithosphere. This zone, left behind as the overlap zone migrates, is bounded by the failed rifts and inner (proximal) pseudofault. Even more complicated geometries occur in some places where the doomed rift, instead of failing monotonically as the propagator steadily advances, occasionally propagates in the opposite direction.

Standard plate tectonic geometry holds for the area outside the pseudofaults and zone of transferred lithosphere, but rigid plate tectonics breaks down in the overlap zone where some of the lithosphere formed on the doomed rift is progressively transferred to the other plate by the rift propagation and resulting migration of the overlap zone. Shear between the overlapping propagating and failing rifts appears to be accommodated by bookshelf faulting, probably along the pre-existing abyssal hill faults. This produces oblique seafloor fabric, with trends quite different from the ridge-parallel and-perpendicular structures expected from classic plate tectonic theory.

Figure 2 is a relief map of the type-example propagating rift, at 95.5° W along the Cocos–Nazca spreading centre. This area closely resembles the geometry in Figure 1C, except that rift failure occurs more discontinuously. This propagator is breaking westward away from the Galapagos hotspot through 1-My-old Cocos lithosphere at a velocity of about 50 km My $^{-1}$. Well-organized seafloor spreading begins about 10 km behind the faulting, fissuring, and extension at the propagating rift tip. This 200 000-year time lag between initial rifting and the rise of asthenosphere through the lithospheric cracks to form a steady-state spreading centre suggests an asthenospheric viscosity of about 10^{18} Pa s. The combination of seafloor spreading (about 60 km My $^{-1}$) and propagation produces a V-shaped wedge of young lithosphere bounded by pseudofaults and pre-existing lithosphere. The propagating rift lithosphere is characterized by high-amplitude magnetic anomalies and by unusual petrological diversity, including highly fractionated ferrobasalts. This propagator is replacing a pre-existing spreading system about 25 km to the south, and thus spreading-centre jumps and failed rifts result. Although propagation is continuous, segmented failing rift grabens seem to die episodically on a time-scale of about 200 000 years. This has produced a very systematic pattern of spreading-centre jumps identified from magnetic anomalies, in which each jump was younger and slightly longer than the preceding jump. The spreading-centre orientation is being changed clockwise by about 13°, and more than 10^{4} km^{3} My $^{-1}$ of Cocos lithosphere is being transferred to the Nazca plate.

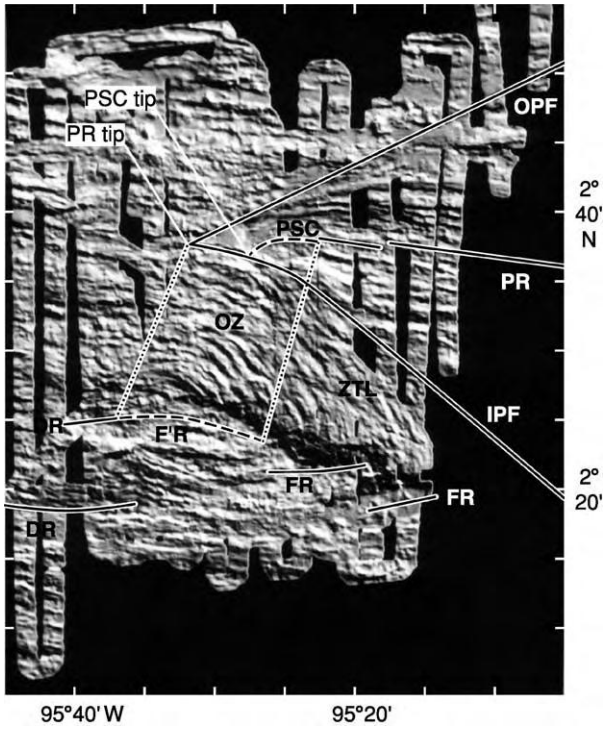

Figure 2 Shaded relief map of digital Sea Beam swath bathymetry at the Galapagos propagating rift system (95.5° W). The relative plate motion is nearly north south; propagation is to the west. The oblique structures in the overlap zone and its wake, the zone of transferred lithosphere, are clearly evident. PR, Propagating rift; PSC, propagating spreading centre; OPF, IPF, outer and inner pseudofaults; OZ, overlap zone; ZTL, zone of transferred lithosphere; DR, doomed rift; F'R, failing rift; FR, failed rift grabens. Adapted by permission from Hey RN, Sinton JM, and Duennebier FK (1989) Propagating rifts and spreading centers. In: Winters EL, Hussong DM, and Decker RW (eds.) *Decade of North American Geology: The Eastern Pacific Ocean and Hawaii*, pp. 161 176. Boulder, CO: Geological Society of America.

The active propagating and failing rift axes overlap by about 20 km and are connected by a broad and anomalously deep zone of distributed shear deformation rather than by a classic transform fault. Most of the seismic activity occurs within this 'non-transform' zone, where the pre-existing abyssal hill fabric originally created on the doomed rift is sheared and tectonically rotated into new oblique trends. Simple equations accurately describe this geometry in terms of ratios of propagation and spreading rates, together with the observed propagating and doomed rift azimuths. For example, for the simplest continuous propagation geometry, if u is the spreading half-rate and v is the propagation velocity, the pseudofaults form angles $\tan^{-1}(u/v)$ with the propagator axis, and the isochrons and abyssal hill fabric in the zone of transferred lithosphere have been rotated by an angle $\tan^{-1}(2u/v)$.

The boundaries of the Galapagos high-amplitude magnetic anomaly zone, the ferrobasalt province, and the spreading-centre jumps are all coincident with the pseudofaults bounding the propagating rift lithosphere. All of these observations can be explained as mechanical and/or thermal consequences of a new rift and spreading centre breaking through cold lithosphere, with increased viscous head loss and diminished magma supply on the propagating spreading centre close to the propagator tip. This leads to an unusually deep axial graben and unusually extensive fractional crystallization and differentiation. The 95.5° W propagator tip is also a mantle geochemistry boundary, implying that this rift propagation is associated with plume-related subaxial asthenospheric flow away from the Galapagos hotspot.

Causes of Rift Propagation

One important observation is that many rifts and spreading centres propagate down topographic gradients away from hotspots or shallow ridge axis topography. For example, all six known active Galapagos propagators are propagating away from the hotspot. Plume-related asthenospheric flow generates gravitational stresses on the shallow spreading-centre segments near the hotspot that promote crack propagation away from the hotspot. Flow of asthenosphere into these cracks produces new lithosphere at propagating seafloor-spreading centres. Regionally high deviatoric tensile stresses associated with regional uplift provide a quantitatively plausible driving mechanism. Crack growth occurs when the stress concentration at the tip, characterized in elastic fracture mechanics by a stress intensity factor, exceeds the resisting stress intensity contribution. The spreading-centre propagation rate could be limited by the viscosity of the asthenosphere flowing into the rift, producing viscous suction forces at a local tip depression, or by process zone deformation at the rift tip. The overlap/offset ratio of propagating and failing rifts tends to be ~1, close to the ratio at which the stress intensity factor is maximized (*see* **Tectonics:** Seismic Structure At Mid-Ocean Ridges).

Although many rifts appear to propagate in response to hotspot-related stresses, others appear to propagate because of stresses producing changes in plate motion. Subduction-related stresses appear to be a common mechanism for producing propagation in the North-east Pacific. This probably explains most of the massive reorganizations of the spreading geometry as the Pacific–Farallon ridge neared the Farallon–North America trench, as clearly evident even in the classic Raff–Mason magnetic anomaly data (Figure 3), although some propagation away from the Axial Seamount hotspot has also occurred in the Juan de Fuca area. Propagation may be produced in many ways over a wide range of scales, including small-scale propagation of overlapping spreading centres away from local magmatic centres. The larger reorganizations sometimes involve transient microplate formation, geometrically similar to the broad overlap zone model of Figure 1C, but on a much larger scale.

Microplates

Microplates are small, mostly rigid areas of lithosphere, located at major plate boundaries but rotating as more or less independent plates. They can form in many tectonic settings. The two main types along mid-ocean ridges, those formed at triple junctions and those formed away from triple junctions, share many similarities. Although it was once thought that stable, growing microplates could eventually grow into major oceanic plates, it now appears that these are transient phenomena resulting from large-scale rift propagation. When the overlap zone becomes too big and strong to deform by pervasive bookshelf faulting, it changes mechanical behaviour and accommodates the boundary plate motion shear stresses by beginning to rotate as a separate microplate. The most well-studied oceanic microplates are the Easter microplate along the Pacific–Nazca ridge and the Juan Fernandez microplate at the Pacific–Nazca–Antarctica triple junction (Figure 4). Despite their different tectonic settings, they show many striking similarities.

The scales of the Easter (~500 km diameter) and the Juan Fernandez (~400 km diameter) microplates are similar. The eastern and western boundaries of both microplates are active spreading centres, propagating north and south, respectively. Both microplates began forming about 5 Ma, and both

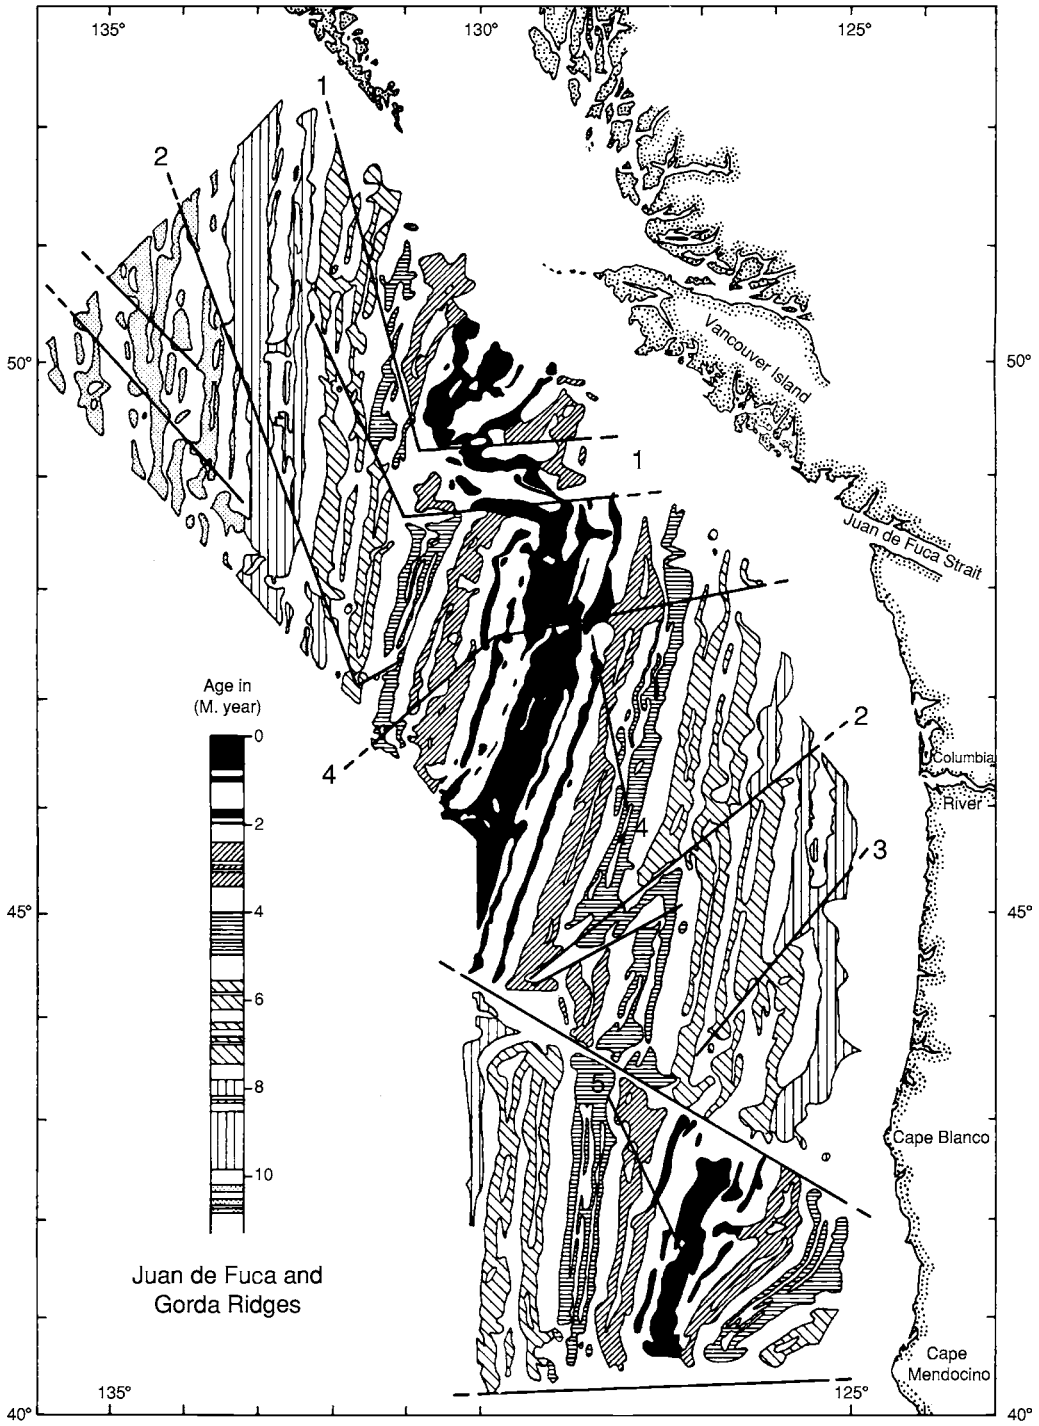

Figure 3 Raff Mason magnetic anomalies in the Juan de Fuca area. Positive anomalies are shaded. Numbers denote major propagation sequences. Reproduced with permission from Hey RN (1977) A new class of pseudofaults and their bearing on plate tectonics: A propagating rift model. *Earth and Planetary Science Letters* 37: 321 325.

East rifts have been propagating into roughly 3-My-old Nazca lithosphere. Extremely deep axial valleys occur at their tips, ~6000 m at Pito Deep at the north-eastern Easter microplate boundary, and ~5000 m at Endeavour Deep at the north-eastern Juan Fernandez microplate boundary. The northern and southern boundaries are complicated deformation zones, with zones of shear, extension, and significant areas of compression. The dominant (East) rift of the Easter microplate, the dominant (West)

EPR, East Pacific Rise; FZ, fracture zone; NAZ, Nazca; PAC, Pacific; SA, South America; ANT, Antarctic; WOPF, WIPF, EOPF, and EIPF are western outer and inner and eastern outer and inner pseudofaults, respectively. Numbers (e.g. 2, 2A) identify magnetic chrons from magnetic reversal time scale, J is Jaramillo reversal ~1 Ma, PT is paleotransform. Reproduced with permission from Bird RT and Naar DF (1994) Intratransform origins of mid ocean ridge microplates. *Geology* 22: 987 990.

rift of the Juan Fernandez microplate, and the dominant (West) rift of the duelling propagators between the microplates, are all propagating away from the Easter mantle plume (or the intersection of this plume with the ridge axis), suggesting that microplate formation as well as rift propagation can be driven by plume-related forces.

Both microplates have large ($\sim 100 \times 200$ km), complex, pervasively deformed cores, which may have formed by bookshelf faulting in overlap zones during an initial large-scale propagating rift stage of evolution. Both show more recent stages of growth as independent microplates, with deformation concentrated along the plate boundaries. At present, both microplates are rotating clockwise very rapidly about poles near the microplate centres, spinning like roller-bearings caught between the major bounding plates. The Easter microplate rotation velocity is about 15° My^{-1} and the Juan Fernandez velocity is about 9° My^{-1}. The roller-bearing analogy has been quantified in an idealized edge-driven model of microplate kinematics. If microplate rotation is

indeed driven by shear on the boundaries between the microplate and surrounding major plates, the rotation velocity (in radians) is $2u/d$, where $2u$ is the major plate relative velocity and d is the microplate diameter. This follows because the total spreading on the microplate boundaries must equal the major plate motion if the microplate did not exist. The rotation (Euler) poles describing the motion of the microplate relative to the major plates will lie on the microplate boundaries, at the farthest extensions of the rifts, which must continually lengthen by a different kind of rift propagation as the microplate rotates.

This idealized geometry (Figure 5) requires a circular microplate shape, yet also requires seafloor spreading on the dual active ridges, which must constantly change this shape. The more the microplate grows, the more deformation must occur as it rotates, and the less successful the rigid plate model will be. Although it would appear that this inevitable plate growth would soon invalidate the model, numerous episodes of rift propagation helping to maintain the necessary geometry are observed to have occurred at the Easter and Juan Fernandez microplates. All propagation was on the microplate interior side of the failing rifts, thus transferring microplate lithosphere to the surrounding Pacific and Nazca plates, shaving the new microplate growth at the edges and maintaining a shape circular enough for the edge-driven model to be very successful.

According to the edge-driven model, a microplate may stop rotating if one of the bounding ridge axes

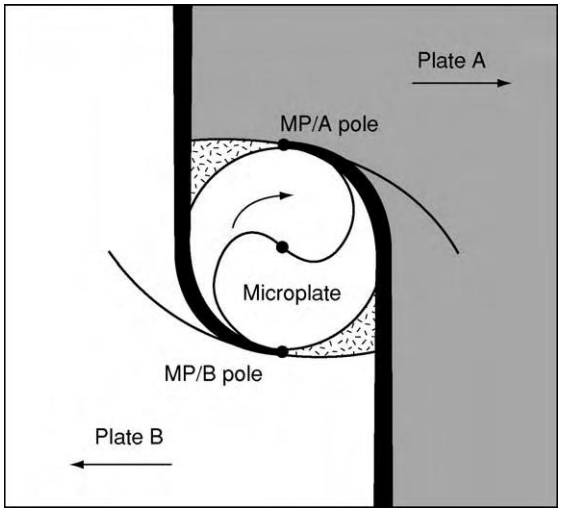

Figure 5 Roller bearing model of microplates based on a simple, concentrically rotating bearing. The microplate is approximated by a circular plate that is caught between two major plates (MP/A and MP/B). The main contacts between microplate and major plates are also the positions of the relative rotation poles (dots). Dark shading shows major spreading centres, overlapping about the microplate. Cross hatched corners are areas of compression. Medium curved lines are predicted pseudofaults; plate arrows show relative motions. This schematic model assumes growth from an infinitesimal point to a present circular shape; the model can be extended to take account of growth from a finite width, eccentric motions, and growth of the microplate. Reproduced with permission from Searle RC, Bird RT, Rusby RI, and Naar DF (1993) The development of two oceanic microplates: Easter and Juan Fernandez microplates, East Pacific Rise. *Journal of the Geological Society* 150: 965–976.

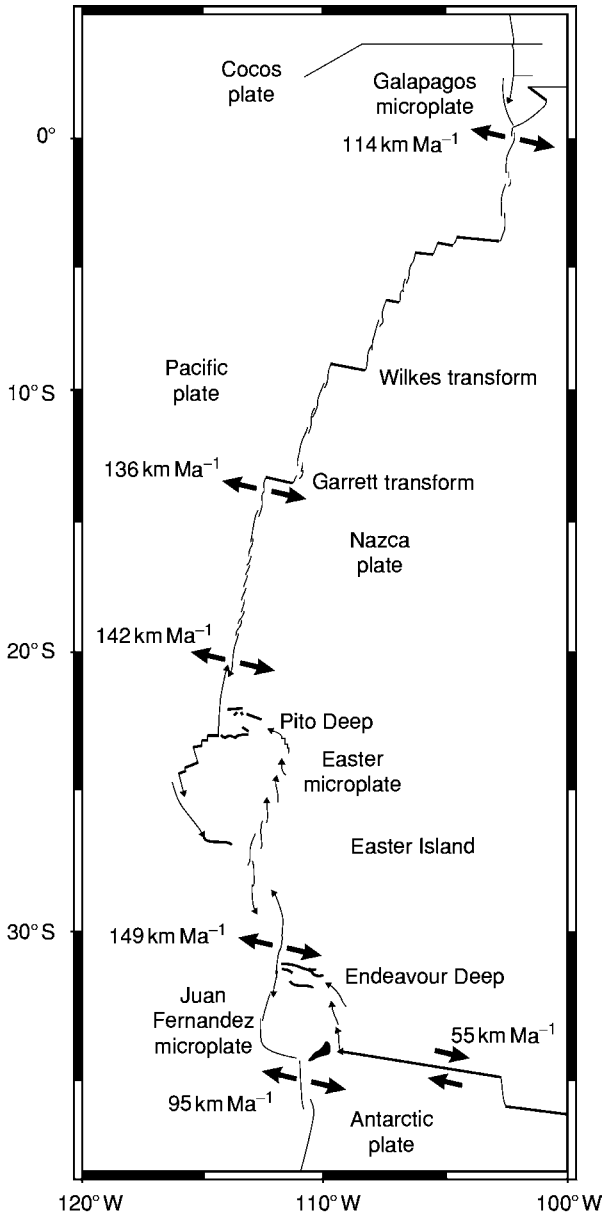

Figure 6 Plate tectonic geometry and relative plate motions along the southern East Pacific Rise. Light lines are ridges, and those with arrows are propagating. Heavy straight lines are transform faults. Reproduced with permission from Hey RN, Johnson PD, Martinez F, *et al.* (1995) Plate boundary reorganization at a large offset, rapidly propagating rift. *Nature* 378: 167–170.

propagates through to the opposite spreading boundary, eliminating coupling to one of the bounding plates. Dual spreading would no longer occur, spreading would continue on only one bounding ridge, and 10^6–10^7 km^3 of microplate lithosphere would accrete to one of the neighbouring major plates. Active microplates are thus modern analogues for how large-scale (hundreds of kilometres) spreading centre jumps occur. There is evidence in the older seafloor record that this happened many times along the ancestral East Pacific Rise.

All large right-stepping offsets along the Pacific–Nazca spreading centre are transform faults, whereas all large left-stepping offsets are microplates or the giant duelling propagators (possible protomicroplate) between the Easter and Juan Fernandez microplates (Figure 6). The Galapagos microplate at the Pacific–Cocos–Nazca triple junction also fits this pattern. This suggests that a recent clockwise change in Pacific–Nazca plate motion could have been an important factor triggering the formation of these microplates. Earth's fastest active seafloor spreading occurs in this area, and all parts of the plate boundary presently spreading faster than 142 km My^{-1} are reorganizing by duelling propagators or microplates (Figure 6). The combination of thin lithosphere produced at these 'superfast' seafloor spreading rates, and the unusually hot asthenosphere produced by an Easter mantle plume, would reduce the forces resisting propagation and thus make these plate boundary reorganizations easier, perhaps explaining their common occurrence in this area.

Microplates also occur in convergent settings, where small pieces of lithosphere are caught between large plates. A well-studied continental convergence example is the Mediterranean, where small plates the size of Turkey and the Aegean adapt to Africa–Eurasia convergence. Oceanic microplates can also form along convergent margins, e.g., in the West Pacific, to accommodate Pacific, Australia, and Asia convergence.

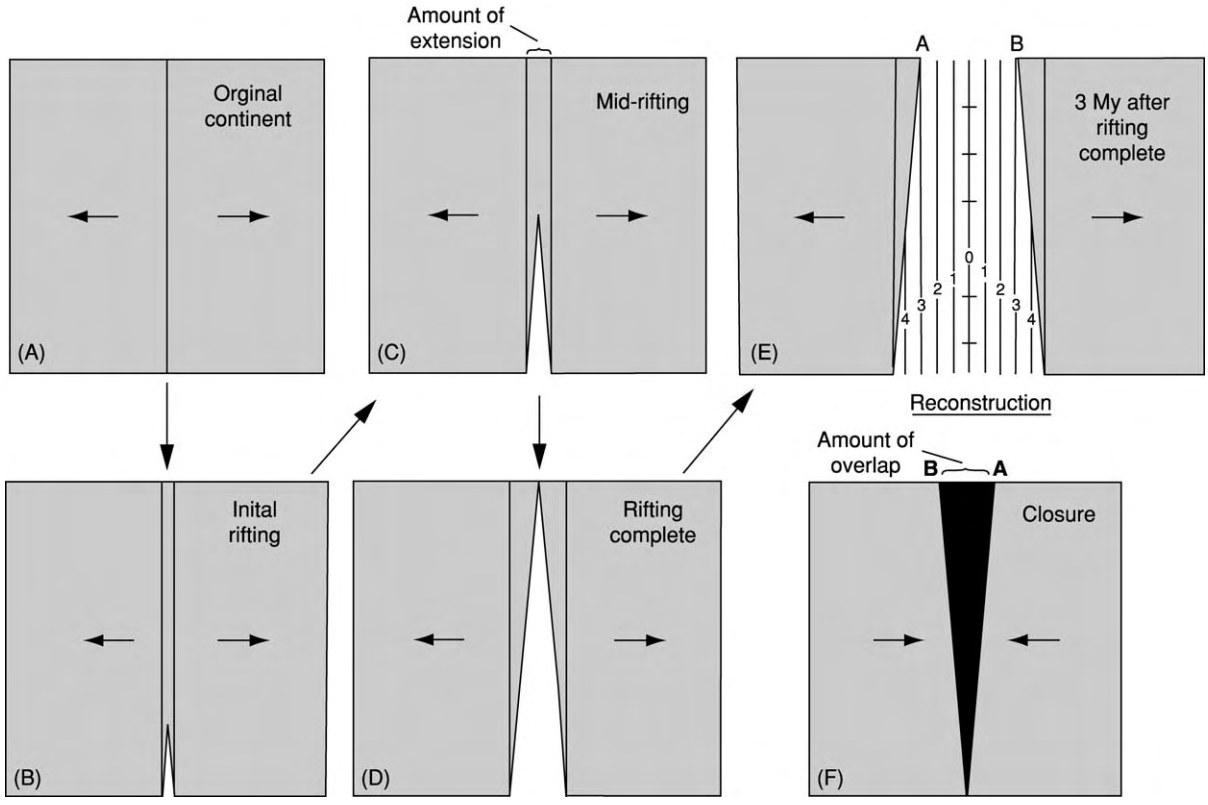

Figure 7 Propagating rift model for continental breakup (map view). (A) Original continent under tension; (B) initial rifting, with the amount of extension represented between parallel lines; (C) mid rifting (seafloor spreading is occurring in the lower half of the continent while crustal thinning and extension occur in the upper half); (D) rifting complete (continental edges have undergone extension that increases in the direction of rifting); (E) 3 My after rifting is complete (oldest seafloor is found in the part of the ocean where rifting began; oldest isochrons converge with the ocean continent boundary; continental edge is not an isochron); (F) reconstruction of the pre rift configuration (extension due to rifting results in apparent overlap when the continents are returned to their pre rift geometry). Reproduced with permission from Vink GE (1982) Continental rifting and the implications for plate tectonic reconstructions. *Journal of Geophysical Research* 87: 10 677 10 688.

Continental Propagators

Continents break apart progressively as well, and thus continental margins are not isochrons but instead are a type of pseudofault boundary. During breakup, the margins bound V-shaped wedges of propagating rift lithosphere pointing in the direction of propagation. The relative azimuths of the margin and the first magnetic isochrons formed on the new seafloor-spreading centre give the propagation velocity. For example, the South Atlantic began forming at the southern tip of Africa–South America ~130 Ma and reached the area that became the great equatorial mid-Atlantic ridge (MAR) offset 30–40 My later, for an average northward propagation velocity of 10–15 km My ^{1}, similar to the spreading rate.

Predictable extensional rift deformation occurs ahead of the propagating spreading-centre tip (Figure 7). Plate reconstructions that take this new understanding of breakup deformation into account differ from classic reconstructions, such as the Bullard fits, which have equal amounts of continental overlap and underlap. Instead, increasing deformation ahead of the growing spreading centre means continental reconstruction fits should be exact where propagation begins, and should slow increasing overlap in the direction of propagation, with no areas of continental margin underlap (Figure 8).

Occasional rifts may propagate locally along globally unfavorable paths and eventually fail, resulting in failed rifts (aulocogenes) along margins. Systematic patterns of small failed rifts, or one huge one such as the Greenland–Canada failed rift in the Labrador Basin, would produce asymmetries in the conjugate margins. Occasional episodes of duelling propagation may also occur, forming ephemeral microplates eventually welded to one of the major plates, with corresponding margin asymmetries. One well-studied area of continental propagation is the Afar depression, where the Gulf of Aden propagator is presently breaking west into the African continent in Djibouti; a Red Sea propagator is simultaneously breaking south into the continent in Ethiopia (Figure 9). The interaction of these duelling propagators has produced changes in their propagation directions and the same kind of pervasive bookshelf faulting between the ridges as seen in oceanic rift propagation.

Implications

Rift propagation, which occurs on scales ranging from overlapping spreading centres with offsets of

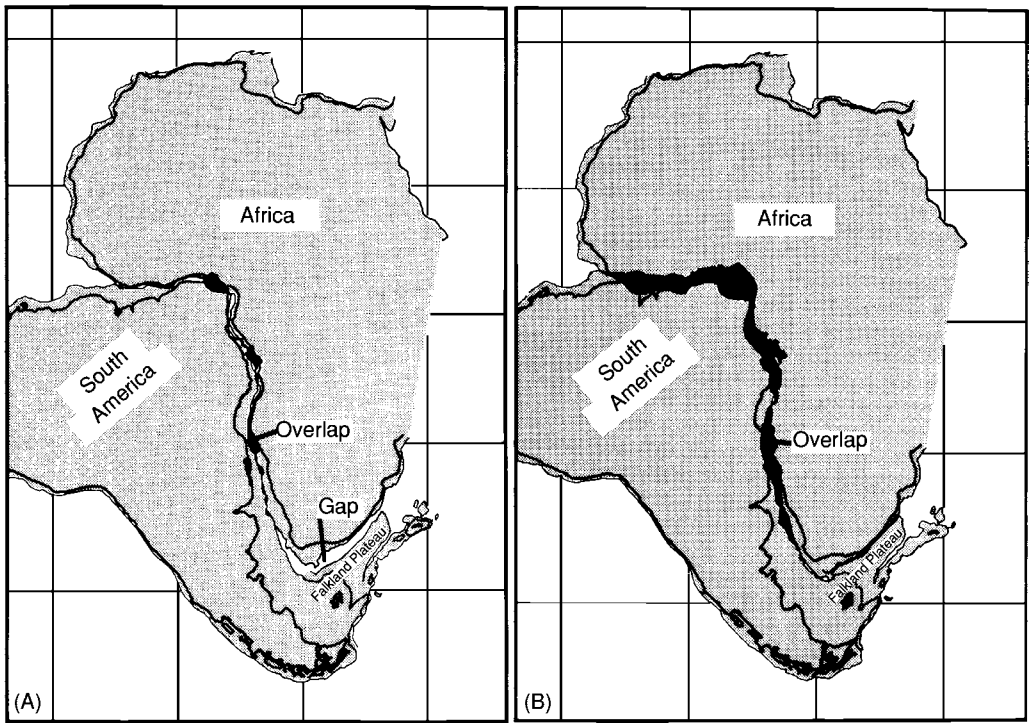

Figure 8 (A) The Bullard South America Africa reconstruction, using the 1000 m isobath to represent the continental edge and the 3000 m isobath for the Falkland Plateau. (B) The Vink reconstruction, using the propagating rift model and the same isobaths, obtained by rotating South America 58.00° counterclockwise around a pole at 47.00° N, 33.80°. Dark regions represent areas of overlap. only a few kilometres, through oceanic propagators with offsets on the order of 10–100 km, up to offsets of several hundred kilometres at microplate tectonic scales, and several thousand kilometres at continental rifting scales, appears to be the primary mechanism by which Earth's accretional plate boundary geometry is reorganized. Although conceptually simple, the propagating-rift hypothesis has important implications for plate tectonic evolution. It explains quantitatively the existence of several classes of structures, including pseudofaults, failed rifts, and zones of transferred lithosphere, that are oblique to ridges and transform faults and thus previously seemed incompatible with plate tectonic theory. It explains why passive continental margins are not parallel to the oldest seafloor isochrons, but are instead pseudofaults, bounding lithosphere created on propagating spreading centres and indicating the direction of the continental breakup propagators. It also explains the large-scale reorganization of many seafloor-spreading systems, including both the origination and the termination of many fracture zones, as well as the

formation of some transient microplates that appear to be the modern analogues of large-scale spreading-centre jumps. This hypothesis provides a mechanistic explanation for the way in which many (if not all) spreading-centre jumps occur, why they occur in systematic patterns, and how spreading centres reorient when the direction of seafloor spreading changes. It also explains the origin of large areas of petrologically diverse seafloor, including the major abyssal ferrobasalt provinces. The common occurrence of rift propagation over a wide range of tectonic environments and spreading rates indicates that it represents an efficient mechanism of adjustment of extensional plate boundaries to the forces driving plate motions.

Seismic Structure At Mid-Ocean Ridges

S M Carbotte, Columbia University, New York, NY, USA

Introduction

Oceanic crust is created at mid-ocean ridges (*see* **Tectonics:** Mid-Ocean Ridges) as mantle material upwells and undergoes pressure-release melting in response to ongoing seafloor spreading. As mantle melts rise to the surface and freeze, they form an internally stratified crust of extrusive basalts and sheeted dykes underlain by layered and massive gabbros. Spreading rate has long been recognized as a fundamental variable governing crustal accretion at ridges, with first-order differences observed in a wide range of ridge properties. However, significant changes in ridge properties are also observed along the ridge axis at any given spreading rate, which suggests that factors other than the rate of plate separation contribute to the local supply and distribution of magma from the mantle. Seismic methods permit imaging of structures within the crust that result from magmatic processes at mid-ocean ridges and provide important insights into the role of spreading rate and magma supply in crustal creation.

Since the early days of seafloor exploration, seismic studies, which rely on the propagation of sound waves through rocks, have been the primary tool used to investigate the internal structure of the oceanic crust (*see* **Seismic Surveys**). These studies reveal two primary seismic layers, which are generally believed to correspond to lithological structures in the crust: seismic layer 2 corresponds to the dykes and basaltic lava

flows that form the shallow crust, and layer 3 is associated with the massive and sheeted gabbros that form the lower crust. Seismic methods fall into two categories: reflection studies, which are based on the reflection of near-vertical seismic waves from interfaces where large contrasts in density and/or elastic properties are present, and refraction studies, which exploit the characteristics of seismic energy that travels horizontally as head waves through rock layers. Reflection methods provide continuous images of crustal horizons and permit efficient mapping of small-scale variations over large regions. Locating these horizons at their correct depths within the crust requires knowledge of the seismic velocity of crustal rocks, which is poorly constrained from reflection data. Refraction techniques provide detailed information on crustal velocity structure but typically result in relatively sparse measurements that represent large spatial averages. Hence, the types of information obtained from reflection and refraction methods are highly complementary, and these data are often collected and interpreted together.

At mid-ocean ridges, three crustal horizons are found where contrasts in elastic properties are sufficiently large that the horizons can be mapped with reflection techniques. These include seismic layer 2A (which is commonly assumed to correspond to the layer of lava flows (extrusives) that caps the oceanic crust), the shallow magma chamber from which the crust is formed, and the Moho (which marks the crust–mantle boundary). Each of these three structures and their main characteristics at mid-ocean ridges will be described here, and the implications of these observations for understanding how oceanic crust is created will be summarized. In the final section, changes in crustal structure at ridges spreading at different rates and the prevailing models to account for these variations will be described.

Seismic Layer 2A

Early Studies

Seismic layer 2A was first identified in the early 1970s from analysis of refraction data at the Reykjanes Ridge south of Iceland. This layer of low P-wave velocities (less than 3.5 km s $^{-1}$), which comprises the shallowest portion of the oceanic crust (Figure 1), was attributed to extrusive rocks with high porosities due to volcanically generated voids and extensive crustal fracturing. In the late 1980s a bright event corresponding to the base of seismic layer 2A was imaged for the first time using multichannel seismic-reflection data. This event is not a true reflection but rather a refracted arrival resulting from turning waves within a steep-velocity-gradient zone that marks the base of seismic layer 2A. Within this gradient zone, P-wave velocity rapidly increases to values typical of seismic layer 2B (more than 5.0 km s $^{-1}$) over a depth interval of about 100–300 m (Figure 1A). The 2A event is seen in the far offset traces of reflection data collected with long receiver arrays (more than

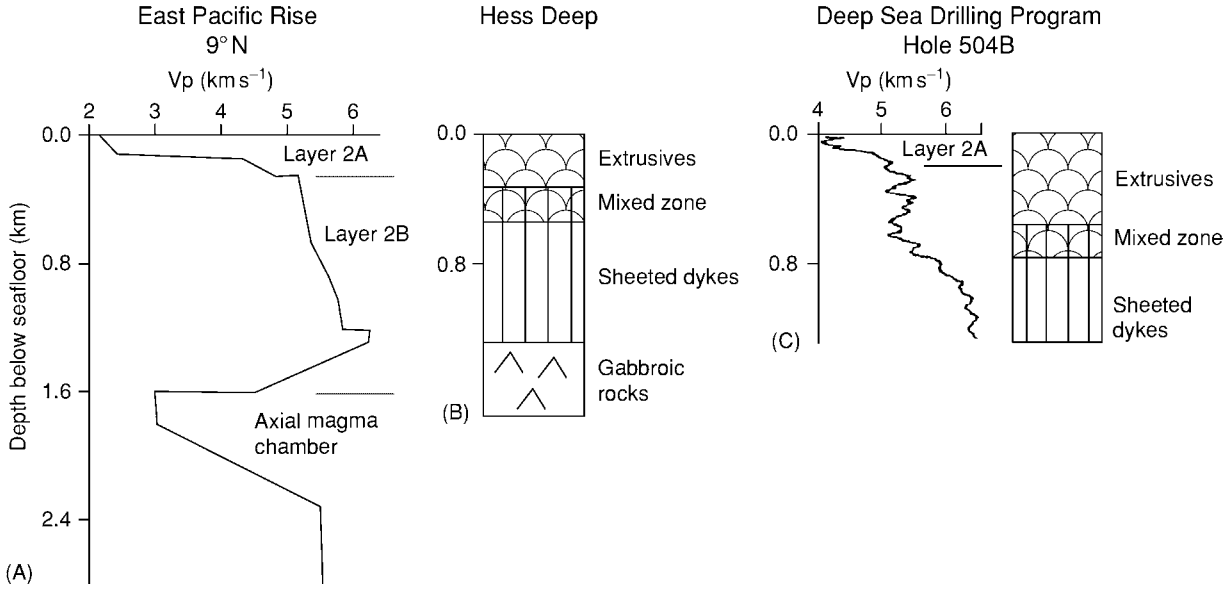

Figure 1 (A) Variations in seismic velocity with depth for newly formed crust at the East Pacific Rise. Layers 2A and 2B and the low velocities associated with the axial magma chamber are identified. 2 km) and can be successfully stacked, providing essentially continuous images of the base of layer 2A at mid-ocean ridges.

The Geological Significance of the Layer 2A–2B Transition: A Lithological Transition from Extrusives to Dykes or a Porosity Boundary within the Extrusives?

In most recent studies layer 2A near the ridge axis is assumed to correspond to extrusive rocks, and the base of layer 2A is assumed to correspond to a lithological transition to the sheeted-dyke section of the oceanic crust. The primary evidence for this lithological interpretation comes from studies at Hess Deep in the equatorial eastern Pacific. In this area, observations of fault exposures made from manned submersibles show that the extrusive rocks are on average 300–400 m thick, similar to the thickness of layer 2A measured near the crest of the East Pacific Rise (compare Figure 1A and B). However, the Hess Deep studies also revealed significant variability in the thickness of the extrusive layer (total range of 200–800 m) over horizontal distances of only a few hundred metres. Variability on this scale is well below the spatial resolution of seismic studies, which can provide only a smoothed view of the lithological heterogeneity that may be present.

Other researchers have suggested that the base of layer 2A may correspond to a porosity boundary within the extrusive section associated, perhaps, with a fracture front or hydrothermal alteration. This interpretation is based primarily on observations from a deep crustal hole located off the coast of Costa Rica, which was drilled as part of the Deep Sea Drilling Program (DSDP). Within this hole (504B) there is a velocity transition zone that is located entirely within the extrusive section (Figure 1C). Here, a thin high-porosity section of rubbly basalts and breccia with P-wave velocities of approximately 4.2 km s^{-1} overlies a thick lower-porosity section of extrusives with higher P-wave velocities (5.2 km s^{-1}). However, the relevance of these observations to the geological interpretation of the velocity structure of the ridge crest is questionable. Crust at DSDP hole 504B is 5.9 Ma old, and it is well established that the seismic velocity of the shallow crust increases with age owing to crustal alteration (see below). Indeed the velocities within the shallowest extrusives at DSDP 504B (*ca.* 4 km s^{-1}) are much higher than those observed at the ridge crest (2.5–3 km s^{-1}), indicating that significant crustal alteration has occurred (compare Figure 1A and C).

Conclusive evidence of the geological nature of seismic layer 2A will probably require drilling or observations of faulted exposures of the crust made where seismic observations are also available. At present, the bulk of the existing sparse information favours the lithological interpretation, and layer 2A is commonly used as a proxy for the extrusive crust. If this interpretation is correct, mapping the layer 2A–2B boundary provides direct constraints on the eruption and dyke-injection processes that form the uppermost part of the oceanic crust.

Characteristics of Layer 2A at Mid-Ocean Ridges

At the East Pacific Rise, layer 2A is typically 150–250 m thick within the region where crust is currently being formed (Figures 2 and 3). Only minor variations in the thickness of this layer are observed along the ridge crest, except near transform faults and other ridge offsets where the layer thickens.

Across the ridge axis, layer 2A approximately doubles or triples in thickness over a zone approximately 2–6 km wide, indicating extensive accumulation of extrusives within this wide region (Figures 4 and 5). This accumulation may occur through lava flows that travel up to several kilometres from their eruption sites at the axis, either over the seafloor or perhaps through subsurface lava tubes. Volcanic eruptions that occur off-axis may also contribute to building the extrusive pile.

Along the axis of the intermediate-spreading Galapagos spreading centre, located in the equatorial Pacific, layer 2A displays a wide range of thicknesses, which are closely linked with other characteristics of the ridge axis (Figure 6). Closest to the Galapagos Hotspot, a thin layer 2A is observed (150–350 m) beneath a shallow axial high, similar to that seen at fast-spreading ridges. Away from the hotspot-dominated portion of the ridge, the axial high disappears and layer 2A is thicker (*ca.* 300–600 m) and more variable along the axis. At the slow-spreading Mid-Atlantic Ridge the sparse existing data indicate that layer 2A does not systematically thicken away from the ridge axis, and it appears that the extrusive section is built largely within the floor of the median valley.

Axial Magma Chamber

Early Studies

Drawing on observations of the crustal structure of ophiolites (sections of oceanic or oceanic-like crust exposed on land) and the geochemistry of seafloor basalts, it was initially thought that mid-ocean ridges were underlain by large, essentially molten, magma reservoirs. However, prior to the 1980s, few actual constraints on the dimensions of magma chambers at ridges were available. Early seismic studies on the East Pacific Rise detected a zone of lower seismic

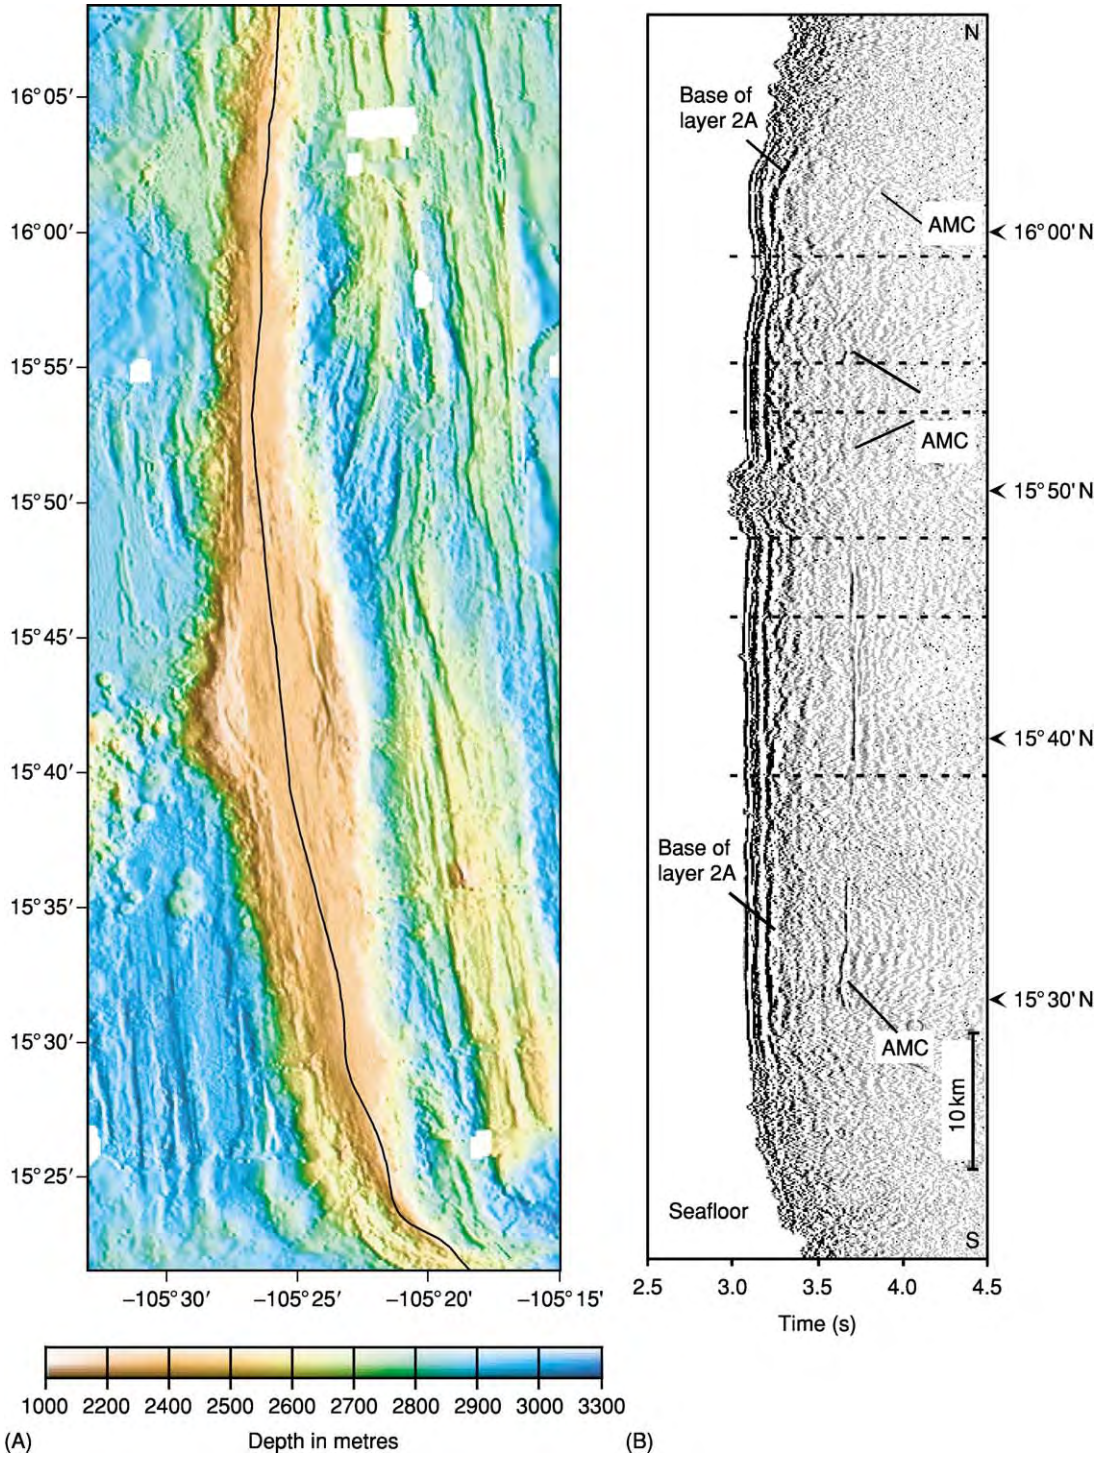

Figure 2 Example of a multichannel seismic line collected along the axis of the East Pacific Rise, showing the base of the extrusive crust (layer 2A) and the reflection from the top of the axial magma chamber (AMC). velocity beneath the ridge axis, as expected for a region containing melt. A bright reflector was also found, indicating the presence of a sharp interface with high acoustic impedance contrast within the upper crust. In the mid-1980s an extensive seismic reflection and refraction experiment was carried out on the northern East Pacific Rise by researchers from the University of Rhode Island, Lamont–Doherty Earth Observatory, and Scripps Institution of Oceanography. This study imaged a bright sub-horizontal reflector located 1–2 km below the seafloor along much of the ridge. In several locations this reflector was found to be phase reversed relative to the seafloor reflection, indicating that it resulted from an interface

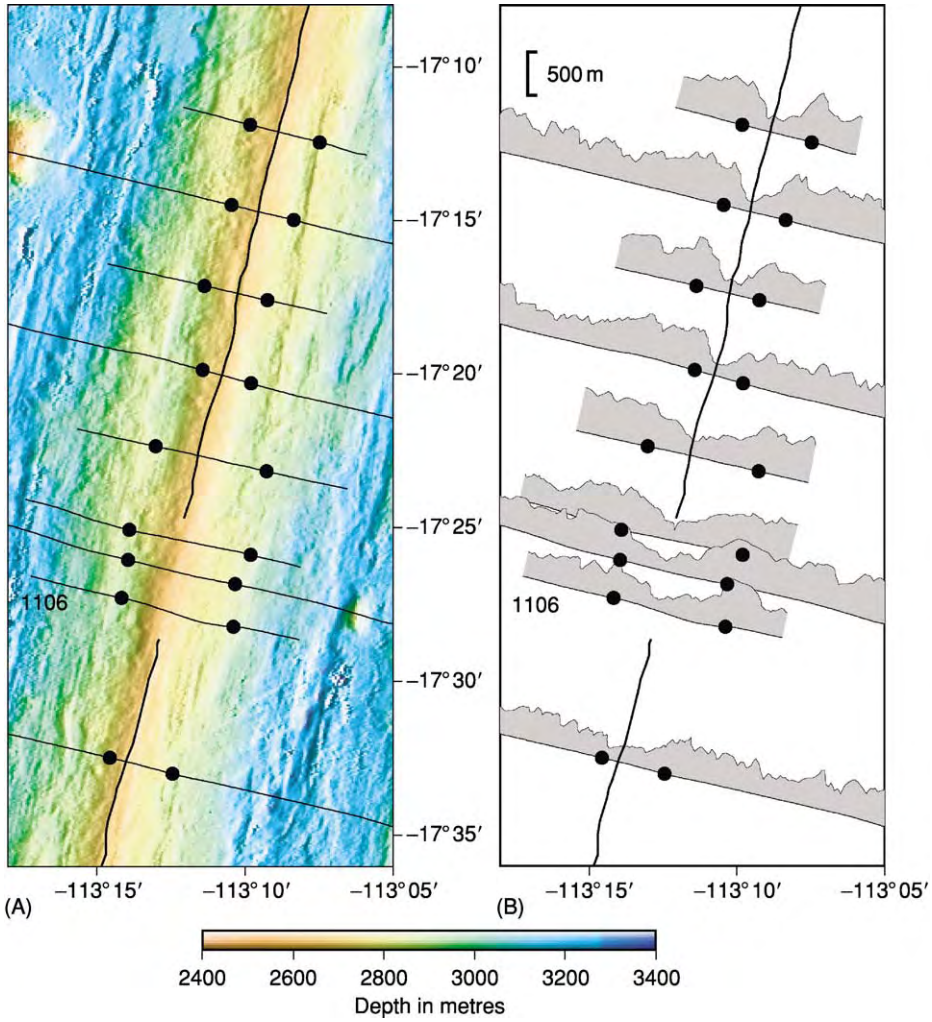

Figure 5 The thickening of the seismically inferred extrusive crust (layer 2A) across the axis of the southern East Pacific Rise. (A) Bathymetry map of the region with the locations of cross axis seismic lines shown as light lines. The bold black line shows the location of the narrow depression along the ridge axis where most volcanic activity occurs. The black dots indicate the width of the region over which the seismically inferred extrusives accumulate, as interpreted from the data shown in **Figure 5B**. (B) Thickness of the extrusive crust inferred from the seismic data along each cross axis line. Black dots mark where layer 2A reaches its maximum thickness away from the axis. Seismic line 1106 (shown in **Figure 4**) is labelled.

with an abrupt drop in seismic velocity. Based on its reversed phase and high amplitude, this event is now recognized as a reflection from a lens of magma located at the top of what is commonly referred to as an axial magma chamber.

Seismic refraction and tomography experiments show that this reflector overlies a broader region within which seismic velocities are reduced relative to normal crust (**Figure 7**). This low-velocity zone is approximately 5 km wide at shallow depths, possibly widening slightly at the base of the crust. Because of the relatively small velocity anomaly associated with much of this low-velocity zone (less than 1 km s $^{-1}$), this region is interpreted as hot largely solidified rock and crystal mush containing only a few percent partial melt.

Characteristics of the Axial Magma Chamber at Mid-Ocean Ridges

Several seismic-reflection studies have now been carried out along the fast-spreading East Pacific Rise, imaging over 1400 km of ridge crest (**Figure 3**). A reflection from the roof of the magma chamber is detected beneath about 60% of the surveyed region and can be traced continuously in places for tens of kilometres. This reflector is found at a depth of 1–2 km below the seafloor and deepens and disappears towards major offsets of the ridge axis, including transform faults and overlapping spreading centres (**Figure 3**). Most volcanic activity along the East Pacific Rise is concentrated within a narrow depression, less than 1 km wide, which is interrupted by

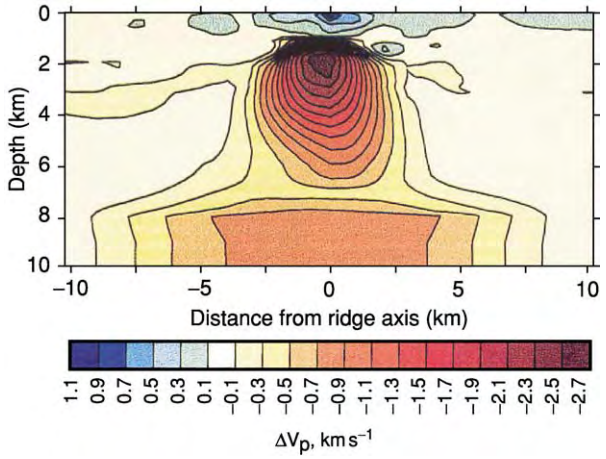

Figure 7 Seismic velocity structure of a fast spreading ridge, showing the region of low velocities associated with melt and hot rock at the ridge axis. The velocity model is derived from a tomography experiment at 9°30′ N on the East Pacific Rise. (Reproduced from Dunn RA, Toomey DR, and Solomon SC (2000) Three dimensional seismic structure and physical properties of the crust and shallow mantle beneath the East Pacific Rise at 9°30′ N. *Journal of Geophysical Research* 105: 23 537 23 555.)

small steps or offsets, which may be the boundaries between individual dyke swarms. In many places, the magma-chamber reflector does not disappear beneath these offsets (Figure 3). However, changes in the depth and width of the reflector are often seen. Seismic-tomography studies show that the broader region of low velocities associated with the crustal magmatic system pinches and narrows beneath these small offsets. These results suggest that segmentation of the axial magma chamber is associated with the full range of offsets observed along the ridge axis.

Migration of seismic profiles shot perpendicular to the ridge axis reveals that the magma-chamber reflection arises from a narrow feature that is typically less than 1 km wide (total range from 200 m to 4 km; Figure 4). Refraction data and waveform studies of the magma-chamber reflection suggest that it arises from a thin body of magma a few hundred to perhaps a few tens of metres thick, leading to the notion of a magma lens or sill. Initial studies assumed that this lens contained pure melt. However, recent research suggests that much of the magma lens may have a significant crystal content (more than 25%), with regions of pure melt limited to pockets only a few kilometres or less in length along the axis.

Magma-lens reflections similar to those imaged beneath the East Pacific Rise have been imaged along intermediate-spreading ridges, including the Galapagos Spreading Centre (Figure 6), south-east Indian Ridge, and Juan de Fuca Ridge, and at the back-arc spreading centre in the Lau Basin. In these areas,

magma-lens reflectors are typically found deeper in the crust, at depths of 2.5–3 km, although shallower reflections are observed in a few places.

Along the slow-spreading Mid-Atlantic Ridge, evidence for magma lenses has been found along the Reykjanes Ridge. Here, an intracrustal reflection at a depth of approximately 2.5 km is observed, which is similar to the depths of magma-lens events observed beneath the intermediate-spreading ridges. Seismic data have been collected elsewhere along the Mid-Atlantic Ridge with little evidence of magma-lens reflections, possibly owing to imaging problems associated with the rough seafloor topography typical of this ridge. However, there is evidence from refraction data and seismicity studies that large crustal magma bodies are not common beneath this ridge. Microearthquake data show that earthquakes can occur to depths of 8 km beneath the Mid-Atlantic Ridge, indicating that the entire crustal section is sufficiently cool for brittle failure. In other areas, slightly reduced velocities within the crust have been identified, indicating warmer temperatures and possibly the presence of small pockets of melt within the crust.

The prevailing model for magma chambers beneath ridges (Figure 8) incorporates both the geophysical constraints on chamber dimensions described above and geochemical constraints on magma-chamber processes. At fast-spreading ridges (Figure 8A), the magma chamber consists of a narrow and thin melt-rich magma lens, which overlies a broader crystal-mush zone and a surrounding region of hot but solidified rock. The dyke-injection events and volcanic eruptions that build the upper crust are assumed to tap the magma lens. The lower crust is formed from the crystal residuum within the magma lens and from the broader crystal-mush zone. Observations of ophiolites suggest that the injection of sills that tap magma directly from the upper mantle also contributes to the lower crustal section. Both seismic and seafloor compliance studies from the 9°–10° N region of the East Pacific Rise indicate melt accumulation at the base of the crust, within either melt-rich sills or a broader partially molten zone.

At slow-spreading ridges (Figure 8B) a short-lived dyke-like crystal-mush zone without a steady-state magma lens is envisioned. At these ridges volcanic eruptions occur and the crystal-mush zone is replenished during periodic magma-injection events from the mantle. Observations of seafloor fault exposures of crust created at slow-spreading ridges reveal a heterogeneous crustal section, where altered and deformed lower-crustal and upper-mantle rocks are unconformably overlain by lavas in some locations. Crustal accretion at these ridges is inferred to be a highly episodic process, with the internal structure of the crust being strongly disrupted by faulting.

Moho

The base of the crust is marked by the Mohorovicic Discontinuity, or 'Moho', where P-wave velocities increase from values typical of lower-crustal rocks (7–7.5 km s^{-1}) to mantle velocities (more than 8.0 km s^{-1}). The change in P-wave velocity is often sufficiently abrupt that a sub-horizontal Moho reflection is observed in reflection data, from which the base of the crust can be mapped. Depths to the Moho derived from seismic-refraction studies provide our best estimates of crustal thickness and are used to study how total crustal production varies in different ridge settings.

Characteristics of the Moho at Mid-Ocean Ridges

Reflection Moho is imaged in much of the data collected at the East Pacific Rise (Figure 9). It can often be traced beneath the region of lower-crustal velocities found at the ridge and occasionally beneath the magma-lens reflection itself. Where information on crustal velocities is available, average crustal thicknesses of 6–7 km are measured. There is no evidence for thickening away from the ridge crest, indicating that the crust acquires its full thickness within a narrow zone at the axis.

Unlike at the fast- and intermediate-spreading ridges, at the slow-spreading Mid-Atlantic Ridge the Moho is difficult to identify in seismic-reflection data, possibly owing to poor imaging conditions or a difference in the geological nature of this boundary. At this ridge, information on crustal thickness and variations in crustal structure is derived primarily from seismic-refraction studies. Average crustal thicknesses are similar to those observed at fast-spreading ridges (6–7 km). However, significant crustal thinning is observed (by 1–4 km) towards transform faults and smaller ridge offsets (Figure 10B). These results are interpreted as reflecting a three-dimensional pattern of mantle upwelling or melt migration to the ridge, resulting in greater crustal production within the central regions of ridge segments away from ridge offsets.

Variations in crustal thickness within ridge segments are also observed along the East Pacific Rise (Figure 10A). However, in the region with the best data constraints (9°–10° N), the spatial relationships are opposite to those observed at the Mid-Atlantic Ridge. Here, the crust is approximately 1 km thinner, not thicker, in the portion of the segment where a range of ridge-crest observations indicate that active

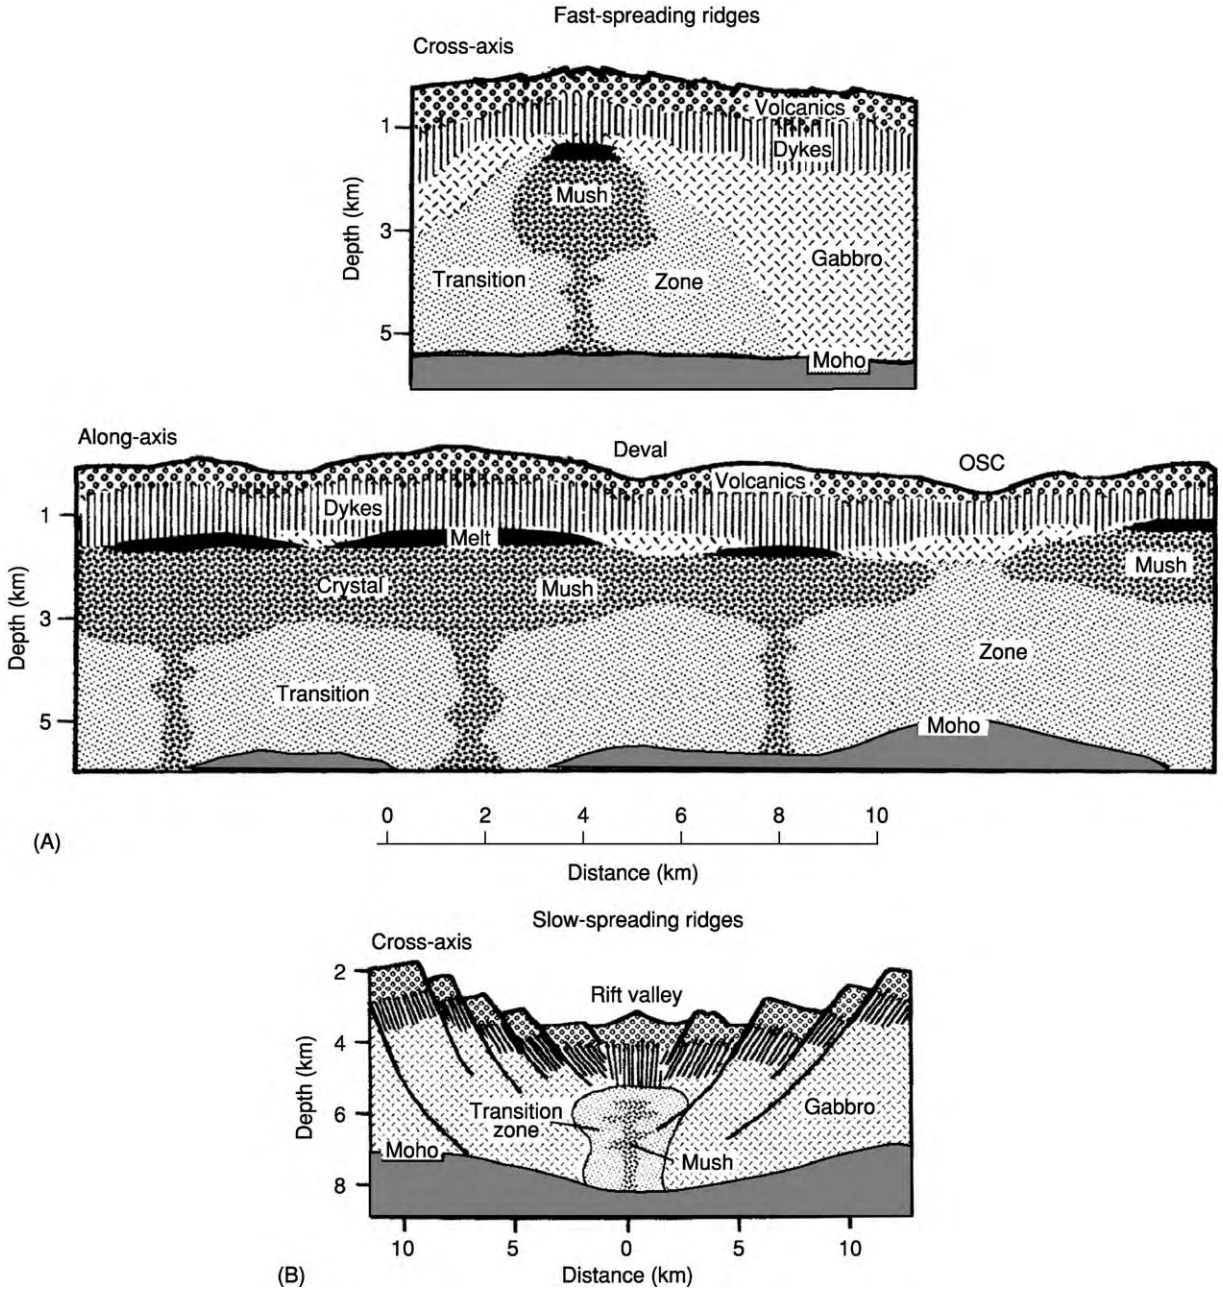

Figure 8 Schematic representation of the axial magma chamber beneath (A) fast and (B) slow spreading ridges. (A) At a fast spreading ridge a thin zone of predominantly melt (black region) is located 1–2 km below the seafloor, grading downwards into a partially solidified crystal mush zone. This region is in turn surrounded by a transition zone of solidified but hot rock. Along the ridge axis, the 'melt' sill and crystal mush zone narrows and may disappear at the locations of ridge discontinuities (labeled Deval and OSC in the along axis profile). (B) At a slow spreading ridge a steady state melt region is not present. Magma is periodically injected into the crust from the mantle with volcanic eruptions and the emplacement of small intrusive bodies, which crystallize to form the oceanic crust. (Reproduced from Sinton JA and Detrick RS (1992) Mid ocean ridge magma chambers. *Journal of Geophysical Research* 97: 197–216.)

crustal accretion is focused. At this fast-spreading ridge the presence of a steady-state magma chamber and a broad region of hot rock (Figure 8) may permit efficient redistribution of magma away from regions of focused delivery from the mantle. The absence of a steady-state magma chamber beneath the slow-spreading Mid-Atlantic Ridge may prohibit significant along-axis transport of magma, such that, at this ridge, thicker crust accumulates at the site of focused melt delivery.

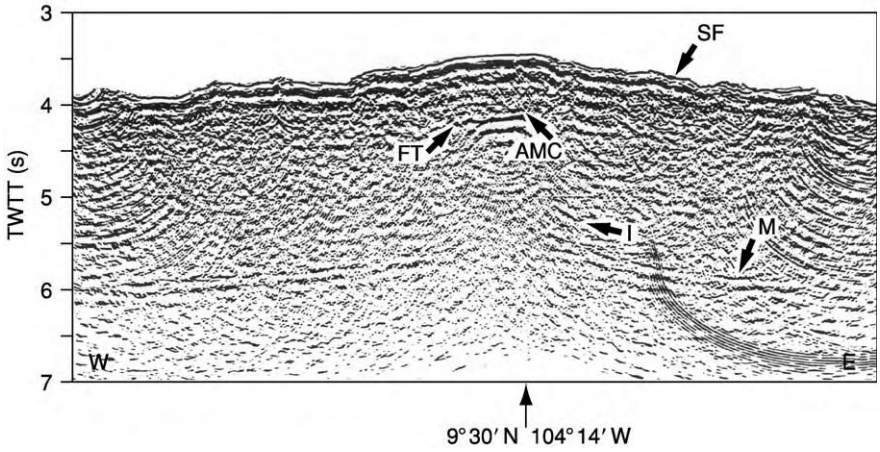

Figure 9 Multichannel seismic line crossing the East Pacific Rise at 9°30′ N, showing the Moho reflection (M), the seafloor (SF), the axial magma chamber (AMC) reflection, and other intracrustal reflections (FT, I). Variations in Mid-Ocean Ridge Structure

The seismic observations described in the previous sections reveal significant differences in the internal structure of the crust at fast- and slow-spreading ridges as well as within individual spreading segments, with important implications for crustal creation at mid-ocean ridges. Large gradients in crustal structure are observed at slow-spreading ridges, with crustal thickness often varying by a factor of two within individual ridge segments (Figure 10B). In comparison, at fast-spreading ridges only minor variations in crustal structure are observed within ridge segments, and crustal accretion appears to be a more uniform process at these rates. Indeed, throughout the fast-spreading-rate range (85–150 mm year ^{1}), average crustal structure is remarkably constant, with magma lenses imaged beneath much of the axis at similar widths and depths (Figure 11). In contrast, at slow-spreading ridges, steady-state magma bodies within the crust are rarely detected. Intermediate-spreading ridges (less than 85 mm year ^{1}) are of particular interest because they display characteristics from across the spreading-rate spectrum, the distribution of which appears to be closely linked with spatial variations in the supply of magma to the ridge. Where the ridge forms a shallow axial high, magma bodies have been observed at the shallow depths (less than 2 km) characteristic of fast-spreading ridges. Beneath the shallowly rifted sections that are more typical of intermediate-spreading ridges, magma bodies lie at a deeper level within the crust of 2.5–3 km (Figure 11).

At fast-spreading ridges, the shallowest crust, defined by seismic layer 2A, is uniformly thin along the ridge axis (*ca.* 200 m; Figure 12) and commonly thickens over a region several kilometres wide about the axis. In comparison, at slow-spreading ridges, the sparse available data suggest that a thicker layer 2A is developed along the axis and that full accretion of this layer occurs within a narrow region confined to the axial valley. Along some sections of intermediate-spreading ridges, layer 2A thickens away from the axis, as observed at the fast-spreading ridges, whereas in other regions, this layer appears to acquire its full thickness within the innermost axial zone. Assuming that layer 2A corresponds to the extrusive section, these differences in the accumulation of this layer could reflect differences in eruption parameters such as eruptive volumes, lava-flow viscosity and morphology, and the dominance of fissure versus point-source eruptions. Where a wide zone of extrusive-layer thickening is observed along fast- and portions of intermediate-spreading ridges, low-viscosity lobate and sheet flows may predominate, forming thin flows that travel for significant distances from eruptive fissures at the axis. Large-volume pillow-flow eruptions and eruptions that quickly localize at point sources forming local volcanic constructions may be more common at the intermediate- and slow-spreading ridges, where little thickening of the extrusive layer away from the axis is inferred from the seismic data. The bounding faults of the axial valleys typically present at these ridges may serve to dam any far-travelling lobate and sheet flows, giving rise to full accumulation of the extrusives at the axis.

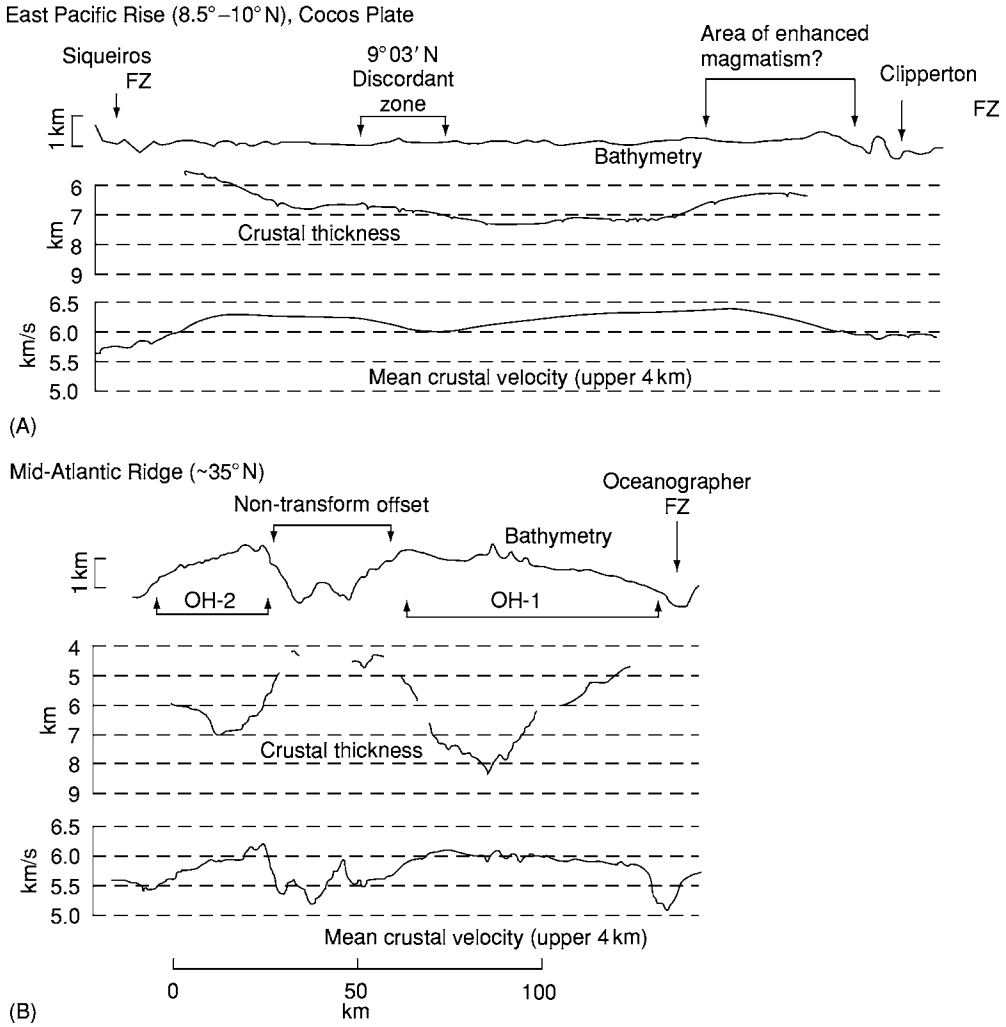

Figure 10 Comparison of crustal structures at (A) fast and (B) slow spreading ridges, showing along axis variations in crustal thickness and the mean seismic velocity of the upper crust. (B) At slow spreading ridges, the crust thins towards fracture zones and non transform offsets. (A) Changes in crustal thickness towards discontinuities are more modest at fast spreading rates. (Reproduced from Canales JP, Detrick RS, Toomey DR, and Wilcock WSD (2002) Segment scale variations in crustal structure of 150 to 300 ky old fast spreading oceanic crust (East Pacific Rise, 8°15′ N 10°15′ N) from wide angle seismic refraction profiles. *Geophysical Journal International* 152: 766 794.)

Although first-order differences are observed in a wide range of ridge properties with differences in spreading rate, several aspects of the seismic structure of ridges are surprisingly similar at all rates. The average thickness of the extrusive layer away from the ridge axis is comparable (*ca.* 350–650 m), and the total volume of extrusives produced by seafloor spreading may be largely independent of spreading rate. Average crustal thickness is also similar (6–7 km) across almost the entire spreading-rate range, and total crustal production does not depend on spreading rate except at the slowest rates (less than 15 mm year ^{1}; Figure 13). Below rates of 15 mm year ^{1}, the crust is thinner (2–4 km) and more variable in thickness, possibly because enhanced conductive heat loss in the uppermost mantle results in reduced melting.

What Controls the Depth at Which Magma Chambers Reside at Ridges?

Two main hypotheses have been put forward to explain the depths at which magma chambers are found at ridges. One hypothesis is based on the concept of a level of neutral buoyancy for magma within the oceanic crust. This model predicts that magma will rise until it reaches a level where the density of the surrounding country rock equals that of the magma. However, magma lenses at ridges lie at considerably greater depths than the neutral-buoyancy level

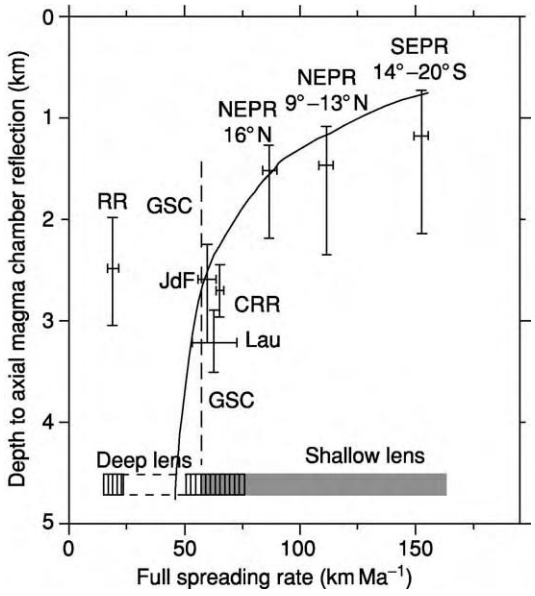

Figure 11 Average depth of magma lens reflections beneath ridges versus spreading rate. Magma lenses lie within two distinct depth ranges of 1–2 km for fast spreading ridges and 2.5–4 km for intermediate and slow spreading ridges. Both shallow and deep lenses are observed at some intermediate spreading ridges. The curved line shows the depth to the 1200°C isotherm calculated from the ridge thermal model of Phipps Morgan J and Chen YJ. Data from different ridges are labelled: RR, Reykjanes Ridge; JdF, Juan de Fuca Ridge; GSC, Galápagos Spreading Centre; CRR, Costa Rica Rift; Lau, Lau Basin; NEPR; northern East Pacific Rise; SEPR, southern East Pacific Rise.

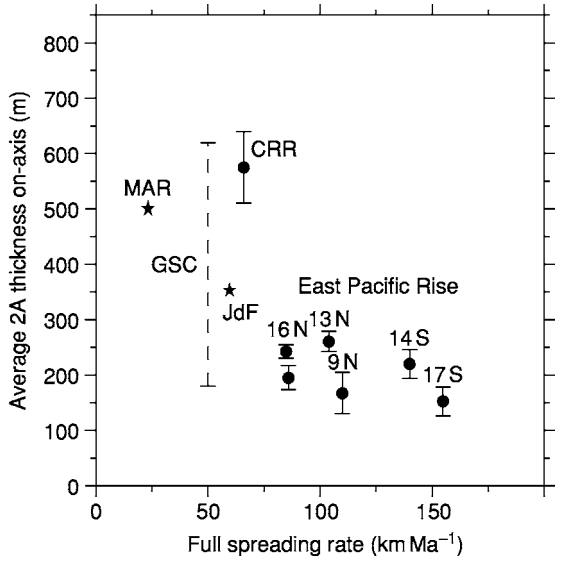

Figure 12 Thickness of the extrusive crust at the ridge axis versus spreading rate. For data obtained from detailed reflection surveys, average thicknesses are shown by black dots with standard deviations where available (solid lines) or thickness ranges (dotted lines). Data derived from other seismic methods are shown by stars. Data for the East Pacific Rise are labelled by survey location. Figure 13 Crustal thickness versus spreading rate. Crustal thicknesses are determined from seismic data obtained away from fracture zones. (Reproduced from Bown JW and White RS (1994) Variation with spreading rate of oceanic crustal thickness and geochemistry. *Earth and Planetary Science Letters* 121: 435–449.)

predicted if the density of the magma is equivalent to that of lavas erupted onto the seafloor (2700 kg m^{-3}). Either the average density of magma is greater or mechanisms other than neutral buoyancy control magma-lens depth.

The alternative model hypothesizes that magma-chamber depth is controlled by the thermal structure of the ridge axis. In this model, a mechanical boundary, such as a freezing horizon or the brittle–ductile transition, prevents magma from rising to its level of neutral buoyancy. The depth of this boundary within the crust will be primarily controlled by the thermal structure of the ridge axis, which is expected to vary with spreading rate. The inverse relation between spreading rate and depth to low-velocity zones at ridges apparent in early seismic datasets provided compelling support for this hypothesis. Numerical models of ridge thermal structure have been developed that predict systematic changes in the depth to the 1200° C isotherm (a proxy for basaltic melts) with spreading rate that match the first-order depth trends for magma lenses (Figure 11). This model predicts a minor increase in lens depth within the fast-spreading-rate range and an abrupt transition to deeper lenses at intermediate spreading rates, consistent with the present dataset. The numerical models also predict that, at intermediate spreading rates, small variations in magma supply to the ridge can give rise to large changes in axial thermal structure. These models are supported by recent

observations of the Galapagos spreading centre and the Southeast Indian Ridge. At these ridges, abrupt steps in the depths of crustal magma bodies occur where the ridge axis changes from an axial high to a shallowly rifted valley, although differences in crustal thickness (a proxy for magma supply) are modest (e.g. Figure 6). These recent investigations of intermediate-spreading ridges highlight the important role of spatial variations in magma supply independent of spreading rate in the process of crustal accretion at mid-ocean ridges.

Mountain Building and Orogeny

M Searle, Oxford University, Oxford, UK

Introduction

The term orogeny, derived from the Greek word 'oros', meaning mountain, and 'genesis', meaning birth or origin, encompasses all the processes of mountain building. Orogenic belts generally occur along plate margins and are characterized by thickened crust, metamorphism, magmatism, flexure of the lithosphere, and large-scale crustal deformation. The average thickness of the oceanic crust is about 5 km, and that of continental crust around 35 km. In the Himalaya–Tibet region the crust has reached 75–80 km thick, double the normal thickness. High topography along mountain belts usually accords with crustal and lithospheric thickening as a result of plate collision.

Most mountain ranges are the result of plate collision processes at convergent plate margins. Oceanic crust is dominantly composed of basaltic or gabbroic rocks, and the oceanic lithosphere is relatively strong and dense. Oceanic crust, composed mainly of olivine and pyroxene, can be subducted along Benioff zones and recycled back into the mantle. Continental crust is composed dominantly of granites, gneisses, and upper crustal sedimentary rocks. The quartz and feldspar-rich continental crust is weaker and more buoyant, and cannot easily subduct into the denser mantle.

Following the advent of plate tectonic theory in the 1960s it was proposed by J T Wilson that the process of orogeny was a 'cycle' beginning with rifting of continents and development of passive 'Atlantic-type' continental margins, followed by seafloor spreading and ocean basin formation, and ending with subduction, ocean closure, and finally, continental collision. This process became known as the Wilson cycle.

Mountain belts can be broadly categorized into three types of plate collision zones. These occur as the result of the collision between two oceanic plates

(e.g., Mariana–Philippine arc or the Caribbean island arc), secondly between a continental plate and an oceanic plate (e.g., Andes, or North American Cordillera), and thirdly between two continental plates (e.g., Alpine–Himalayan belt). Mountain belts can also form under the oceans, for example along the Mid-Atlantic ridge, or above hot spots, such as Hawaii or the Canary Islands, or in oceanic plateaux. Other mountain belts can form in the middle of continents, for example along the East African rift, where the mantle has domed up beneath linear rift valleys, as the continental plate begins to split apart.

Oceanic Island Arc Belts

Oceanic crust is generated along mid-ocean ridges, and becomes progressively older, colder, and denser with increasing distance from the ridge axis. When two oceanic plates converge, one plate flexes and bends beneath the other and begins to subduct. The subduction zone is marked by a deep ocean trench, an inclined zone of deep earthquakes and low heat flow (Wadati-Benioff zone), along which isotherms are buckled down. Subduction of slivers of sedimentary and basaltic rocks along the subduction zone can result in high-pressure metamorphism typical of the blueschist and eclogite facies. Typical examples of subduction zone plate boundaries are the Mariana trench between the Pacific and Philippine plates, or the Tonga–Kermadec trench between the Pacific and Indo-Australian plates. In both cases the mountain belt, comprising the fore arc and island arc complex is largely beneath sea-level. Andesitic island arcs are generated above subduction zones and are composed of explosive calc-alkaline volcanoes. Island arcs can produce small mountain ranges such as those along several West Pacific plate margins, or larger mountain ranges such as the Java–Banda arc in Indonesia. Marginal oceanic basins may open up behind the arc, forming back-arc spreading centres. Along the fore-arc region accretionary prisms of stacked thrust sheets can form as a result of scraping off sediments from the down-going plate. Subduction-related mélanges, including sepentinite mélanges with high-pressure rock clasts, are also typical of fore-arc regions. Ancient examples include the Franciscan complex in California.

Mature island arcs can produce significant mountain ranges, such as in Japan, where andesitic volcanoes are formed above a deep subduction zone. The Japan crust also consists of continental rocks, paired metamorphic belts, typical of fore-arc regions, and intrusive granitic magmas derived from partial melting of the down-going slab. The Japan Sea is a narrow ocean basin between the active margin in Japan and the passive continental margin along the east coast of mainland Asia.

Ophiolites and Mountain Building

Ophiolites are allochthonous sequences of oceanic crust and upper mantle emplaced onto continental margins. Some ophiolites are preserved as highly deformed slivers of serpentinized peridotites along ancient suture zones, or sites of plate collision. Some of the best preserved ophiolites occur as obducted thrust sheets emplaced over passive continental margins, typified by the Semail ophiolite in Oman, the Troodos ophiolite in Cyprus, and the Bay of Islands ophiolite in Newfoundland. In each of these cases a passive continental margin converged with an oceanic plate, which, instead of subducting downwards into the mantle, was detached and obducted on top of the continent. The subduction zone dipped away from the continental margin and the ophiolite complex was one of a series of thin-skinned thrust sheets emplaced onto the depressed continental margin.

In the Oman mountains of eastern Arabia, the ophiolite forms a thrust sheet over 15 km thick, approximately 700 km long, and over 100 km wide . It was formed at a spreading centre above an active subduction zone, along which old, cold oceanic basalts were subducted to depths of about 40 km, metamorphosed to garnet + clinopyroxene amphibolites, and accreted to the base of the mantle sequence peridotite. During the latest stages of ophiolite emplacement and mountain building the thinned leading edge of the passive continental margin was dragged down the subduction zone to depths of around 80 km or more and metamorphosed to eclogite facies. When the continental margin finally choked the subduction zone due to the buoyancy of the continental rocks, the deeply buried eclogites were exhumed rapidly back to the surface along the same subduction zone. The mountain building phase in Oman lasted approximately 25 My during the Late Cretaceous, when approximately 300–400 km width of the Tethyan ocean was closed.

Ophiolite obduction was the earliest phase of mountain building in the Alps and the Himalayas. Later continent–continent collision frequently overprints the earlier phases of orogeny, so mountain belts such as Oman are extremely important for deciphering subduction–obduction processes in the mountain-building cycle. A modern day example of a similar tectonic setting can be seen along the North Australian continental margin, which is currently subducting northwards beneath the accretionary prism of Timor island and the Banda volcanic arc of eastern Indonesia.

Andean-Type Mountain Building

The Andes mountains of South America extend for over 5000 km from Venezuela to southern Chile, and have formed as a result of the collision between the South American continental plate and the oceanic lithosphere of the Nazca and Pacific plates (Figure 1). The oceanic trench, the surficial trace of the subduction zone, lies about 70 km offshore the South American continental margin and reaches a depth of about 7 km off northern Chile. Earthquakes define a slab-like subduction zone inclined at 30°–40° eastwards beneath the Bolivian Andes, although to the south, the subducted lithosphere is almost horizontal beneath southern Peru and northern Chile before descending steeply into the mantle.

The geology of the Andes is dominated by linear belts of subduction-related granite–granodiorite batholiths and calc-alkaline volcanoes with shallow basins filled with continental red-beds. It has been estimated that around 300 km of crustal shortening has occurred in the central Andes as a result of east–west compression. Crustal shortening has resulted in increased crustal

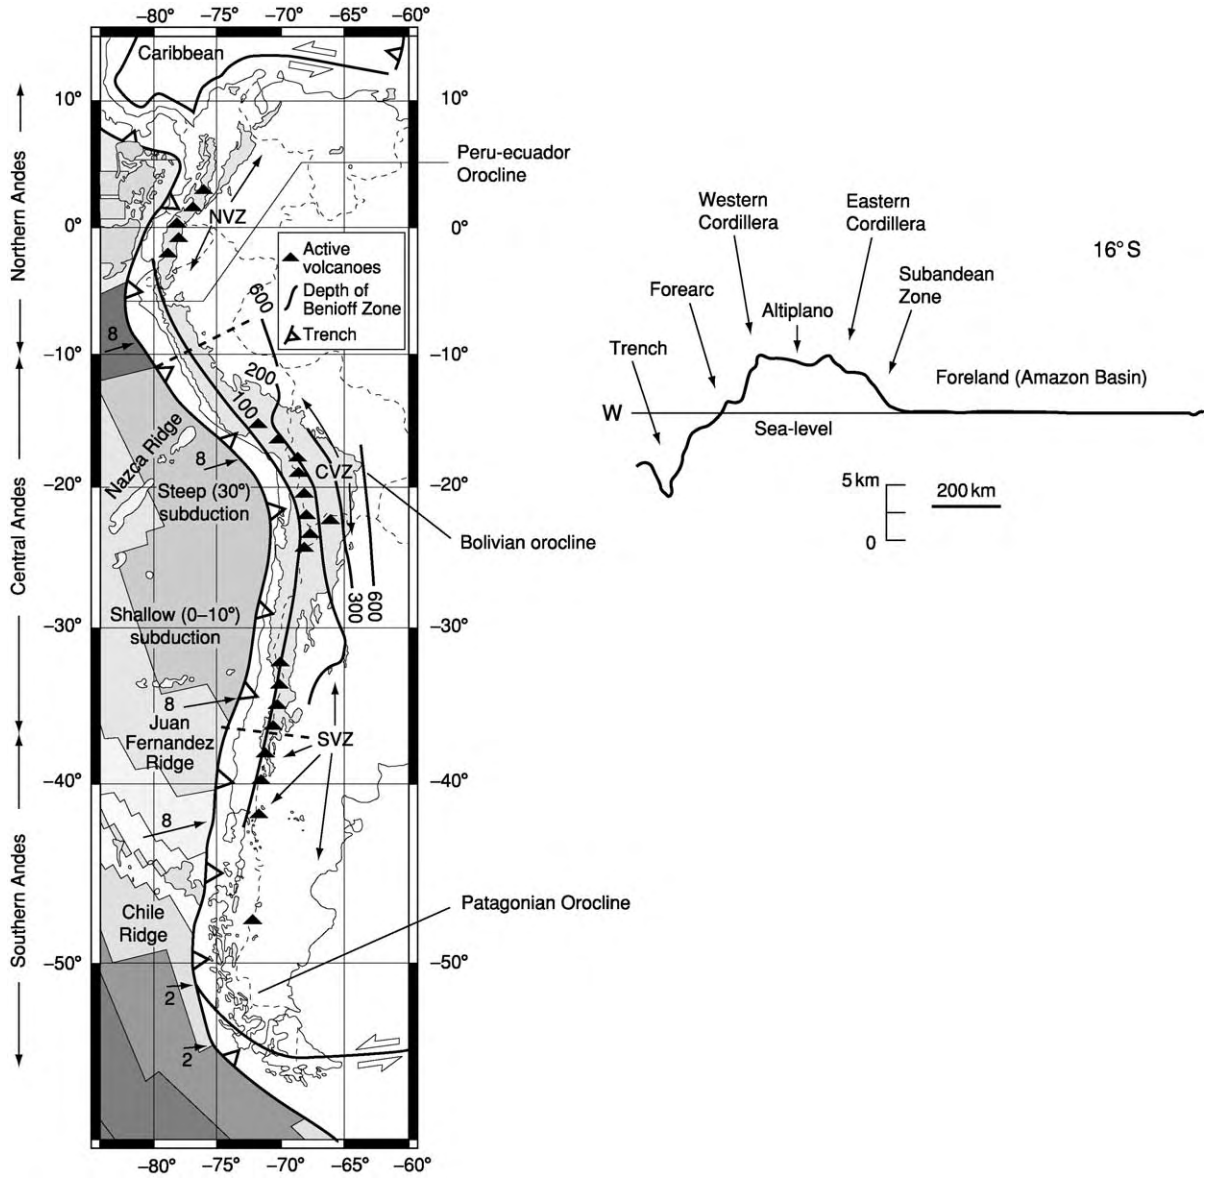

Figure 1 Map of the Andes in South America and topographic profile across the Central Andes showing the main tectonic features. Oceanic lithosphere is being subducted beneath the trench, and the oceanic crust is shaded according to age. Location of active volcanoes and the depth of the Benioff zone beneath the Andes is also shown. After Hancock PL and Skinner BJ (2000) *Oxford Companion to the Earth*, p. 21. © Oxford University Press.

thickening, ranging from ~35 km thickness east of the Andes, up to 80 km beneath the Bolivian Altiplano. The Altiplano has an average elevation of 4000 m above sea-level, and both the elevation and width of the Andes decrease both to the south and north. Along the eastern margin of the Bolivian Altiplano, a fold and thrust belt is present where relatively thin-skinned thrust sheets verge eastwards onto the Amazon foreland.

The North American Cordillera and Rocky Mountains have many geological features similar to those of the Andes, but also show important strike-slip, or transcurrent, faults like the San Andreas fault, movement along which has resulted in large-scale horizontal motion of crustal plates. Oceanic subduction beneath the continental margin has resulted in accretion of subduction-related deformed ophiolites, high-pressure metamorphic rocks, and mélanges. Granite batholiths, similar to the Andean batholiths, are aligned along mountain ranges like the Sierra Nevada, parallel to the continental margin. Andesitic volcanoes like the recently active Mount St Helens are regularly spaced along the range, along a linear belt roughly 200 km east of the trench.

Alpine-Type Mountain Building

The Alpine–Himalayan mountain belt formed as a result of the collision of the Africa–Arabia and Indian plates in the south with the Eurasian plate in the north. The Tethyan ocean, which separated these Gondwana continental fragments to the south from the Laurasian continent to the north, was mainly an east–west-aligned Permian and Mesozoic ocean that closed during the Late Cretaceous. The zone of collision stretches from the European Alps east along the Zagros mountains of Iran to the Himalaya. There are significant differences between the Alps, the Zagros, and the Himalayan mountain ranges, indicating that continental collision processes vary significantly along strike. The Oman mountains in Arabia show the early ophiolite obduction stage of the collision process, prior to continental collision. The Zagros mountains of Iran represent the initial continent–continent collision stage, and the Himalaya–Tibet orogeny represents the final stage of the continental collision process.

Seismic reflection and refraction profiles have revealed the deep crustal structure of the Alps. Together with surface geology, it has become possible to construct a geological section across the Alps (Figure 2). The Alpine orogeny includes a Cretaceous event and a Tertiary event, both of which involved subduction of crustal rocks down to eclogite facies depths and subsequent exhumation. Remnant ophiolites, marking the Tethyan suture zone, are preserved in the Valais region, and along the Ivrea zone. The Zermatt-Saas ophiolites have been subducted to over 80 km depth, metamorphosed to eclogite facies, and then exhumed rapidly during the early stage of Alpine orogeny. They were subsequently deformed by south-vergent backfolding and backthrusting along the Insubric line, a large-scale strike-slip and thrust fault that separates the European crust from the Adriatic crust.

Approximately 500 km of north–south convergence between Europe and Africa has been estimated from the restoration of cross-sections across the Alpine orogeny. Part of this shortening has been taken up by folding and thrusting of upper crustal, mainly sedimentary rocks of the Austro-Alpine, Penninic, and Helvetic nappes (large-scale recumbent folds overlying a thrust plane). The lower crust shows wedging of basement massifs including the Aar, Gotthard, and Mont Blanc thrust sheets in the north-west and the Monte Rosa, Gran Paradiso, and Dora Maira massifs in the south-east. The latter shows coesite-bearing eclogites, indicative of ultra-high-pressure metamorphism and deep subduction (around 100 km depth) of continental crustal material.

The later stage of the Alpine orogeny was characterized along the north and northwest by foreland-propagating thrusts extending from the Helvetic nappes into the Swiss molasse basin. The molasse basin developed in front of the rising Alps by flexural buckling of the European lithosphere caused by the excess load of the Alps. Along the south and south-east parts of the orogeny, the South Alpine nappes and Insubric Line structures show south-vergent backfolds and backthrusts, producing a retroshear, or bivergent orogeny with folds and thrusts verging in both directions.

Himalayan-Type Mountain Building

The Himalayan range stretches for over 2500 km from north-west Pakistan, eastwards across northern India, Nepal, Bhutan, and southern Tibet to south-west China, and is the type-example of a mountain range formed as a result of the collision of two continents. The Indian plate was a part of the southern supercontinent Gondwana until it rifted away from southern Africa, Madagascar, and Antarctica approximately 150 My ago. As the Indian Ocean spreading ridges formed in between the continents, India was pushed northwards at rapid plate tectonic rates of around 20 cm year ^{1}, until it collided with the southern margin of Asia approximately 50 My ago at equatorial latitudes. Palaeomagnetic data suggest that India underwent a marked reduction in the rate of northward motion since the time of collision to around 4–5 cm year ^{1}. The Indian plate has also undergone

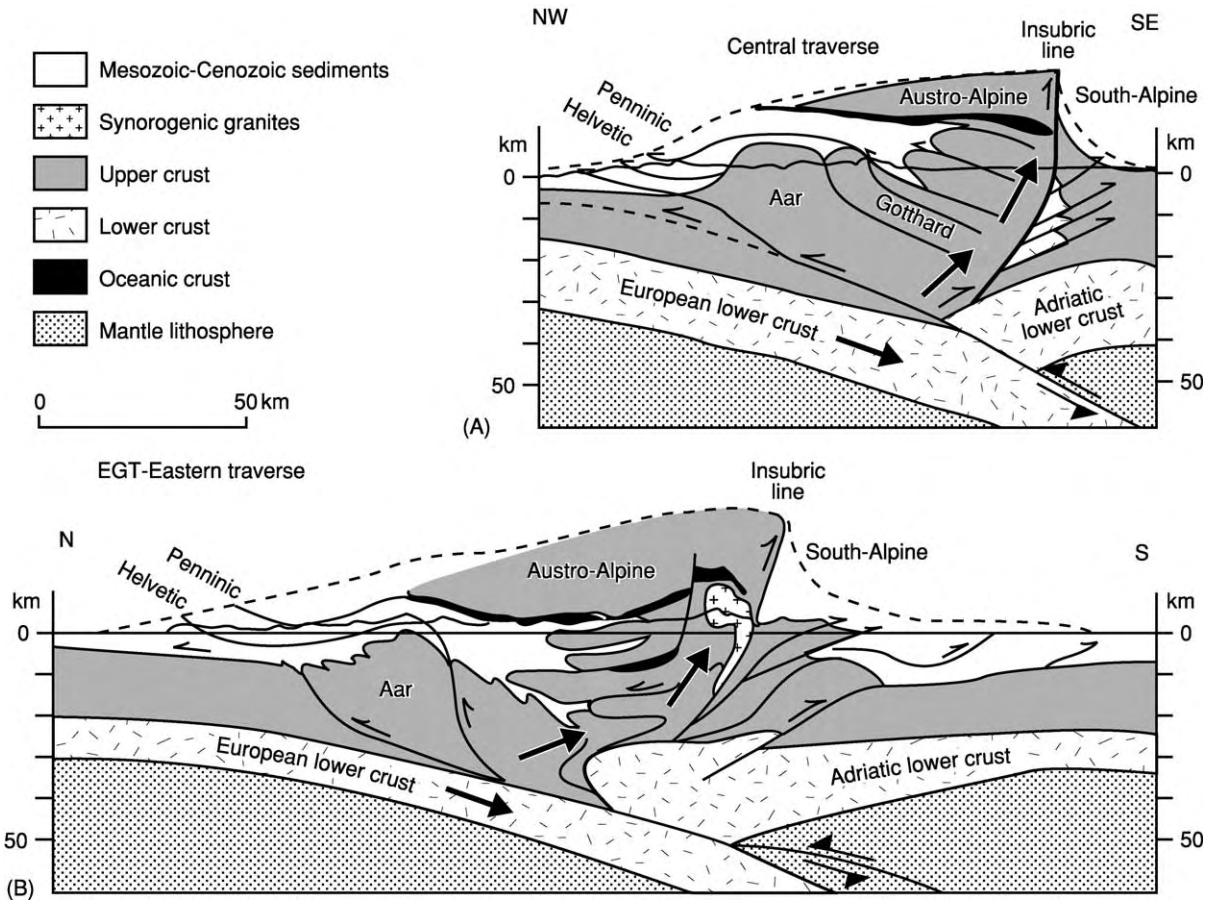

Figure 2 Two sections across the European Alps, showing the overall structure with the stacking of upper crustal sheets above the subducting lower crust. After Schmid *et al.* (1996) Geophysical geological transect and tectonic evolution of the Swiss Italian Alps. *Tectonics* 15: 1036 1064.

20°–30° of counterclockwise rotation. GPS measurements suggest that the present rate of contraction across the Himalaya is about $17.5 \pm 2\,\text{mm year}^{-1}$. Earthquake focal mechanisms show that the majority of earthquakes are a result of north–south compression and occur along the main Himalayan fault, the active plate boundary along which the Indian Shield underthrusts the Lesser Himalaya.

The collision of India with Asia was the most recent of a series of continental plate collisions, which successively accreted smaller continental blocks onto the stable Siberian shield. Since the initial continental collision, India has moved northwards, indenting into Asia by over 2500 km and creating renewed uplift of all the mountain ranges along the southern margin of Asia, including the Pamir, Hindu Kush, the Karakoram, and the Tibetan plateau (Figure 3). The effects of the Indian plate collision extend northwards as far as the Tien Shan and Altay ranges along the border of inner Mongolia.

The earliest effects of the India–Asia collision occurred along the Indus suture zone where the two plates first met. This zone is marked by oceanic rocks including ophiolites, slabs of oceanic crust, and upper mantle emplaced onto continental margins, deep-sea sediments, and occasionally high-pressure metamorphic rocks, indicative of subduction zones. The youngest marine sediments along the suture zone are Early Eocene *Nummulites*-bearing limestones deposited between 52 and 49 My ago. These rocks are frequently used as a proxy for dating the collision. As the collision progressed, the sedimentary rocks along the northern continental margin began to shorten by folding and thrusting processes. The northern mountain ranges of the Himalaya in Zanskar, Spiti, northern Nepal, and southern Tibet show spectacular folding and thrusting of these Tethyan sedimentary rocks. Approximately 150 km of shortening of upper crustal rocks has been estimated across the Tethyan zone. The lower crust that originally underlay these upper crust sediments must have been detached and underthrust northwards beneath the southern margin of the Asian plate (Lhasa block).

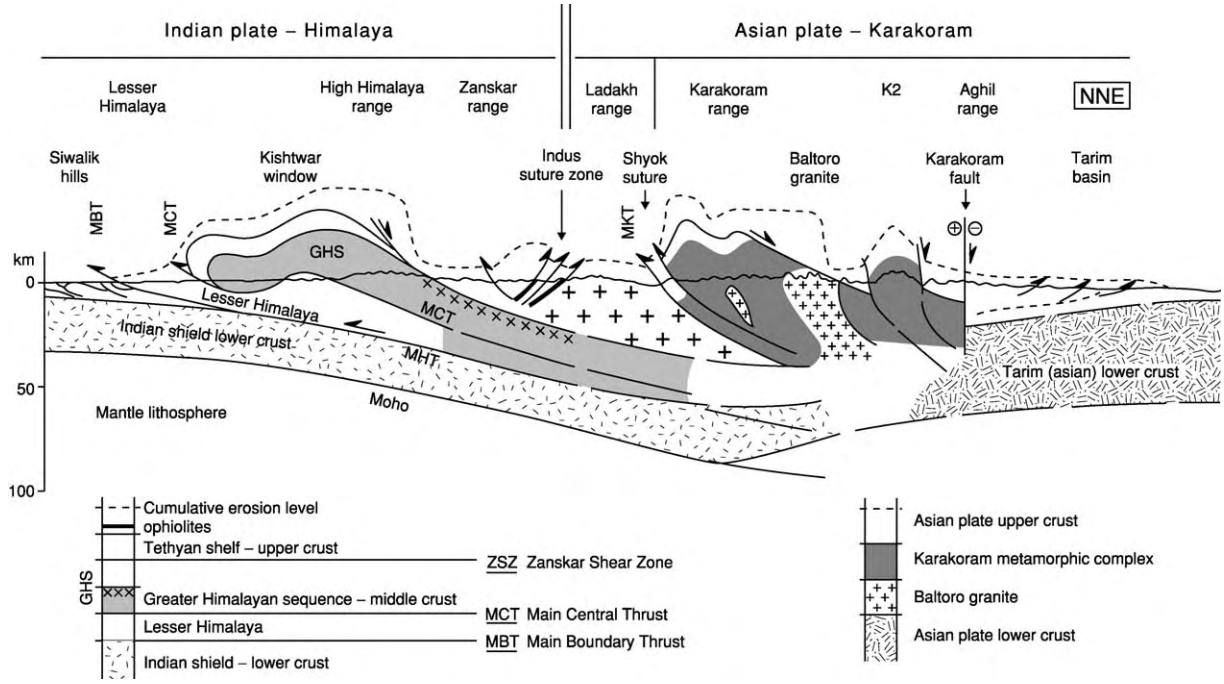

Figure 3 Geological profile across the western Himalaya and central Karakoram mountains. The middle crust metamorphic rocks in the Greater Himalaya and southern Karakoram are shaded and also contain crustal melt granites. The dashed line above shows the approximate cumulative erosion level, the amount of rock material eroded off the mountain range during the Tertiary orogeny. After Searle (1991) *Geology and Tectonics of the Karakoram Mountains*. Chichester, England: Wiley.

Crustal shortening and thickening resulted in increased temperatures and pressures in the deeper crust, causing regional metamorphism along the Greater Himalaya. Many of the highest peaks along the Himalaya are composed of the exhumed deep crustal metamorphic rocks. Dating of monazites by U–Th–Pb methods, and garnets using Sm–Nd isotopes from kyanite- and sillimanite-bearing gneisses in the Greater Himalaya shows that peak *P–T* conditions were initially reached between 35 and 30 My ago, and that temperatures remained high (above 600°C, in the kyanite and sillimanite stability fields) for at least 15 My after that. Around 20 My ago during the Early Miocene, temperatures peaked during a widespread sillimanite-grade metamorphic event that culminated in partial melting of the crust. This melting event resulted in migmatisation of the gneisses and generation of crustal melt leucogranites. The Himalayan leucogranites contain tourmaline, garnet, muscovite, and biotite, and they have very distinctive isotope chemistry (extremely high $^{87}Sr/^{86}Sr$ ratios) characteristic of granites produced from the melting of continental crust. The leucogranites were formed at relatively shallow depths (15–25 km) and were extruded southwards as giant sill complexes.

During the southward extrusion of the Greater Himalayan slab of metamorphic and granitic rocks, the metamorphic isograds were folded and inverted along a giant thrust fault shear zone termed the 'Main Central Thrust'. This thrust fault was active during the Early Miocene (around 20–15 My ago) and carried the entire Greater Himalaya southwards over the relatively unmetamorphosed rocks of the Lesser Himalaya. During this event the metamorphic isograds were recumbently folded and sheared by crustal scale thrusting. As a consequence, an inverted metamorphic isograd sequence characterizes the main central thrust high strain shear zone, with sillimanite- and kyanite-grade rocks structurally above low-grade biotite and garnet-grade rocks. The extrusion of this ductile mid-crustal layer, or channel, of partially molten high-grade gneisses, migmatites, and leucogranites was active during the Miocene (20–17 My ago) with major thrust-related shear zones along the base (Main Central Thrust) and a major normal fault shear zone along the top (South Tibetan detachment).

Around 10 My ago thrusting propagated southwards from the Main Central Thrust into the Lesser Himalaya and eventually to the 'Main Boundary Thrust', the southern boundary of the Himalaya. Active thrust faults have developed during Quaternary and recent times, extending south into the Siwalik hills where the active Himalayan front occurs today. The loading of the Himalaya caused the Indian

plate to flex down and create the Siwalik molasse basin. This basin accumulated all the debris eroded from the rising Himalaya, transported south by rivers. The rivers converge into the Indus River in the west and the Ganges in the east. Sediments eroded from the Himalaya have been transported by these rivers to the Indus Fan in the Arabian Sea and the Bengal Fan in the Bay of Bengal.

Tibetan Plateau

The Tibetan plateau is the largest area of uplifted crust on Earth. The plateau extends for over 3000 km east–west and 1500 km north–south. It lies at an average elevation of just over 5 km above sea-level. The interior of the plateau is very flat with internal drainage, low precipitation, and low erosion rates. The margins of the plateau are ringed by mountain ranges including the Himalaya along the south, the Karakoram and Pamirs to the south-west, the Tien Shan and Kun Lun to the north, and the Long Men Shan along the east. Earthquakes reveal that the high plateau is currently undergoing east–west extension, whilst the margins of the plateau show compression or strike-slip faulting.

The geology of Tibet shows that the plateau region includes several different continental plates that were progressively accreted to the southern continental margin of Asia throughout the Phanerozoic (Figure 4). The most recent and probably the largest of these was the final plate collision, that of India with Asia. The crust beneath the Tibetan plateau is between 65 and 70 km thick, double that of normal continental crust. Several different models have been proposed to account for the thick crust and approximately 1000 km of crustal shortening required. The extreme end-member models include underthrusting of India beneath the entire Tibetan plateau, a model proposed initially by Emile Argand in 1924, and homogeneous thickening of the plateau with very little underthrusting of Indian material at depth.

Recent deep crustal seismic reflection and refraction profiling of Tibet has revealed that the Indian plate lower crust probably underthrusts southern Tibet only as far as the Bangong suture zone approximately 450 km north of the Indus–Yarlung Tsangpo suture zone. The equivalent amount of shortening in the Indian plate upper crust has been taken up by intense folding, thrusting, and crustal thickening in the Tethyan zone and Greater Himalaya. The seismic profiling has also managed to trace the prolongation of the surface faults in the Himalaya, northwards beneath the southern part of the plateau. Seismic and structural data has revealed that the Main Central Thrust and the South Tibetan detachment normal fault bound a mid-crustal layer of hot, partially molten rock that extends southwards to the high Himalaya. Magnetotelluric studies have revealed the presence of 'bright spots' indicative of pockets of fluid or magma at relatively shallow depths beneath southern Tibet today. These have been interpreted as pockets of granitic magma forming today in a structural position similar to those of the 20- to 17-My-old leucogranites cropping out in the high Himalaya. This layer of partial-melt migmatites, high-grade gneisses, and leucogranites was extruded out from beneath the southern part of the Tibetan plateau as a channel of ductile-deforming rock bounded by a rheologically stronger upper crust (Tethyan zone) and lower crust (underplated Indian shield Precambrian and Early Palaeozoic rocks).

Whereas the Tibetan plateau shows little relief despite being 5 km above mean sea-level, the neighbouring Karakoram range of northern Pakistan and Ladakh shows the highest relief of all, with many 7000- to 8000-m-high mountains and deeply incised river valleys. The Karakoram crust has also been tilted, revealing the deep crustal geology not exposed in Tibet (Figure 3). The Karakoram shows multiple episodes of crustal thickening and regional metamorphism spanning the past 65 My and multiple episodes of crustal melting, resulting in granite magmatism. A series of pre-50-My-old granite–granodiorite intrusions indicate that the southern margin of Asia was probably a subduction-related Andean-type continental margin prior to the Indian plate collision 50 My ago. The climax of mountain building in the Karakoram occurred between 24 an – 15 My ago with the emplacement of the huge Baltoro granite batholith, a series of intrusions of biotite monzogranite to biotite–muscovite–garnet leucogranite. A suite of 24- to 22-My-old lamprophyre dykes intruding around the Baltoro granites indicates that parts of the upper mantle were melting at the same time as the lower crust. The ages of the Baltoro granites are similar to the age of the Greater Himalayan leucogranites to the south, which span 24–12 My ago, with the majority between 21 and 17 My ago. This suggests that following the India–Asia collision, crustal thickening, metamorphism, and magmatism spread both across the south Asian margin in the Karakoram and across the north Indian plate margin along the Himalaya.

Earthquake distribution across Tibet shows that the entire plateau region is deforming internally today, and not acting as a rigid plate. Earthquakes in the high plateau show that the crust is undergoing east–west extension, whereas earthquakes in the mountain ranges bordering the high plateau are

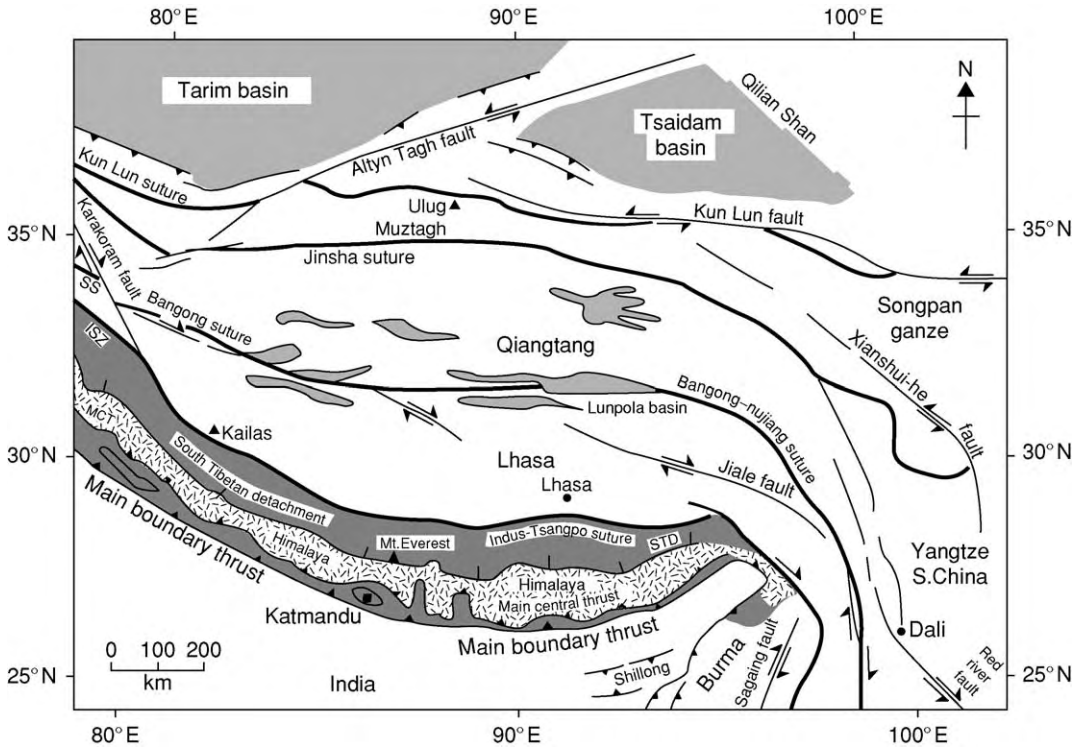

Figure 4 Map of the Tibet region showing the major plate boundaries. The Himalayas are shaded along the southern margin of the plateau. The stable continental blocks of the Tarim basin and Tsaidam basin in the north are shown, together with the major strike slip faults bounding the plateau. Suture zones are progressively younger towards the south from the Kun Lun to the Jinsha, Bangong Nujiang, and Indus Tsangpo suture zones.

mostly a result of either compression or strike-slip deformation. Southern Tibet shows about eight large graben systems, bounded by north–south-aligned steep normal faults. These extensional rifts cut across the northernmost Himalayan range, the Tethyan zone, but die out to the south and do not extend into the Greater Himalayan zone. The rifts are associated with hot springs and active geothermal systems.

The high plateau is bounded by a series of large-scale strike-slip faults, notably the sinistal Altyn Tagh and Kun Lun faults along the north, the dextral Karakoram fault along the south-west, and a series of arcuate, dextral strike-slip faults swinging around the eastern syntaxis (Jiale, Xianshui-he faults). The distribution and slip motion on these faults suggested that the thickened crust of the Tibetan plateau was being extruded horizontally, eastwards out of the way of the Indian plate indentor, a process known as continental extrusion. Despite being impressive faults, many of which show active offsets of Quaternary glacial features, there is relatively limited total geological offset along them, and their timing is generally not concomitant with collision.

The Tibetan plateau region is also remarkable for having a series of shoshonitic volcanic rocks that erupted intermittently over the past 45 My. These volcanic rocks were derived from partial melting of hot asthenospheric mantle. The ages of these volcanics reveal that by 13 My ago, southern Tibet no longer had a hot upper mantle, as relatively cold the Indian plate lithosphere was underplating from the south; however, central and northern Tibet did keep a hot mantle, indicating that any cold lithospheric root to the thickened plateau must have dropped off intermittently and diachronously, rather than as a single catastrophic event.

Conclusions

Although mountain belts can occur along constructive plate margins or even in some intraplate regions, most orogenic belts are the result of plate collision processes along destructive plate margins. Ocean–ocean plate collisions result in island arcs, accretionary prisms, and deep subduction along oceanic trenches. Ocean–continent plate collisions result in Andean-type mountain belts, characterized by calc-alkaline volcanic arcs and granite–granodiorite batholiths. Continent–continent collision can result in a wide array of mountain belts characterized by the

relatively simple folding and thrusting of the Zagros mountains, to the more complicated structure and metamorphism seen in the Alps and Himalaya. The largest and most extensive such collision, that between India and Asia, resulted in thousands of kilometres of crustal shortening, crustal thickening, metamorphism, melting, and exhumation as seen in the Himalaya, Karakoram, and Tibetan plateau.

Neotectonics

I Stewart, University of Plymouth, Plymouth, UK

Introduction

Neotectonics concerns the study of horizontal and vertical crustal movements that have occurred in the geologically recent past and which may be ongoing today. Though most crustal movements arise directly or indirectly from global plate motions (i.e., tectonic deformation), neotectonic studies make no presumption about the mechanisms driving deformation. Consequently, 'movements' is a vague catch-all term that encompasses a myriad of competing deformation processes, such as the gradual pervasive creep of tectonic plates, discrete (seismic) displacements on individual faults and folds, and distributed tilting and warping through isostatic readjustment or volcanic upheaval. The phrase 'geologically recent past' is also appropriately vague. Early attempts to define the discipline by arbitrary time windows (e.g., Late Cenozoic, Neogene, or Quaternary) have given ground to a more flexible notion that envisages neotectonism starting at different times in different regions. The onset of the neotectonic period, or the 'current tectonic regime', depends on when the contemporary stress field of a region was first imposed. For instance, the current tectonic regime began in the Middle Quaternary ($\sim$700 000 years ago) in the Apennines of central Italy, and even more recently ($<$500 000 years ago) in California; in contrast, in eastern North America, the present-day stress regime has been in existence for at least the past 15 million years.

Typically then, neotectonic movements have been in operation in most regions for the past few million years or so. Over such prolonged intervals, neotectonic actions are revealed by the stratigraphic build-up of sediments in inland and marine basins, the burial or exhumation histories of rocks, and the geomorphological development of landscapes. Geological studies of palaeobotany and palaeoclimate, numerical models of landscape evolution, and techniques such as fission-track analysis and cosmogenic dating are among the disparate tools unravelling this long-term tectonic activity. Over periods of many tens of to several hundreds of thousands of years, the actions of individual tectonic structures (faults and folds) can be determined, unmasked by their deformation of geomorphic markers, such as marine and fluvial terraces, and tracked with reference to the Late Pleistocene glacial–eustatic time-frame. The apparently smooth deformation rates discerned over intermediate time-scales are revealed to be episodic and irregular when faults and folds are examined over Holocene (10 000 years) time-scales. Over millennial time-scales, secular variations in the activity of tectonic structures can be gleaned from a diverse set of palaeoseismological approaches, from interpreting the stratigraphy of beds that have been affected by faulting, to detecting disturbances in the growth record of trees or coral atolls.

Active Tectonics

Although neotectonic movements continue up to the present day, the term 'active tectonics' is typically used to describe those movements that have occurred over the time-span of human history. Active tectonics deals with the societal implications of neotectonic deformation (such as seismic-hazard assessment, future

sea-level rise, etc.), because it focuses on crustal movements that can be expected to recur within a future interval of concern to society. Contemporary crustal movements may be discerned in Earth surface processes and landforms, such as in the sensitivity of alluvial rivers to crustal tilting. In addition, geomorphological and geological studies are important in recording the surface expression of Earth movements such as earthquake ground ruptures, which, due to their subtle, ephemeral, or reversible nature, are unlikely to have been preserved in the geological record. However, active tectonics also employs an array of high-technology investigative practices; prominent among these are the monitoring of ongoing Earth surface deformation using space-based or terrestrial geodetic methods (tectonic geodesy), radar imaging (interferometry) of ground deformation patterns produced by individual earthquakes and volcanic unrest, and the seismological detection and measurement of earthquakes (seismotectonics). These techniques are applied globally via the World-Wide Standardized Seismograph Network and regionally via local seismographic coverage.

The modern snapshots of tectonism can be pushed back beyond the twentieth century through the analysis of historical accounts and maps to infer past land surface changes or to deduce the parameters of past seismic events (historical seismology). In addition, earthquakes can leave their mark in the mythical practices and literary accounts of ancient peoples, recorded in the stratigraphy of their site histories and in the damage to their buildings (archaeoseismology). The time covered by such human records varies markedly, ranging from many thousands of years in the Mediterranean, Near East, and Asia to a few centuries across much of North America. Generally records confirm that regions that are active today have been consistently active for millennia, thereby demonstrating the long-term nature of crustal deformation, but occasionally records reveal that some regions that appear remarkably quiet from the viewpoint of modern seismicity (such as the Jordan rift valley) are capable of generating large earthquakes. In reality, the distinction between neotectonics and active tectonics is artificial; the terms simply describe different time slices of a continuum of crustal movement. This continuum is maintained by the persistence of the contemporary stress field, which means that inferences of past rates and directions of crustal movement from geological observations can be compared directly with those measured by modern geodetic and geophysical methods.

Although the terms 'neotectonic' and 'active' are somewhat blurred and are often used interchangeably, societal demands (for instance, regulatory authorities for seismic hazard, nuclear safety, etc.) often require the incidence of tectonic movements to be defined strictly. For instance, in the United States, under California law, an 'active fault' is presently defined as one that has generated surface-rupturing earthquakes in the past 11 000 years (i.e., the time period was established to relate to the time when the Holocene was considered to have begun). Other regulatory bodies recognize a sliding scale of fault activity: Holocene (activity in the past 10 000 years), Late Quaternary (activity in the past 130 000 years), and Quaternary (activity in the past 1.6 million years). Neotectonic faults, by comparison, are simply those that formed during the imposition of the current tectonic regime. 'Real' structures, of course, are unconstrained by such legislative concerns. Many modern earthquakes rupture along older (i.e., palaeotectonic) basement faults. Indeed, it is important to recognize that any fault that is favourably oriented with respect to the stress currently being imposed on it has the potential to be activated in the future, regardless of whether it has moved in the geologically recent past.

Global Tectonics

A useful way to differentiate styles and degrees of neotectonic activity is in terms of tectonic strain rate, which is a measure of the velocity of regional crustal motions and, in turn, of the consequent tectonic strain build-up. Crustal movements are most vigorous, and therefore most readily discernible, where plate boundaries are narrow and discrete. In these domains of high tectonic strain, frequent earthquakes on fast-moving ($>10\,\text{mm year}^{-1}$) faults ensure that a century or two of historical earthquakes and a few years of precise geodetic measurements are sufficient to capture a consistent picture of the active tectonic behaviour. Intermediate tectonic strain rates characterize those regions where plate–boundary motion is distributed across a network of slower moving ($0.1–10\,\text{mm year}^{-1}$). Examples of such broad deforming belts are the Basin and Range Province of the western United States or the Himalayan collision zone, where earthquake faults rupture every few hundred or thousand years, ensuring that the Holocene period is a reasonable time window over which to witness the typical crustal deformation cycle. In contrast, areas with low strain rates ensure that intraplate regions, often referred to as 'stable continental interiors', are low-seismicity areas with slow-moving ($<0.1\,\text{mm year}^{-1}$) faults that rupture every few tens (or even hundreds) of thousands of years, making the snapshot of human history an unreliable guide to the future incidence of tectonic activity.

The global pattern of present-day crustal motions can be accounted for by 'plate tectonic' theory, that elegant kinematic framework in which rigid plates variously collide, split apart, and slide along their actively deforming boundaries (*see* **Plate Tectonics**). Closer inspection, however, reveals that the basic rules that govern global plate motions (i.e., rigid blocks separated by narrow deforming boundaries) break down at the regional and local scales. This is particularly so on the continents, where a patchwork of preexisting geology and structure ensures that tectonic stresses are not applied in a uniform, straightforward fashion. Studies of how the contemporary stress field varies across Earth's surface distinguish between first- and second-order stress provinces. First-order provinces have stresses generally uniformly oriented across several thousands of kilometres. The largest of these are the midplate regions of North America and western Europe, where the stress fields are largely the far-field product of ridge push and continental collision. In contrast, first-order stress provinces in tectonically active areas are dominated by the downgoing pull of subducting slabs and the resistance to subduction. Second-order stress provinces are smaller, typically less than 1000 km across, and are related to crustal flexure induced by thick sequences of sediments and postglacial rebound, and to deep-seated rheological contrasts. Although the bulk of Earth's crust is in compression, significant regions of extension occur. In both the continents and the oceans, these extensional domains are long and narrow and correspond to topographically high areas, though notable exceptions are the Basin and Range provinces and the Aegean region of the eastern Mediterranean. Most first-order stress provinces, and many second-order stress provinces, coincide with distinct physiographic provinces.

Glacial Isostatic Adjustment

Plate-driving forces may exert the dominant control on the contemporary stress field, but another process contributes to crustal deformation at a global scale. That process is glacial isostatic adjustment (GIA), the physical response of Earth's viscoelastic mantle to surface loads imposed and removed by the cycles of glaciation and deglaciation, to which the planet has been subjected for the past 900 000 years (*see* **Tertiary To Present:** Pleistocene and The Ice Age). Because large ice-mass fluctuations induce the subcrustal flow of material, measurable crustal deformation extends for thousands of kilometres beyond the limits of the former ice margins; consequently, the effects of GIA are felt globally. In addition, though the crust's elastic response to ice-sheet decay is geologically immediate, the delayed viscoelastic response of the mantle ensures that GIA can persist long after the ice has gone. Although the effects of GIA can now be detected from space geodesy, its legacy is most clearly visible in the worldwide pattern of postglacial sea-level changes. Regions that were ice covered at the Last Glacial Maximum are uplifting (i.e., relative sea-level is currently falling) as a consequence of postglacial rebound of the crust. Likewise, the regions peripheral to the former ice sheets are subsiding (i.e., relative sea-levels are rising) due to collapse of the 'glacial forebulge'. The effect of this subsidence outside the area of forebulge collapse is to draw in water from the central ocean basins, which is compensated by uplift in the ocean basin interiors in the far-field of the ice sheets. The final GIA component is the hydro-isostatic tilting of continental coastlines due to the weight applied to Earth's surface by the returning meltwater load, which produces a 'halo' of weak crustal subsidence around the world's major landmasses. For the most part, geological studies of Holocene relative sea-level changes are consistent with the uplift/subsidence pattern predicted by global viscoelastic theory. The key areas of misfit are along plate boundary seaboards (especially subduction zones), where tectonic deformation dominates, and those areas 'contaminated' by local anthropogenic effects (groundwater extraction, etc.).

The neotectonic implications of GIA are not confined to the coastline. Glacial rebound is now widely considered as an effective mechanism for exerting both vertical and horizontal stresses, not only within the limits of the former ice sheets, but for several hundred kilometres outside. Within the former glaciated parts of eastern North America and northern Europe, both tectonic and rebound stresses are required to explain the distribution and style of both postglacial and contemporary seismotectonics. Outside in the ice-free forelands, predicted glacial strain rates are still likely to be one to three orders of magnitude higher compared to tectonic strain rates typical of continental interiors. Consequently, some workers argue that an apparent 'switching on' of Holocene earthquake activity in the eastern United States and the occurrence of atypically large seismic events, such as the great (magnitude >8) earthquakes that struck the Mississippi valley area of New Madrid in 1811–1812, may be associated with areas where glacial strains are particularly high. Glacial loading and unloading may also disturb the build-up of tectonic strain at glaciated plate boundaries, such as today in Alaska or previously when the Cordilleran ice sheet capped part of the Cascadia subduction zone. More recently, the isostatic component of glacier erosion in the mountain-building process is becoming appreciated.

Global Perspective

The worldwide patterns of vertical and horizontal crustal movements arise from the global effects of plate motions and glacial isostatic adjustment. Regionally and locally, this is augmented by flexure from eustatic or sediment loading, volcanic deformation, or anthropogenic change (e.g., dam impoundment). Though many neotectonic investigations seek to disentangle movements arising from the imposition of tectonic strains from those augmented by non-tectonic processes, this is often a fruitless holy grail; because deformation of Earth's crust typically induces compensatory flow underlying the mantle, neotectonic movements are applied globally. Nevertheless, these disparate contributory mechanisms, coupled with the varying time-scales over which their actions can de discerned, ensure that neotectonics encompasses a remarkable breadth of research disciplines. Few other fields easily blend topics as disparate as space science, seismology, Quaternary science, geochronology, structural geology, geomorphology, geodesy, archaeology, and history. It is this interdisciplinary marriage that makes neotectonics particularly exciting and especially challenging.

Ocean Trenches

R J Stern, The University of Texas at Dallas, Richardson, TX, USA

Introduction

An oceanic trench is a long, narrow, and generally very deep depression of the seafloor. Oceanic trenches are the deepest places on the Earth's solid surface and range down to 11 km below sea-level. These tremendous depths mark fundamental breaks in the Earth's lithosphere, the great plates that we all ride on (*see* **Plate Tectonics**). If mid-ocean ridges are where the Earth turns itself inside out, trenches are where the Earth swallows its skin. The asymmetry of trenches reflects a deeper phenomenon: as one plate bends down to return to the mantle, the other plate strains to fill the growing void. The depths of trenches are governed by many things, most importantly sediment flux but also the age of the downgoing lithosphere, the convergence rate, intermediate slab dip, and even the width of the sinking plate. Trenches are sites where fluids are 'squeezed' out of the subducted sediments and a newly recognized biosphere thrives.

Early Years of Study

Trenches are the most spectacular morphological features on the Earth's solid surface, but they were not clearly defined until the late 1940s and 1950s. The depths of the oceans were scarcely imagined until we began to lay telegraph cables between the continents in the late nineteenth and early twentieth centuries. The elongated bathymetric expression of trenches was not recognized early, and the term 'trench' does not appear in Murray and Hjort's classic oceanography overview. Instead they used the term 'deep' to describe the deepest parts of the ocean, such as the Challenger Deep, which is now recognized as the greatest gash on the solid surface of the Earth. Experiences in the World War I battlefields emblazoned the concept of a trench as an elongate depression defining an important boundary, so it is no surprise that the term 'trench' was used to describe natural features in the early 1920s. The term was first used in a geological context by SJ Scofield two years after the war ended to describe a structurally controlled depression in the Rocky Mountains. James Johnstone, in his 1923 textbook *An Introduction to Oceanography*, first used the term in its modern sense to describe a marked elongate depression of the seafloor.

During the 1920s and 1930s, Vening Meinesz developed a unique gravimeter that could measure gravity in the stable environment of a submarine and used it to measure gravity over ocean trenches. His gravity measurements revealed that trenches are sites of downwelling in the solid Earth. The concept of downwelling at trenches was characterized by DT Griggs in 1939 as the tectogene hypothesis, for which he developed an analogous model using a pair of rotating drums. The war in the Pacific led to great improvements in bathymetry, especially in the western and northern Pacific, and the linear nature of the trenches became clear. The rapid growth of deep-sea research efforts, especially the widespread use of echo-sounders in the 1950s and 1960s, confirmed the morphological utility of the term. The important trenches were identified and sampled, and their greatest depths were sonically plumbed. The heroic phase of trench exploration culminated in the 1960 descent of the bathyscaphe *Trieste*, which set an unbeatable world record by diving to the bottom of the Challenger Deep. Following Dietz' and Hess' articulation of the seafloor-spreading hypothesis in the early 1960s and the plate-tectonic revolution in the late 1960s, the term 'trench' has been redefined so that it now has tectonic as well as morphological connotations.

Trenches mark one of the most important types of natural boundary on the Earth's solid surface, that between two lithospheric plates. There are three types of lithospheric-plate boundary: divergent (where lithosphere and oceanic crust are created at mid-ocean ridges (*see* **Tectonics:** Convergent Plate Boundaries and Accretionary Wedges; Mid-Ocean Ridges), convergent (where one lithospheric plate sinks beneath another and returns to the mantle (*see* **Tectonics:** Convergent Plate Boundaries and Accretionary Wedges), and transform (where two lithospheric plates slide past each other). Trenches are the spectacular and distinctive morphological features of convergent plate boundaries (Figure 1). Plates move together along convergent plate boundaries at rates that vary from a few millimetres to ten or more centimetres per year. Trenches form where oceanic lithosphere is subducted at a convergent plate margin,

presently at a global rate of about a tenth of a square metre per second.

Geographical Distribution

There are about 50 000 km of convergent plate margins in the world, mostly around the Pacific Ocean – the reason that they are sometimes called 'Pacific-type' margins – but they also occur in the eastern Indian Ocean, and there are relatively short convergent-margin segments in the Atlantic and Indian Oceans and in the Mediterranean Sea (Figure 2). Trenches are sometimes buried and lack bathymetric expression, but the fundamental structures that they represent mean that the name should still be applied in these cases. This applies to the Cascadia, Makran, southern Lesser Antilles, and Calabrian trenches (Table 1). Trenches, magmatic (island) arcs, and zones of earthquakes that dip under the magmatic arc as deeply as 700 km are diagnostic of convergent plate boundaries and their deeper manifestations, subduction zones. Trenches are related to but distinguished from zones of continental collision, where continental lithosphere enters the subduction zone. When buoyant continental crust enters a trench, subduction eventually stops and the convergent plate margin becomes a collision zone. Features analogous to trenches are associated with collision zones; these include sediment-filled

foredeeps, referred to as peripheral foreland basins, such as that which the Ganges and Tigris–Euphrates rivers flow along.

Morphological Expression

Trenches are the centrepieces of the distinctive physiography of a convergent plate margin. Transects across trenches yield asymmetric profiles, with relatively gentle (*ca.* 5°) outer (seaward) slopes and steeper (*ca.* 10–16°) inner (landward) slopes. This asymmetry is due to the fact that the outer slope is defined by the top of the downgoing plate, which must bend as it begins its descent. The great thickness of the lithosphere requires that this bending be gentle. As the subducting plate approaches the plate boundary, it is first bent upwards to form the outer swell and then descends to form the outer trench slope. The outer trench slope is disrupted by a set of subparallel normal faults, which staircase the seafloor down into the trench (Figure 3). The plate boundary is defined by the trench axis itself. Beneath the inner trench wall, the two plates slide past each other along the subduction décollement, which intersects the seafloor along the base of the trench. The overriding plate generally contains a magmatic arc and a fore arc. The magmatic arc is created as a result of physical and chemical interactions between the subducted plate at depth and the asthenospheric mantle associated with the overriding plate. The fore arc lies between the trench and the magmatic arc. Fore arcs have the lowest heat flow of any place on Earth because there is no asthenosphere (convecting mantle) between the forearc lithosphere and the cold subducting plate.

The inner trench wall marks the edge of the overriding plate and the outermost fore arc. The fore arc consists of igneous and metamorphic basement, and this basement may act as a buttress to a growing accretionary prism, depending on how much sediment is supplied to the trench. If the sediment flux is high, material will be transferred from the subducting plate to the overriding plate. In this case an accretionary prism grows, and the location of the trench migrates away from the magmatic arc over the life of the convergent margin. Convergent margins with growing accretionary prisms are called accretionary convergent margins and make up nearly half of all convergent margins. If the sediment flux is low, material will be transferred from the overriding plate to the subducting plate by a process of tectonic ablation known as subduction erosion and carried down the subduction zone. Fore arcs undergoing subduction erosion typically expose igneous rocks. In this case,

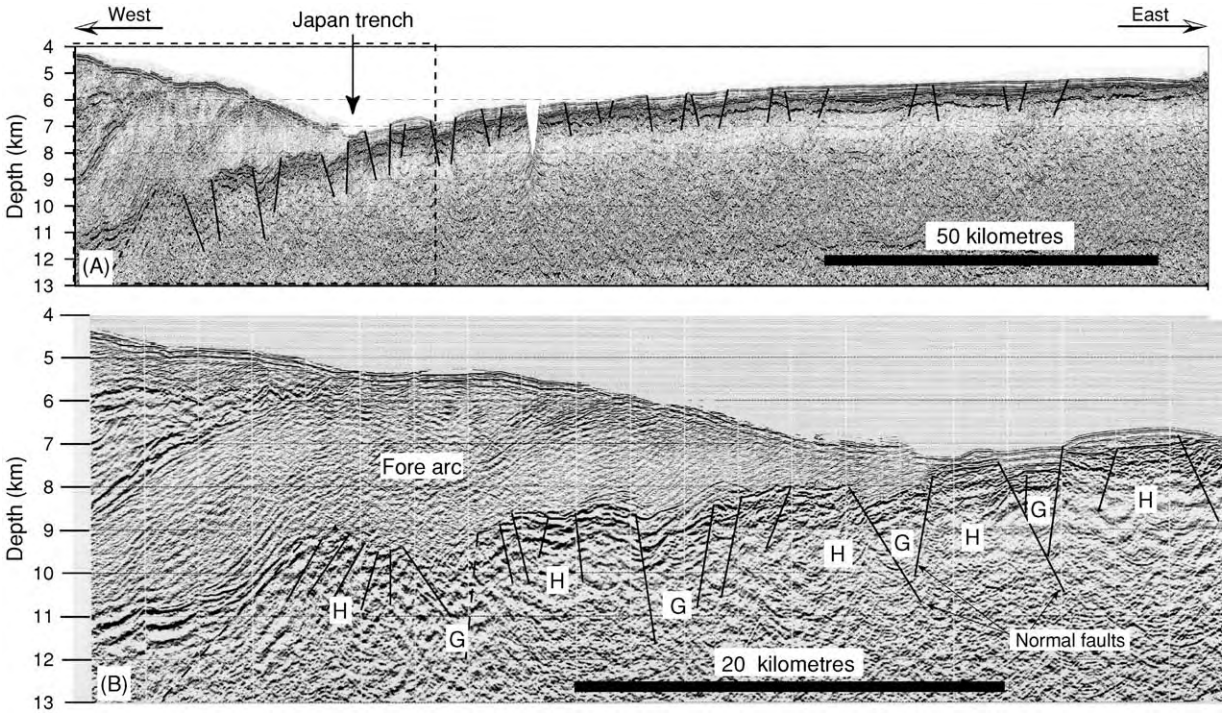

Figure 3 Horst (H) and graben (G) structures with normal faults associated with the subduction of the Pacific plate in the Japan Trench. Vertical exaggeration is four times in (A) and twice in (B). Dashed box in (A) indicates the region shown in detail in (B). Modified from Tsuru T, Park J O, Takahashi N, *et al.* Tectonic features of the Japan Trench convergent margin off Sanriku, northeastern Japan, revealed by multichannel seismic reflection data. *Journal of Geophysical Research* 105: 16 403 16 413.

the location of the trench will migrate towards the magmatic arc over the life of the convergent margin. Convergent margins experiencing subduction erosion are called nonaccretionary convergent margins and comprise more than half of convergent plate boundaries. This is an oversimplification, because a convergent margin can simultaneously experience sediment accretion and subduction erosion.

The asymmetric profile across a trench reflects fundamental differences in materials and tectonic evolution. The outer trench wall and outer swell are composed of seafloor, which takes a few million years to move from where subduction-related deformation begins near the outer trench swell to where the plate sinks beneath the trench. In contrast, the inner trench wall is deformed by plate interactions throughout the life of the convergent margin. The fore arc is continuously subjected to subduction-related earthquakes. This protracted deformation and shaking ensures that the slope of the inner trench wall is controlled by the angle of repose of whatever material it is composed of. Because they are composed of igneous rocks instead of deformed sediments, nonaccretionary trenches have steeper inner walls than accretionary trenches.

Filled Trenches

The composition of the inner trench slope is determined by sediment supply, which also exerts a first-order control on trench morphology. Active accretionary prisms are especially common in trenches that are located near continents where large rivers or glaciers reach the sea. These filled trenches cause some confusion because they are tectonically indistinguishable from other convergent margins but lack the bathymetric expression of a trench. The Cascadia margin off the north-west coast of the USA is a filled trench, the result of sediments delivered by the rivers of the north-western USA and south-west Canada. The Lesser Antilles convergent margin shows the importance of proximity to sediment sources for trench morphology. In the south, near the mouth of the Orinoco River, there is no morphological trench, and the fore arc and the accretionary prism have a total width of almost 500 km. The accretionary prism is so large that it forms the islands of Barbados and Trinidad. Northwards the fore arc narrows, the accretionary prism disappears, and north of 17 °N only the morphology of a trench is seen. In the extreme north, far away from sediment sources, the Puerto Rico Trench is over 8600 m deep, and there is no active accretionary prism. A similar relationship between proximity to rivers, fore arc width, and trench morphology can be observed from east to west along the Alaskan–Aleutian convergent margin. The convergent plate boundary off the coast of Alaska changes along its strike from a filled trench with a broad fore arc in the east (near the coastal rivers of Alaska) to a deep trench with a narrow fore arc in the west (near the Aleutian islands). Another example is the Makran convergent margin off the coasts of Pakistan and Iran, where the trench is filled by sediments from the Tigris–Euphrates and Indus rivers. Thick accumulations of turbidite deposits along a trench can be supplied by down-axis transport of sediments that enter the trench 1000–2000 km away, as is found in the Peru–Chile Trench south of Valparaiso and in the Aleutian Trench. Convergence rate can also be important in controlling trench depth, especially for trenches near continents, because slow convergence may mean that the capacity of the convergent margin to dispose of sediment is exceeded.

Thus, trench morphology can be expected to evolve continuously as oceans close and continents converge. While the ocean is wide, the trench may be far away from continental sources of sediment and so may be deep. As the continents converge, the trench may increasingly be filled with continental sediments and shoals. A simple definition of the transition from subduction to collision is when a plate boundary previously marked by a trench has filled sufficiently to rise above sea-level.

Accretionary Prisms and Sediment Transport

Accretionary prisms grow by frontal accretion – where sediments are scraped off, bulldozer-fashion, near the trench – or by underplating of subducted sediments and perhaps oceanic crust along the shallow parts of the subduction décollement. Frontal accretion over the life of a convergent margin results in the youngest sediments being found in the outermost part of the accretionary prism and the oldest sediments being found in the innermost portion. Older (inner) parts of the accretionary prism are much more lithified and have steeper structures than the younger (outer) parts. Underplating is difficult to detect in modern subduction zones but may be recorded in ancient accretionary prisms, such as the Franciscan Group of California, in the form of tectonic mélanges and duplex structures. Different modes of accretion are reflected in the morphology of the inner slope of the trench, which generally shows three morphological provinces. The lower slope comprises imbricate thrust slices, which form ridges. The middle part of the slope may comprise a bench or terraces. The upper slope is smoother but may be cut by submarine canyons.

Because accretionary convergent margins have high relief, are continuously deformed, and accommodate

a large flux of sediments, they are sites of vigorous sediment dispersal and accumulation. Sediment transport is controlled by submarine landslides, debris flows, turbidity currents, and contourites. Submarine canyons transport sediment from beaches and rivers down the upper slope. These canyons are formed by channelized turbidites and generally lose definition with depth because continuous tectonic readjustments disrupt the channels. Sediments move down the inner trench wall via channels and a series of fault-controlled basins. The trench itself serves as an axis of sediment transport. If enough sediment moves into the trench, it may be completely filled, and turbidity currents will then be able to carry sediment well beyond the trench and may even surmount the outer swell. Sediments from the rivers of southwest Canada and the north-western USA spill over where the Cascadia trench would be and reach the Juan de Fuca spreading ridge several hundred kilometres to the west.

The slope of the inner trench wall of an accretionary convergent margin continuously adjusts to the thickness and width of the accretionary prism. The prism maintains a 'critical taper', established by the Mohr–Coulomb failure criterion for the pertinent materials. A package of sediments scraped off the downgoing lithospheric plate will deform until it and the accretionary prism that it has been added to attain a critical-taper (constant slope) geometry. Once critical taper is attained, the wedge slides stably along its basal décollement. Strain rate and hydrological properties strongly influence the strength of the accretionary prism and thus the angle of critical taper. Fluid pore pressure can modify rock strength and is an important determinant of critical taper angle. Low permeability and rapid convergence may lead to pore pressures that exceed lithostatic pressure and result in a relatively weak accretionary prism with a shallowly tapered geometry, whereas high permeability and slow convergence lead to lower pore pressures, stronger prisms, and steeper geometry.

The Hellenic Trench system is unusual because its convergent margin subducts evaporites. The slope of the southern flank of the Mediterranean Ridge (its accretionary prism) is low, about 1°, which indicates very low shear stress on the décollement at the base of the wedge. Evaporites influence the critical taper of the accretionary complex, because their mechanical properties differ from those of siliciclastic sediments and because of their effect upon fluid flow and fluid pressure, which control effective stress. In the 1970s, the linear deeps of the Hellenic Trench south of Crete were interpreted as being similar to trenches in other subduction zones, but, with the realization that the Mediterranean Ridge is an accretionary complex, it became apparent that the Hellenic Trench is actually a starved fore arc basin, and that the plate boundary lies south of the Mediterranean Ridge.

Water and Biosphere

The volume of water escaping from within and beneath the fore arc results in some of the Earth's most dynamic and complex interactions between aqueous fluids and rocks. Most of this water is trapped in pores and fractures in the upper lithosphere and the sediments of the subducting plate. The average fore arc is underlain by a solid volume of oceanic sediment that is 400 m thick. This sediment enters the trench with 50–60% porosity. The sediment is progressively squeezed as it is subducted, reducing void space and forcing fluids out along the décollement and up into the overlying fore arc, which may or may not have an accretionary prism. Sediments accreted to the fore arc are another source of fluids. Water is also bound in hydrous minerals, especially clays and opal. The increasing pressure and temperature experienced by the subducted materials convert the hydrous minerals to denser phases that contain progressively less structurally bound water. Water released by dehydration accompanying phase transitions is another source of fluid introduced to the base of the overriding plate. These fluids may travel diffusely through the accretionary prism, via interconnected pore spaces in sediments, or may follow discrete channels along faults. Sites of venting may take the form of mud volcanoes or seeps and are often associated with chemosynthetic communities. Fluids liberated in the shallowest parts of the subduction zone may also escape along the plate boundary but have rarely been observed to drain along the trench axis. All of these fluids are dominated by water but also contain dissolved ions and organic molecules, especially methane. Methane is often sequestered in an ice-like form (clathrate) in the fore arc. Gas hydrates are a potential energy source and can rapidly break down. The destabilization of gas hydrates has contributed to global warming in the past and will probably do so in the future (*see* **Petroleum Geology:** Gas Hydrates).

Chemosynthetic communities thrive where fluids seep out of the fore arc. Cold seep communities have been discovered on inner trench slopes in the western Pacific, especially around Japan, in the Eastern Pacific, along the North, Central, and South American coasts from the Aleutian to the Peru–Chile Trenches, on the Barbados prism, in the Mediterranean, and in the Indian Ocean, along the Makran and Sunda convergent margins. These communities have been found down to depths of 6000 m. They have received much less attention than the chemosynthetic communities associated with hydrothermal vents. Chemosynthetic

communities are located in a variety of geological settings: above over-pressured sediments in accretionary prisms, where fluids are expelled through mud volcanoes or ridges (Barbados, Nankai, and Cascadia); along active erosive margins with faults; and along escarpments caused by debris slides (Japan Trench, Peruvian margin). Surface seeps may be linked to massive hydrate deposits and destabilization (e.g. Cascadia margin). High concentrations of methane and sulphide in the fluids escaping from the seafloor are the principal energy sources for chemosynthesis (*see* **Tectonics:** Convergent Plate Boundaries and Accretionary Wedges).

Empty Trenches and Subduction Erosion

Trenches distant from an influx of continental sediments lack an accretionary prism, and the inner slope of such trenches is commonly composed of igneous or metamorphic rocks. Nonaccretionary convergent margins are characteristic of (but not limited to) primitive arc systems. Primitive arc systems are those that are built on oceanic lithosphere, such as the Izu–Bonin–Mariana, Tonga–Kermadec, and Scotia (South Sandwich) arc systems. The inner trench slopes of these convergent margins expose the crust of the fore arcs, including basalt, gabbro, and serpentinized mantle peridotite. These exposures allow easy access to materials from the lower oceanic crust and upper mantle, and provide a unique opportunity to study the magmatic products associated with the initiation of subduction zones. Most ophiolites are probably formed in a fore-arc environment during the initiation of subduction, and this setting favours ophiolite emplacement during collision with blocks of thickened crust. Not all nonaccretionary convergent margins are associated with primitive arcs. Trenches adjacent to continents where there is a low influx of sediments from rivers, such as the central part of the Peru–Chile Trench, may also lack an accretionary prism.

The igneous basement of a nonaccretionary fore arc may be continuously exposed by subduction erosion. This transfers material from the fore arc to the subducting plate and can take the form of frontal erosion or basal erosion. Frontal erosion is most active in the wake of seamounts being subducted beneath the fore arc. Subduction of large edifices (seamount tunnelling) oversteepens the fore arc, causing mass failures that carry debris towards and ultimately into the trench (Figure 4). This debris may be deposited in graben of the downgoing plate and subducted with it. In contrast, structures resulting from basal erosion of the fore arc are difficult to recognize on seismic-reflection profiles, so the occurrence of basal erosion is difficult to confirm. Subduction erosion may also diminish a once-robust accretionary prism if the flux of sediments into the trench diminishes.

Nonaccretionary fore arcs may also be sites of serpentinite mud volcanism. Serpentinite mud volcanoes form where fluids released from the downgoing plate percolate upwards and interact with the cold mantle lithosphere of the fore arc. Peridotite is hydrated into serpentinite, which is much less dense than peridotite and so will rise diapirically when there is an opportunity to do so. Some nonaccretionary fore arcs, for example the Marianas, are subjected to strong extensional stresses, which allows buoyant serpentinite to rise to the seafloor and form serpentinite mud volcanoes. Chemosynthetic communities are also found on non-accretionary margins such as the Marianas, where they thrive on vents associated with serpentinite mud volcanoes.

Outer Trench Swell

The outer rise is where the descending plate begins to flex and fault as it approaches the subduction zone. Here, the lithosphere is bent upwards by plate stresses, just as the plate is bent downwards in the trench – in neither case is the plate in isostatic equilibrium. Typically, the gravity over the outer swell is about 50 mGals higher than expected from isostasy, while gravity over the trench is about 200 mGals less than that expected from isostatic considerations. The bending of the plate is associated with tension in the upper 20 km, and shallow earthquakes, caused by tensional failure induced by the downward bending of the oceanic plate, are common: about 20 extensional outer-rise earthquakes of magnitude 5 or greater occur annually. Most axes of tension are perpendicular to the trench, regardless of the direction of relative motion between the two plates, indicating that failure is controlled by bending stresses in the plate. Plate bending also causes deeper (down to 50 km) earthquakes due to compression. The width of the outer rise is directly related to the flexural rigidity of the lithosphere. The thickness of the elastic lithosphere varies between 20 km and 30 km for most trench profiles. Faulting related to plate bending and stair-stepping of the descending slab into the trench may allow seawater to infiltrate deep into the crust and perhaps into the upper mantle. Faulting of the downgoing plate results in a horst-and-graben structure, which allows sediment that reaches the trench to be deposited in graben and carried downward. This faulting also breaks up seamounts as they approach the trench (Figure 5). The mechanism of frontal erosion may operate through the combined effects of seamount tunnelling, mass wasting and

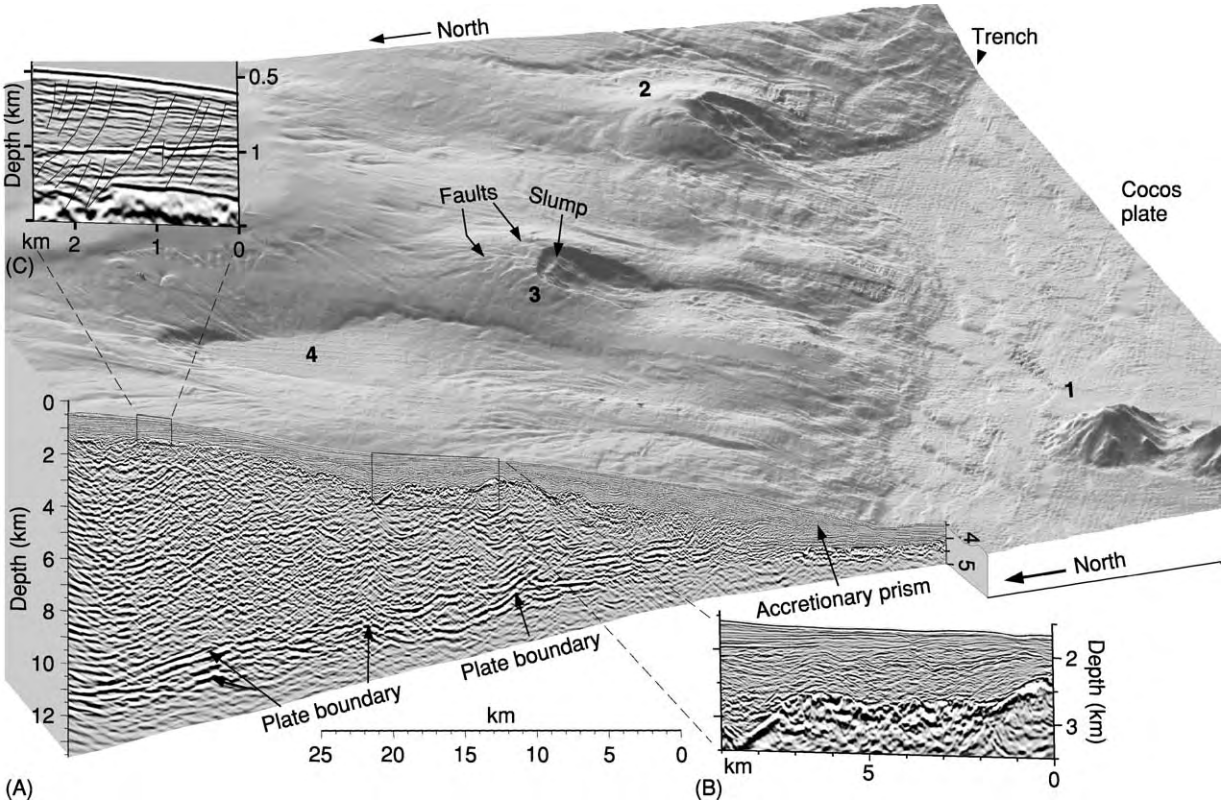

Figure 4 Downgoing seamounts and subduction erosion in the Middle America Trench off the coast of Costa Rica, where the Cocos Plate is being rapidly subducted (80 mm yr ^{1}). (A) Four seamounts in various stages of subduction (1 4) are particularly well manifested in the bathymetry of the inner trench wall. Seamount 1 (about 1 km tall) is approaching the trench and will enter it in about 200 000 years. Seamount 2 entered the trench about 200 000 years ago and is destroying the inner trench wall. The collision has caused oversteepening, with relief locally exceeding 0.5 km, leading to collapse at the sides and especially in the wake of the seamount. Note the slump and fractures. Oversteepening causes submarine landslides and flows of debris towards the trench, rebuilding the angle of repose and flooding the trench floor. Seamount 3 entered the trench about 400 000 years ago and has been swallowed beneath the accretionary prism. Debris continues to be shed from the impact zone and flows into the trench. Seamount 4 entered the trench about 600 000 years ago, and the region above it has almost completed its collapse above the sunken seamount. Subduction erosion usually occurs when debris flows fill graben (**Figure 3B**) in the downgoing plate and are carried down. Note also the seismic reflection profile across the Central American fore arc. (B) Detail of part of the seismic reflection profile. The frontal *ca.* 40 km of the margin has a rough margin wedge top produced by seamount subduction. (C) Where the margin wedge is more than 6 8 km thick its top is smooth, cut only by normal faulting. transport to the trench, deposition in a graben on the downgoing plate, and descent into the mantle.

Controls on Trench Depth

There are several factors that control the depths of trenches. The most important is the supply of sediment, which may fill the trench so that there is no bathymetric expression. It is therefore not surprising that the deepest trenches are all nonaccretionary. Table 1 shows that all trenches deeper than 8000 m are nonaccretionary. In contrast, all trenches with growing accretionary prisms are shallower than 8000 m. A second factor controlling trench depth is the age of the lithosphere at the time of subduction. Because oceanic lithosphere cools and thickens as it ages, it subsides. The older the seafloor, the deeper it lies, and this controls the minimum depth from which the seafloor begins its descent. This obvious correlation can be removed by looking at the relative depth (Δd), which is the difference between the regional seafloor depth and the maximum trench depth. The relative depth is affected by the age of the lithosphere at the trench, the convergence rate, and the dip of the subducted slab at intermediate depths. Finally, narrow slabs can sink and roll back more rapidly than broad plates, because it is easier for the underlying asthenosphere to flow around the edges of the sinking plate. Such slabs may have steep dips at relatively shallow depths and so may be

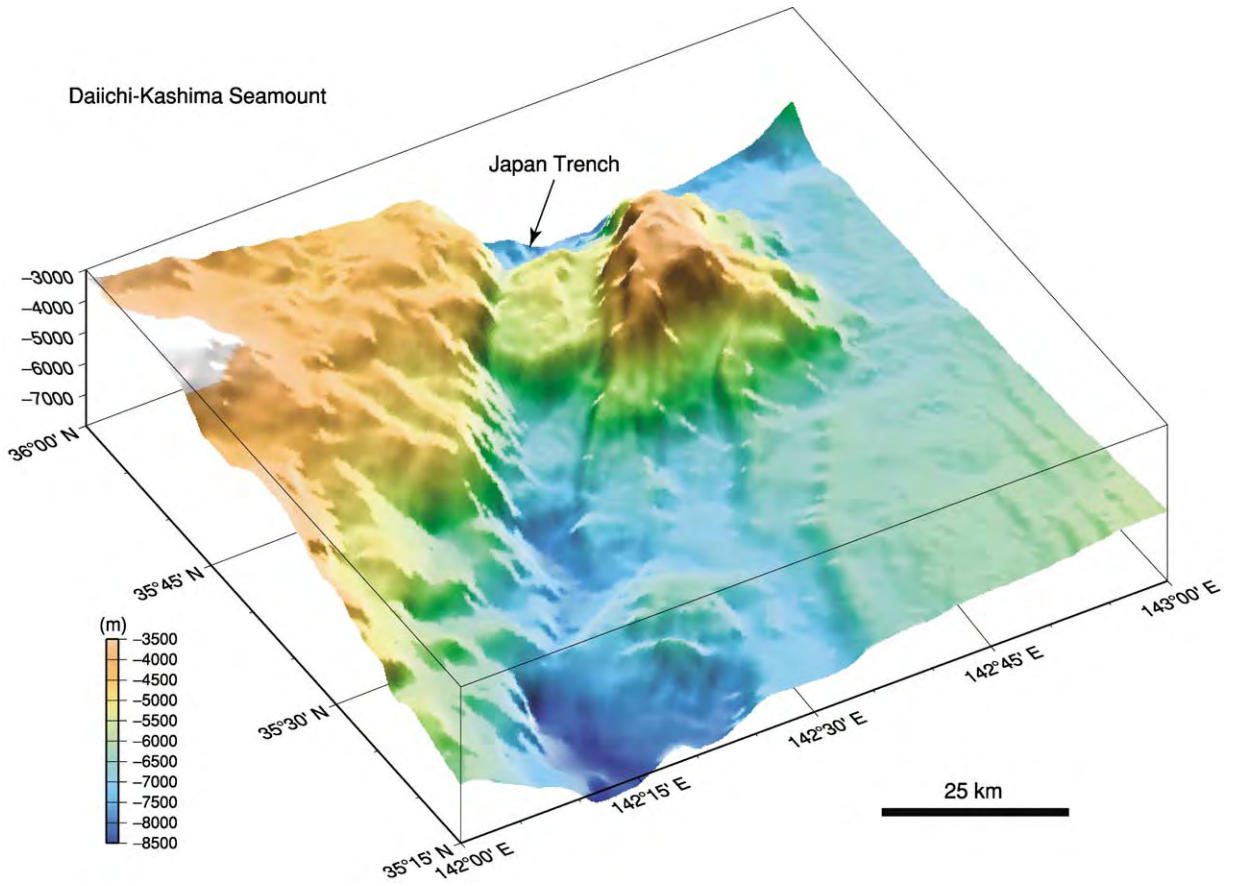

Figure 5 Bathymetric profile showing normal faulting affecting the Daiichi Kahima Seamount as it enters the Japan Trench, east of Tokyo. The seamount, which was originally a guyot (conical sides and a flat top), has been cut by a normal fault that drops its western third by about 1 km. Smaller normal faults related to bending of the plate as it approaches the trench affect the eastern part of the seamount and the seafloor around it. Rift Valleys

L Frostick, University of Hull, Hull, UK

Introduction

Rift valleys are generally long narrow depressions in the Earths' crust that often contain major lakes and rivers (e.g. Lake Baikal and the Rhine and Rio Grande rivers; see Figure 1). They form as a result of the crust being stretched by plate-tectonic movements, for example during the extension that leads to the opening of new oceans. Rifts have been a feature of geological processes since the solid crust first formed, and early examples of rift valleys have been recognized in rocks as old as the Precambrian, more than 700 Ma ago. Those that have developed during more recent geological time form impressive features of the landscape, with the sides of the rift rising several kilometres above the rift floor. One good example is the East African Rift, which dominates the landscape from Ethiopia in the north to Malawi in the south (*see* **Africa:** Rift Valley).

Rift valleys have been the subject of considerable research and interest for more than a century, partly because of the inherent beauty of deep valleys but also because they are sites where both fossiliferous and economically important deposits are found (e.g. fossil hominids in East Africa, and the oil and gas found in ancient rift deposits of the North Sea; Figure 2). The reason rifts are so productive is linked directly to their mechanism of formation and to the geological structure that sits beneath the very visible surface valley.

Morphology and Structure

The surface expressions of all rifts are similar; there is a central depression or valley flanked by two uplifted shoulders, each of which is cut by a series of faults that step down towards the central lowland. The original interpretation of the geological structure that underlies this morphology was that it is like the keystone of an arch: a central piece of rock drops down between two faults (Figure 3A) to form a structure known by the German word 'graben'. This interpretation was schooled by the surface appearance of rifts and generally ignored the fact that the flat bottoms of rift valleys are almost always clothed in sediments, which mask the underlying geology. With the development of geophysical techniques, especially seismology, that have allowed geologists to glimpse the subsurface, it has become evident that the structure of many rifts is asymmetric, with one margin being higher than the other and the floor being tilted (Figure 3B). The higher margin is cut by the largest faults, which are referred to as the main border faults. The faults are generally normal ones, with one side of a slightly inclined fracture dropping downwards relative to the other and resulting in a near-vertical step in the geology. The lower of the two margins is generally associated with a series of smaller faults inclined both towards and away from the rift axis, which fragment the geology into a series of small horst blocks with intervening valleys. These are termed synthetic faults when the fault plane is inclined in the same direction as that of the border fault and antithetic faults when the inclinations are opposed.

The precise location and magnitude of the faulting is controlled by the thickness and character of the crust undergoing rifting and by the presence of pre-existing lines of weakness, which can be exploited by new faults if they have the right orientation. In some parts of rifts there are a few very large faults, which can have total vertical displacements in excess of 2 km; in other parts there are much smaller faults and the overall displacement is much less. Often the rocks between subparallel marginal faults are

Figure 1 Satellite remote sensing image of the Rio Grande Rift and River, USA. Image taken by the TERRA satellite using the MODIS instrument (moderate resolution imaging spectroradiometer) and enhanced with SRTM30 shaded relief.

tilted away from the rift axis, forming small valleys between the fault blocks.

The margins of rift valleys cut by the main border fault are almost always subject to uplift, which accentuates the topographical step down to the central floor. The distance from margin to margin varies considerably, but continental examples are normally between 30 km and 200 km wide. However, the largest rift system in the world is invisible beneath the surface of our major oceans. The mid-ocean ridges are the centres at which ocean floor is created, and they dominate the seafloor topography (*see* **Tectonics:** Mid-Ocean Ridges). Typically they are between 1000 km and 2000 km wide and 2–3 km high, and they are the foci of considerable volcanic and earthquake activity.

The length of continental rifts varies considerably. The East African Rift is perhaps the best-documented example, and it runs from Afar in Ethiopia in the north to the Zambesi river in the south, a total distance of over 3000 km. However, the rift is not equally deep all along its length; there are deeper areas, often occupied by lakes, and shallower areas, often flanking lake basins. The alternation of shallow and deep areas along the rift reflects segmentation in the underlying structure. Rifts are cut into segments by cross-rift structures that delimit sections dominated by faulting on a particular margin and in a particular orientation. In adjacent segments the main border fault can be on opposite margins, have different orientations, or move laterally with regard to the rift axis. Where such changes occur, the basement rocks come closer to the surface and effectively isolate parts of the rift, ponding water to form lakes. The cross-rift structures in recent rifts may be sufficiently prominent to be seen from space (**Figure 4**), and the string of lakes that results is clearly seen in the African rift (**Figure 5**).

Origin

Although it is generally accepted that rifts form where the crust is stretched as a result of tension, the plate-tectonic setting of rifts is very variable. Rifts can be associated with all three plate-margin types (constructive, destructive, and conservative) and are also found within otherwise-stable plates. There is therefore no single underlying mechanism of formation that can explain all rifts, and hence, the ways in which a rift develops and evolves are very variable. Whatever the mechanism, all rifts are situated in areas where the crust has been stretched and has thinned, much like the thinning that occurs in warm wax when it is pulled apart. As the crust thins, hot low-density mantle material is pulled upwards towards the surface, resulting in relatively high heat flows in the rocks around most rifts. In some rifts the heating of the crust is linked with the development of major domes, which cover vast areas, and with major volcanic outpourings. A good example of areas of doming linked with volcanism can be seen in the East African Rift, where there are two domes, each over 1000 km in diameter.

Volcanic activity can commence at an early stage of rift development and can be extensive; for example, in East Africa an area of over 500 000 km^2 is covered with rift-based volcanic rocks, and many of the most notable peaks of the area are, in fact, active or dormant volcanoes, e.g. Kilimanjaro. The rock types that spill out of the volcanoes are very varied and range from basic to acidic in nature. They also include some rocks that are rarely found outside rifts, such as carbonatites (*see* **Igneous Rocks:** Carbonatites), which

contain high levels of various salts that can be dissolved and swept into lakes, making them saline.

The Impact of Rifting on Hydrology, Climate, and Ecology

The development of a rift has a major impact on the overall environment. Continental rifts are often formed in major landmasses that are crossed by large rivers that have spent millions of years wearing down the surface. Rifting produces new topography to which the surface processes adapt, and the consequences of rifting can include the disruption of weather patterns, the diversion of rivers, and the formation of new lakes.

The uplift that occurs along the rift margins will decrease the ambient temperature and can increase rainfall. In contrast, the rift-valley floor remains warmer and can experience a rain-shadow effect since rain forms where clouds are forced to rise, and this occurs preferentially on the higher topographical areas of the flanks. As a result there are often different types of vegetation on the flanks and in the valley bottom. This can include the development of rainforest if the rift is in the tropics. Both the topography and the contrast in habitats across the rift valley can act as barriers to the migration of animals and, to a lesser extent, the spread of plant species. Where a rift forms in a previously undivided continent it produces new diversity of habitat and isolates individuals, both of which can boost evolution. This is one of the reasons

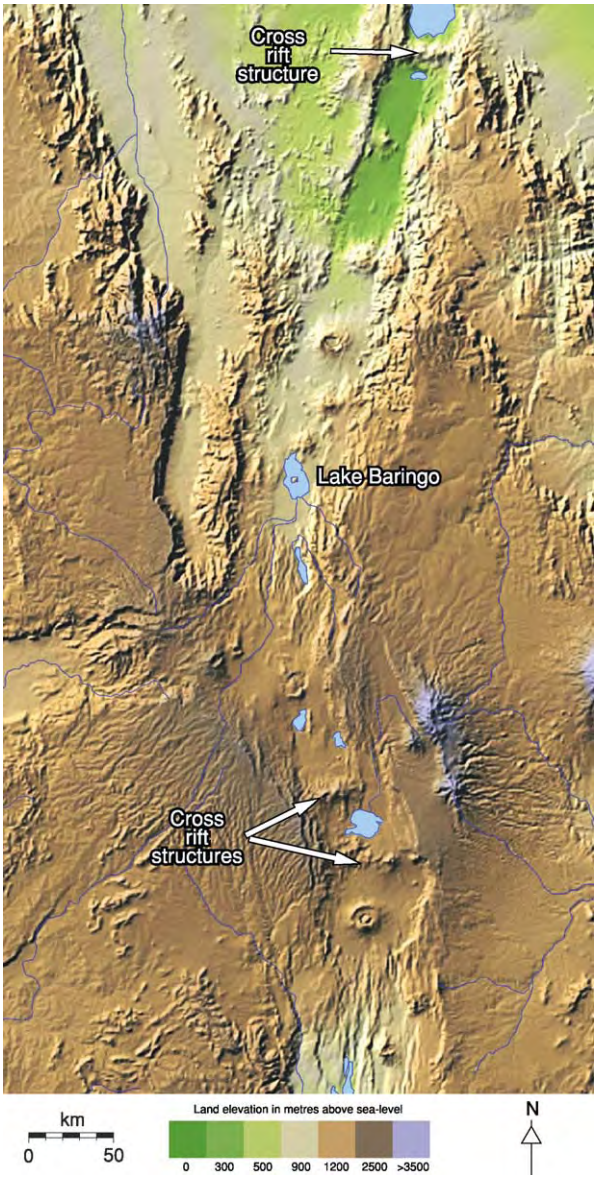

Figure 4 Cross rift structures seen clearly in this satellite image of the East African Rift. This is a shaded relief map produced from SRTM30 data with colour added to indicate land elevations.

Figure 5 Satellite remote sensing image of the northern Kenyan Ethiopian section of the East African Rift showing a string of separate lakes. Image taken by the TERRA satellite using the MODIS instrument (moderate resolution imaging spectroradiometer) and enhanced with SRTM30 shaded relief.

why many early hominid remains have been located in rift sediments. Of particular importance in this regard are the deposits in the East African Rift, which have been excavated and studied by many palaeoanthropologists, including successive members of the Kenyan Leakey family.

The development of the new topographical features of a rift will disrupt pre-existing continental drainage patterns and result in a very different landscape. Before rifting the topography is often subdued, with a very small number of large and ancient rivers draining towards the continental margin. The impact of rifting on the rivers will depend on their orientation. If the new rift parallels existing rivers, it can capture most or all of them, but if it cuts across the general trend of the drainage, streams can be beheaded, diverted, or even reversed. Domed sections of rifts are particularly effective at diverting rivers. The effect is similar to that of piling up soil into a heap so that water falling onto it is shed in all directions, giving rise to a radial pattern of channels.

Active faults form steps in the landscape, which can also affect rivers. Where there is more than one parallel fault, rivers can be caught between the two steps and flow parallel to the rift axis for many hundreds of miles. Margin uplift and tilting of fault blocks both tend to divert rivers away from rift basins. Drainage that has been affected in this way is often captured by continental river systems; for example, the Nile was augmented by the waters of rivers that were diverted away from the Red Sea and Gulf of Aden rifts. In some rifts cross-rift structures form topographical barriers that pond up drainage systems to form lakes. Good examples of this aspect of rifts are Lakes Baikal and Magadi in the Baikal and East African Rifts, respectively (Figure 5). In some rifts

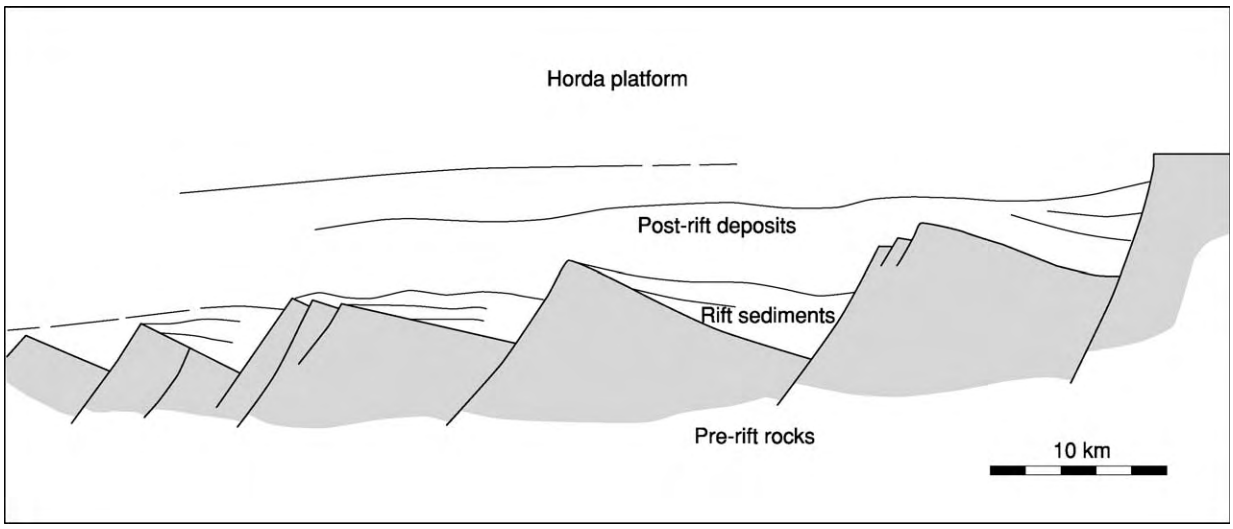

Figure 6 Diagrammatic cross section of the rift and post rift sedimentary fills of the Horda platform in the Norwegian North Sea. Note the tilting of the lower deposits, labelled 'rift sediments', which were emplaced during the period of active rift faulting. Adapted from Steel R and Ryseth A (1990) The Triassic Early Jurassic succession in the northern North Sea: megasequence stratigraphy and intra Triassic tectonics. there are no large lakes, and in these there is often a large river that drains the length of the valley, for example in the Rhine and Rio Grande Rifts. Fault scarps are rarely crossed by large rivers, but small streams flow down the step created by the fault, cutting small steep valleys and depositing sediment in alluvial fans at the base of the slope.

Rifts as Sedimentary Basins

In an active rift the floor of the basin can continue to subside for millions of years. Throughout that time, sediments will be swept into the basin to fill the hole being created and will build up into a sequence of deposits with common characteristics that make it possible to identify a rift basin long after the surface expression has disappeared. The main characteristics are wedge-shaped deposits thickening towards the main border fault and river or lake deposits in the deepest part of the basin flanked by alluvial-fan and river deposits on either side. As subsidence is often asymmetrical, lower layers become progressively tilted relative to the surface (Figure 6) as whole sequences of sediment wedges are superimposed on each other. If subsidence ceases, the structure will eventually lose its topographical expression and the basin will stop accumulating sediments. Rifts can remain active for very long periods of time and will therefore accumulate many

Figure 7 Satellite image of the salt pans at the southern end of the Dead Sea. The very saline waters of this lake are directed into shallow pans and evaporated to extract salts rich in bromine. This is a LANDSAT 7 ETM image using bands 3, 2, and 1 for red, green, and blue colour channels.

kilometres of sediment. Good examples of ancient buried rifts are the Reconcavo basin in Brazil, the Jeanne d'Arc basin off the coast of Newfoundland, and the Triassic Richmond and Taylorsville basins of eastern Virginia, USA.

Economic Deposits in Rifts

The sedimentary sequences that fill rifts can host a range of economic deposits, which are exploited around the world. Of these, the most significant are oil and gas; for example the Jurassic basins of the North Sea between the UK and Norway and the Tertiary basins of the Red Sea are rifts that contain appreciable reserves of oil and gas (Figure 2). The oil is derived from organic-rich fine sediments that accumulated in the deeper quieter part of the basin and which, when buried and heated, migrated into adjacent deposits and filled the pore spaces. Salts that accumulate in both marine and nonmarine rifts have a long history of exploitation; for example, the bromine-rich salts of the Dead Sea Rift (Figure 7) have been extracted since the Bronze Age – a period of more than 4000 years. The processes of rock erosion and sediment deposition can lead to the enrichment of parts of the new rift deposit with heavy minerals such as metals and gemstones, and the sediments themselves can be an extractable resource, particularly if the rift is close to areas of human population where there is a demand for sands and gravels as building materials.

Perhaps the most significant property of rifts is the spectacular scenery associated with them, which attracts tourists and is economically significant. One good example of this is Death Valley in the USA (Figure 8), which is in an area of low rainfall and as such has sparse vegetation, allowing the structure to be seen very clearly even by non-geologists.

Figure 8 Satellite image of Death Valley, USA, showing clearly the fault scarps and surface deposits. This is a LANDSAT 5 TM image using bands 3, 2, and 1 for red, green, and blue colour channels.

TEKTITES

G J H McCall, Cirencester, Gloucester, UK

Introduction

Tektites, natural glass objects of unknown origin, were described in the tenth century in China and in the eighteenth century in Europe; Charles Darwin described one of these objects from Western Australia while on the Beagle, and four strewn fields were recognized by the twentieth century. An immense volume of work in the past 50 years, involving many state-of-the-art laboratory techniques, has conclusively shown that tektites are the product of a handful of the ~170 terrestrial large-scale events in the geological record. A number of similar events that produced analogous, but somewhat different, glass bodies are also recognized in the geological record, ranging back through the Pleistocene, Pliocene, Oligocene, Eocene, Cretaceous–Tertiary (K–T) boundary, Late Devonian, and possibly even the Archaean. The primary processes of formation of the splash forms of tektites (projection from the target site) and the secondary ablation process that produces flanged, glassy objects (on descent to the strewn field) are now well understood, but much is still unresolved concerning the processes at the target site and the manner of dispersion; the largest of the strewn fields represents a dispersion that covered one-tenth of Earth's surface with glassy objects.

Historical

For centuries, tektites were one of the mysteries of geology. Found in certain sediments of Cenozoic or Quaternary age or strewn on the surface of present-day salt lakes or sand dunes, restricted to four well-defined strewn fields of different geological ages, tektites were once the subject innumerable hypotheses, invoking such visitations as atmosphere-grazing or-skipping comets and lunar ejections. The late twentieth century saw the advent of the Space Age and intensified research showed conclusively that tektites are terrestrially sourced and are the product of immense-scale impact events. Further occurrences of related objects in rocks of Pleistocene, Pliocene, and Eocene ages, at the Cretaceous–Tertiary (K–T) time boundary, in the Late Devonian and possibly in the Precambrian, were recognized at the same time, and research on seafloor sediments in drill cores revealed microscopic tektites (microtektites) associated with three of the four originally defined strewn fields.

In Europe, Cro-Magnon man valued tektites 30 000 years ago, using the glass for ornaments. The Chinese recorded the occurrence of these objects in the *Record of Heterodoxy outside Nanling*, compiled in the tenth century. The objects found strewing fields in the Leizhou Peninsula were attributed to thunderstorms, being termed *Lei-gong-mo* or *Lei-gong-shih* (the 'ink stocks' or 'stools' of the 'thunder god') (**Figure 1A**). Tektites from the Austrian empire (the present-day Czech Republic) were described by Josef Mayer in 1788. Because of the glass industries there, a connection with prehistoric glass making was suspected. Charles Darwin was shown a tektite at Albany, Western Australia, in the 1830s and deemed it to be a volcanic 'bomb' (**Figure 1B**). In the 1930s, Alfred Lacroix described occurrences of these objects in Indochina and the Ivory Coast, and Henryk Stenzel described tektites from Texas.

Explanations advanced for the formation of tektites have included lightning strikes, volcanic eruption, prehistoric and historic glass manufacture, burning coal seams, and desiccation of silica gel masses. Extraterrestrial origin related to meteorites was advanced first by Charles Walcott in 1898 and Eduard Suess in 1900, and this was followed by a rash of extraterrestrial hypotheses (for example, oxidation of the tail of comets; plastic seepings from meteorites passing through the atmosphere; debris from an Earth-like celestial planet blanketed by sedimentary rocks; light-metal meteorites plunging into the atmosphere and producing glass; cometary flight skipping through Earth's atmosphere). Ejected material following lunar impacts became popular as a proposed source of tektites from 1940 up to the time of the Apollo XI landing and the Luna unmanned sample recovery mission, which together dealt a death blow to such provenance because of the data on the silica-poor nature of the lunar surface rocks. Spencer, in 1933, appears to have been the first scientist to come to the right answer – "some form of spallation of melts from impacts on the Earth". In 1962, Ross Taylor, in Australia, concluded from the isotopic evidence that the material of tektites came from Earth, and the immense volume of research carried out on tektites since the Apollo XI landing has confirmed this relationship; besides geochemical, mineralogical, and isotopic evidence, the Ivory Coast strewn field has been conclusively related to the Bosumtwi, Ghana, impact crater, and the Central European strewn field has been related to the Ries

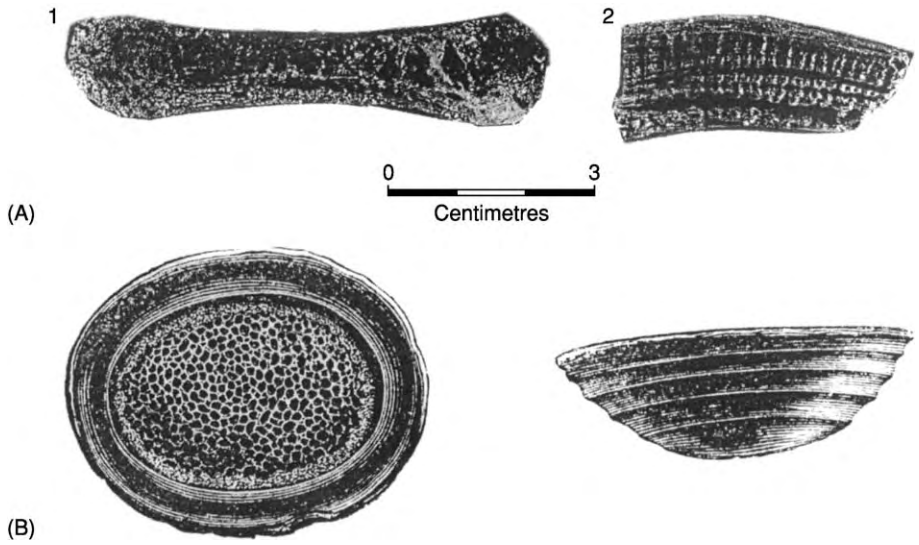

Figure 1 (A) Tektites from China, showing the (1) dumbbell shape (2) layered, Muong Nong type. impact structure in south-east Germany (though there remain some aspects of this relationship still difficult to explain).

Strewn Fields

There are four strewn fields, all of which are of Late Eocene age or younger. However, there are other occurrences of related glassy objects and two of anomalous natural glasses, both of which are not tektites by definition, but are almost certainly closely related to them. The four strewn fields are summarized in Table 1; their distribution is shown together with other related occurrences in Figure 2.

Tektites commonly display primary regularly shaped 'splash' forms characteristic of spinning masses of melt solidifying while travelling through the atmosphere following ejection (though some are irregularly shaped); they may also have superimposed on these forms secondary shapes that were the product of ablation during their descent through the atmosphere hundreds or thousands of kilometres away from the target area. They may then be further modified by terrestrial agencies after falling to Earth.

North American Strewn Field

In North America, tektites were first discovered in Grimes County, Texas, USA, where they occur in the Eocene Jackson Formation and overlying Pleistocene gravels: they were called 'bediasites', a name derived from the Bidai Indians of south-eastern Texas. Bediasites consist of black glass, commonly deeply etched (Figure 3A), and shapes include splash-form spheres, discs, teardrops, and peardrops. Secondary ablation shapes are extremely rare, but at least one example has been reported (Figure 3B). Tektites subsequently recovered from Dodge County, Georgia, are similar, and the single recovery from Martha's Vineyard is like these, rather than those from Texas. All specimens yield the same radiometric age (K/Ar, Ar/Ar, or fission track), dating to 34.9 Ma, consistent with their presence in Eocene sediments. Microtektites of the same radiometric and microfossil controlled age are known from a number of drill cores in the Caribbean, and both microtektites and tektite fragments have been found in Uppermost Eocene sediments on land in Barbados; microtektites of this age have also been found in a drill core from as distant a site as the Weddell Sea, Antarctica. The source of this strewn field is believed to be the 85-km-diameter Chesapeake Bay impact structure in Delaware, which is of the right age.

Central European Strewn Field

Tektites have long been known to occur in the Czech Republic, Austria, and near Dresden and Kottbus in Germany, where they are called 'moldavites'. Many are of a greenish, translucent tint, and these have been used as gemstones. They occur in Miocene sediments, consistent with their radiometric age dating to 15.1 Ma, but also are found in reworked Pleistocene gravels. They exist in a variety of splash forms (ovoids, discs, teardrops, and rods) and their surface is commonly rough (Figure 4). Again, secondary shapes due to ablation are extremely rare.

Table 1 Tektite distribution

Strewn field	*Area covered*	*Age (isotopically determined)*
North American (~4000 tektites recovered)	Texas, Georgia, Martha's Vineyard, Barbados (microtektites in the Caribbean and Weddell Sea)	34.9 ± 2.5 Ma (Eocene)
Central European (55 000 tektites recovered)	Czech Republic, Austria, Germany	15.1 ± 0.1 Ma (Miocene)
Ivory Coast (~200 tektites recovered)	Ivory Coast (microtektites offshore West Africa)	~1 Ma (Pleistocene)
Australasian (South east Asia, >600 000 tektites recovered; Australia, ~100 000 tektites recovered)	China, Indochina, Thailand, Malaysia, Philippines, Indonesia, Australia, Central Indian Ocean (microtektites over wide area of the Indian Ocean, China Seas, and around Australia)	0.77 0.78 Ma (Pleistocene)

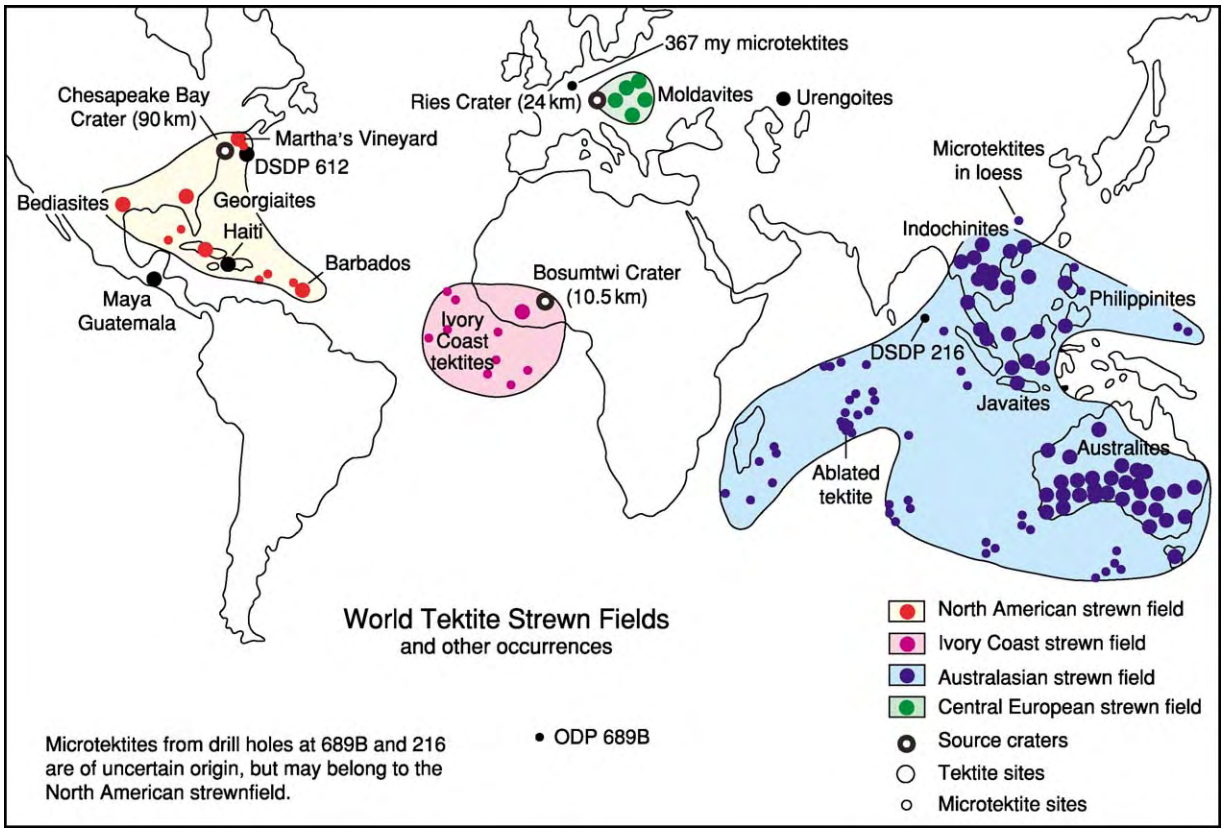

Figure 2 Strewn field distribution of tektites and sites of related occurrences. Deep Sea Drill ng Project (DSDP) and Ocean Drilling Program (ODP) sites are also indicated. Reproduced with permission from McCall GJH (2001) *Tektites in the Geological Record: Showers of Glass from the Sky*. Bath: Geological Society Publish ng House, and McNamara K and Bevan A (2001) *Tektites*. Perth: Western Australian Museum.

Microtektites are unknown in this strewn field. The source is believed to be the 24-km-diameter Ries impact structure in south-east Germany, which is of the correct radiometric and stratigraphic age, but there are some unsolved questions relating to how exactly they were expelled and what rock formation supplied the material to form the melt and subsequent glass.

Ivory Coast Strewn Field

A very small number of tektites have been recovered from an area to the west of the Camoe River, near Ouelle, in the Ivory Coast, West Africa. They occur in surficial alluvial deposits over Precambrian (Birrimian) rocks in a gold-mining area. They are of black pitted glass and several splash forms are

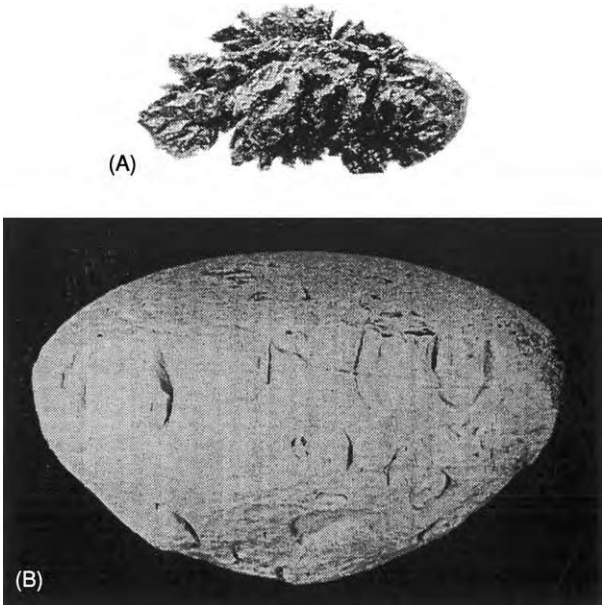

Figure 3 Two bediasites from Texas, USA. (A) Specimen deeply etched by terrestrial agencies. (B) Specimen showing secondary ablation (maximum dimension, 25 mm). recorded (discs, spheroids, teardrops, and peardrops) (Figure 5). Radiometric ages are ~1 million years. An extensive area of the Atlantic Ocean off the coast of West Africa has yielded numerous microtektites in drill cores, and these occur close to the Jaramillo Magnetic Reversal dated at 0.97 Ma, consistent with the radiometric age of the tektites. This strewn field is attributed to the Bosumtwi Crater to the east, in Ghana, as the source impact structure, this being confirmed by radiometric dating, geochemistry, and isotopic methods. Very sophisticated methods related to Os/Re isotopes have shown that the bulk of the osmium in the tektites is extraterrestrial.

Australasian Strewn Field

The Australasian strewn field covers one-tenth of Earth's surface. The northern part of the field includes China, Indochina, Thailand, Malaysia, the Philippines, Borneo, and Indonesia (especially Java, Belitung, and Flores), and the microtektites from marine cores adjacent to these territories are also included. Though several names exist for these tektites (e.g., indochinites, thailandites, javanites, billitonites, rizalites, and philippinites), radiometric dating yields the same age of formation (0.77–0.78 Ma) for all specimens; thus they all represent the same event and are best referred to as 'South-east Asian tektites'. They differ greatly in physical form over the geographical

range in which they are found; these differences are explained by climatic influences and the projected swathe of their descent to Earth. For example, the moist climate in the north part of the strewn field can be correlated with much more pitted, etched, and grooved surfaces, and the comparative lack of secondary ablation forms of northern specimens can be contrasted with specimens from the (distal) south.

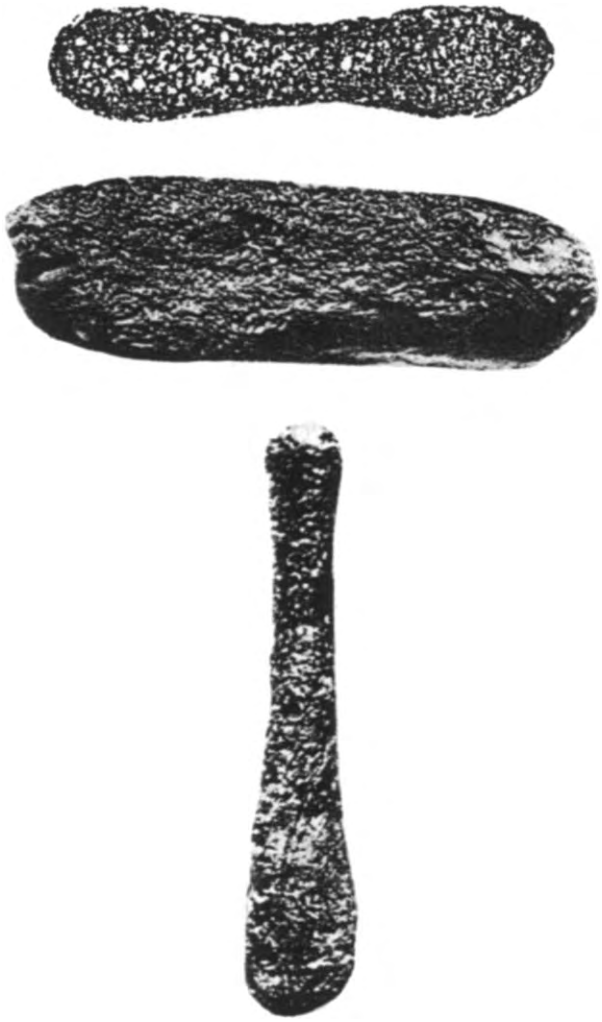

Figure 5 (Top) Dumbbell shaped tektite, 9 cm long, from the Ivory Coast; (middle and bottom) tektites from Indochina, showing the boat shape and teardrop form. Most specimens exhibit only splash-form shapes (spheres, ovoids. discs, dumbbells, boat shapes, teardrops, and peardrops). They typically occur in superficial deposit profiles and may be above or below laterite horizons.

Australasian strewn field tektites include the layered and irregularly shaped Muong Nong-type tektites, which were first identified in Laos. These may weigh up to 24 kg and they occur over hundreds, if not thousands, of kilometres, across the strewn field in Indonesia and Thailand (and possibly the Philippines), and the manner of their transport such distances from their source remains unexplained. These tektites also include suites of relict heavy and refractory minerals familiar in terrestrial sediments (quartz, corundum, monazite, rutile, zircon, chromite, andalusite, sillimanite, and kyanite). Lechatelierite and coesite are reported; the former is never found in volcanic glasses and the latter is a polymorph of quartz associated with high pressures in impact explosion processes, though it can occur in tectonic extreme pressure situations (*see* **Ultra High Pressure Metamorphism**). There are intermediate layered tektites in the Indochina collections, but these are splash-form shaped and are not irregular. Muong Nong-type tektites are of rare occurrence in the North American and Central European strewn fields; are not represented at all in the Ivory Coast strewn field or in the southern Australian part of the Australasian strewn field. Immense numbers of tektites may be recovered from a single site in Indochina, and several hundred thousand are reported from Da Lat alone.

The southern part of the Australasian strewn field covers the Australian continent. The tektites here show all the well-known splash forms, but ablated forms of these, particularly perfectly flanged buttons of relatively smooth black glass, are not uncommon (**Figure 6A**), though the flanges break off easily, leaving chatter-marked collars where the flanges have separated (**Figures 6B** and **12**), thus producing the most common form ('cores'). Dumbbells, boat shapes, and teardrops may also show ablation flanges (**Figure 7**). Some australites have ablated away so much of the body of the splash form that they are preserved as flat discs (**Figure 8**). Radiometric dating yields the same age as for South-east Asian tektites (0.77–0.78 Ma), and the specimens represent the same event. It has been claimed, based on stratigraphic evidence, that many Australian tektites fell to Earth very much later than this, and that an 'age paradox' is at work, but this is now refuted (though radiometric dating does indicate that there is a small cluster of older ~10-million-year-old Na-rich tektites near the Western Australia/South Australia border). A feature of the Australasian subfield is that large splash forms cluster around certain localities, an unexplained development. Australites are mainly found on the surface of salt-pan lakes in Western Australia, where they are washed in; they are also found in diamondiferous deposits in the north of Western Australia, on and between sand dunes in South Australia, and in Quaternary sediments in Victoria.

Microtektites were first discovered in the seas off the coasts of South-east Asia and Australia. Their stratigraphic and radiometric ages are consistent with being part of the strewn field. Some contain coesite and stishovite, both of which are high-pressure polymorphs of quartz associated with impact explosion processes; stishovite is found only associated with these types of processes. A single tektite has been

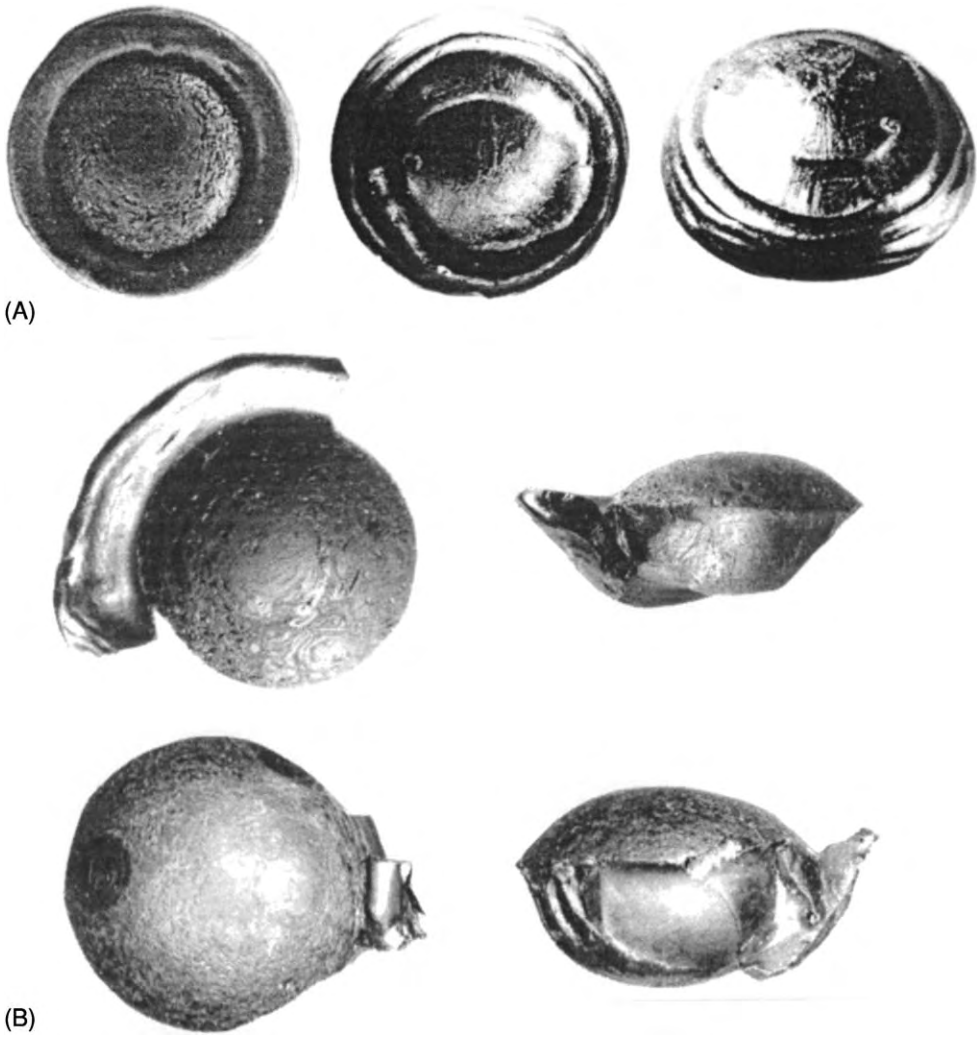

Figure 6 Australites from the Finke River, Central Australia. (A) Three views of a perfect flanged button, showing a posterior surface in flight and two anterior surfaces with ring waves produced by ablation (maximum dimension, 20 mm). (B) Four views of australites with flanges partly preserved as they separated from the remnant 'core' (maximum dimension, 17.5 mm). recovered from a grab sample in the middle of the Indian Ocean (Figure 9) and is attributed to the same event leading to the other Australasian strewn field tektites. Microtektites have been recovered from cores all the way across the Indian Ocean, to sites not distant from Madagascar.

The source of the Australasian tektites remains a complete mystery. Tonle Sap Lake in Cambodia was investigated as a possible impact site, but no evidence was found of impact there. Studies of progressive changes in populations of microtektites and delineation of the restricted area of occurrence of coesite and stishovite content suggest a source in Indochina, in Cambodia, not far from Tonle Sap. The whole character of the strewn field suggests that China and Indochina are proximal to the source, and Australia is distal. It is inexplicable that the source structure, of such a geologically young age, and presumably larger than the 85-km-diameter Chesapeake Bay structure, in view of the strewn field dimensions, is not preserved to some extent. This has led to suggestions that the Australasian tektites derived from an explosive event in the atmosphere, as has been widely accepted for the Tunguska event in Siberia in 1908.

Microtektites

These microscopic glass bodies are seldom larger than 1 mm in diameter. They display the familiar splash forms in miniature (mostly spheres, but also

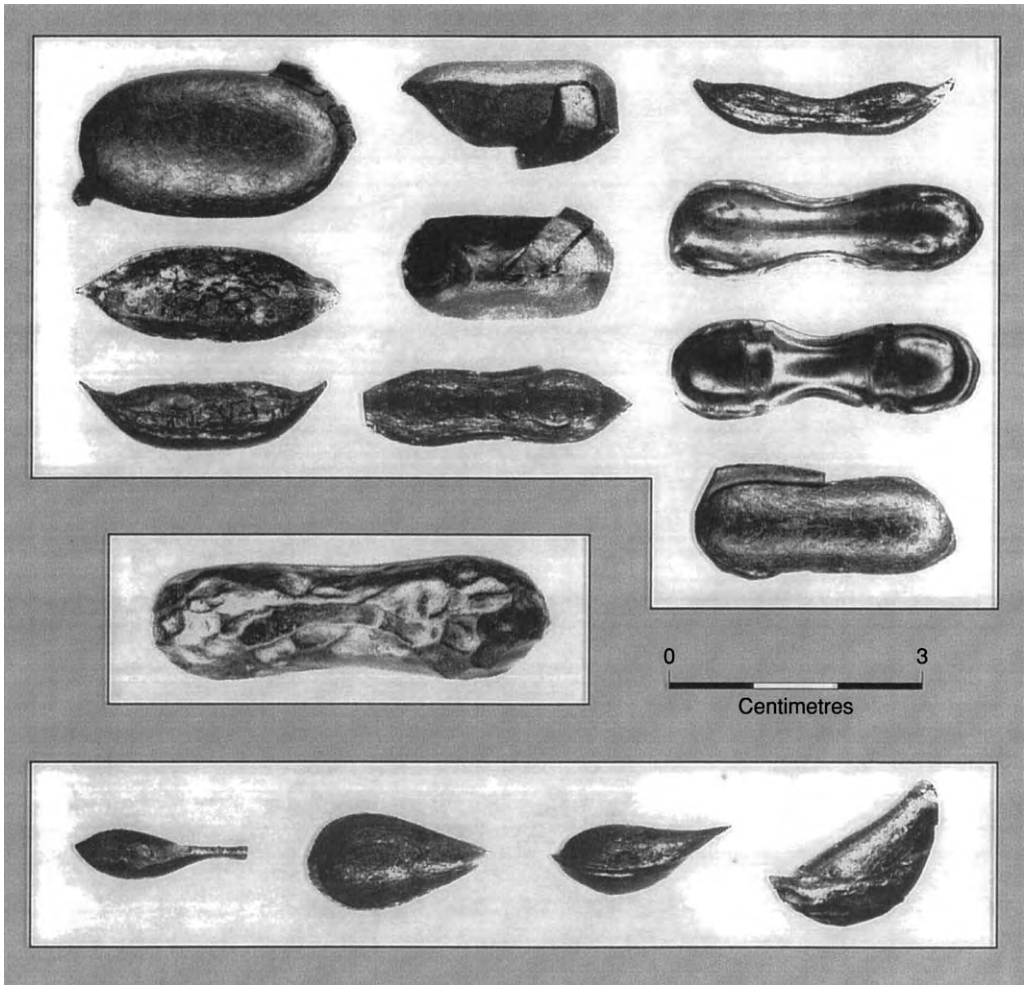

Figure 7 Boat shaped, dumbbell, and teardrop australites from Menangina and Gindalbie Sheep Stations, Western Australia, showing flanges in various stages of detachment from the 'cores'. dumbbells, teardrops, peardrops, and irregular forms) (Figure 10A–C). They occur in deep-sea cores, but the horizons are commonly not entirely sharply defined because of the action of seafloor scavengers. Microtektites do not normally occur in soils on land, because, even in the time-span in which the australites have littered Australia (from 0.77 to 0.78 Ma) on land, the action of groundwater would have dissolved them. The one known occurrence on land is in Eocene sediments in Barbados.

Tektite Composition, Experimental Data, and Theoretical Considerations

Tektites are silica-rich glasses, ranging from an average of 68% (Ivory Coast) to 80% (North American, georgiaites) silica. Refractive indices range from 1.48 to 1.51 and specific gravities from 2.3 to 2.5. Each strewn field has its peculiar range of values. The whole-rock analyses have a different character, as compared to volcanic glasses, and the glass is almost anhydrous, in contrast to the values for volcanic glasses. Microtektites show greater compositional variation than do the tektites found on land because they have a much smaller volume and can be formed of anomalous fractions of the glass, whereas the larger tektites average out. Lechatelierite, coesite, and stishovite are commonly present in tektites and microtektites, whereas they are unknown in volcanic glasses.

Wind-tunnel experiments in 1963 on tektite glass and gelatine by Chapman and Larsen in the United States reproduced exactly the flanged button form of ablated australite tektite found in Australia, and left no doubt concerning the mode of origin of the australites (Figures 11 and 12). Theorizing on the origin of tektites in 1998, H Jay Melosh concluded that

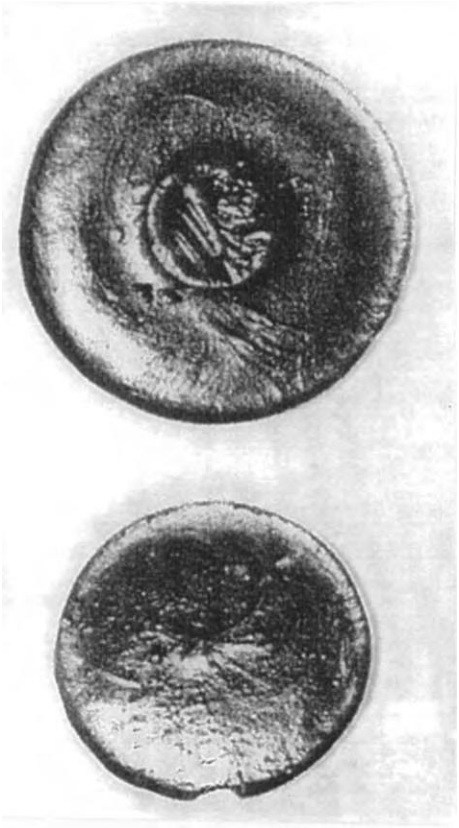

Figure 8 Ablated spherical australites that have lost all but a small relic of the splash form sphere, due to flowage of melt on ablation to the enlarged flange. This type of tektite is found only at Port Campbell, Victoria at the extreme distal end of the strewn field. Photograph by G Baker; reproduced with permission from McCall GJH (2001) *Tektites in the Geological Record: Showers of Glass from the Sky*. Bath: Geological Society Publishing House.

immense shock pressures of 100 GPa occurred during impact explosion processes accompanied by temperatures of up to 50 000 K. Thus arguments related to requirements for high temperatures in glass technology, which have been advanced to refute terrestrial impact generation of tektites, are invalid, because the temperatures involved in impact processes are many orders greater than had been thought.

Related Occurrences

Libyan Desert Glass and Mount Darwin Glass

Anomalous natural glass objects have been found in an area in the extreme south-west of Egypt. Irregular masses weighing up to 800 kg strew the desert in interdune corridors. These objects are highly siliceous, lechatelierite-bearing glass, quite unlike tektites in that they contain 98.2% silica. They seem to be ejected impactites formed of Nubian Sandstone, thrown out

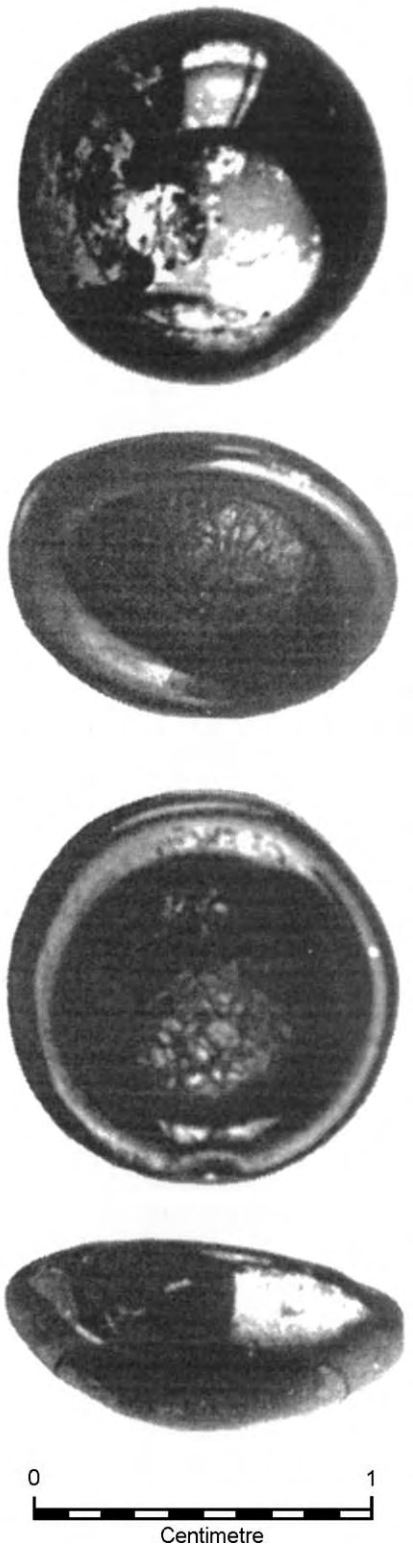

Figure 9 An ablated discoidal tektite with a weakly developed flange from a grab sample in the Central Indian Ocean. Figure 10 (A C) Microtektites and (D) microcrystite (clinopyroxene microspherule), all from Deep Sea Drilling Project 689, Maud Rise, Weddell Sea. The microtektites are equated with the North American strewn field and the microcrystite is equated with the Popigai impact structure, northern Siberia. Reproduced with permission from Glass BP and Koeberl C (1999) Ocean Drilling Project Hole 689B spherules and Upper Eocene microtektite and clinopyroxene bearing spherule strewn fields. *Science* 34: 197 208.

during the Oligocene 29 million years ago from two small craters (named BP and Oasis) that are situated about 100 km to the west. A minute fragment of an iron meteorite has been found with these glass objects. The glass was used to make Acheulian scrapers.

Mount Darwin Glass

Irregular masses of anomalous glass have found on the surface in western Tasmania and near Mt Macedon in Victoria. The glass mass is layered, not unlike Muong Nong-type tektites, but the silica content is much higher (88%, compared to 73%). Radiometric dating indicates formation 0.73 Ma, but the occurrence of these masses clearly has nothing to do with australites. A 1000-m-diameter crater has been recognized close to the occurrences of these glass objects in Tasmania, but there is no evidence of impact on excavation, though this site may be the source of the glass. The similar glass found at Mt Macedon, across the Bass Strait, 560 km to the north, is unexplained.

Zhamanshinites and Irghizites

Slags and glasses have been reported from the 13.5-km Zhamanshin impact structure in Kazakhstan, north of the Aral Sea (see Figure 2), overlying Palaeogene country rock. The best radiometric age derived dates these objects to 1.09 Ma. Zhamanshinites contain rock fragments and are impactite glasses. Irghizites occur within the bounds of the crater structure, not in an external strewn field, and are composed of small 'micro-irghizite' particles, welded together. The silica content of the irghizites is 72–79%, not unlike that of tektites, but the water content is slightly higher. The interest in these objects is that they may represent the separation of microtektites at source.

Urengoites

Three fragments of tektite-like glass have been found buried in Siberia at two sites 40 km apart (see Figure 2); based on radiometric dating, these urengoites were formed at 22–24 Ma.

The Eltanin Glasses

The 25-km-wide Pliocene Eltanin structure on the floor of the southern Pacific Ocean (see Figure 2) has both associated minute fragments of a mesosiderite (stony iron) meteorite and microscopic glass spherules; these objects have been recovered in piston

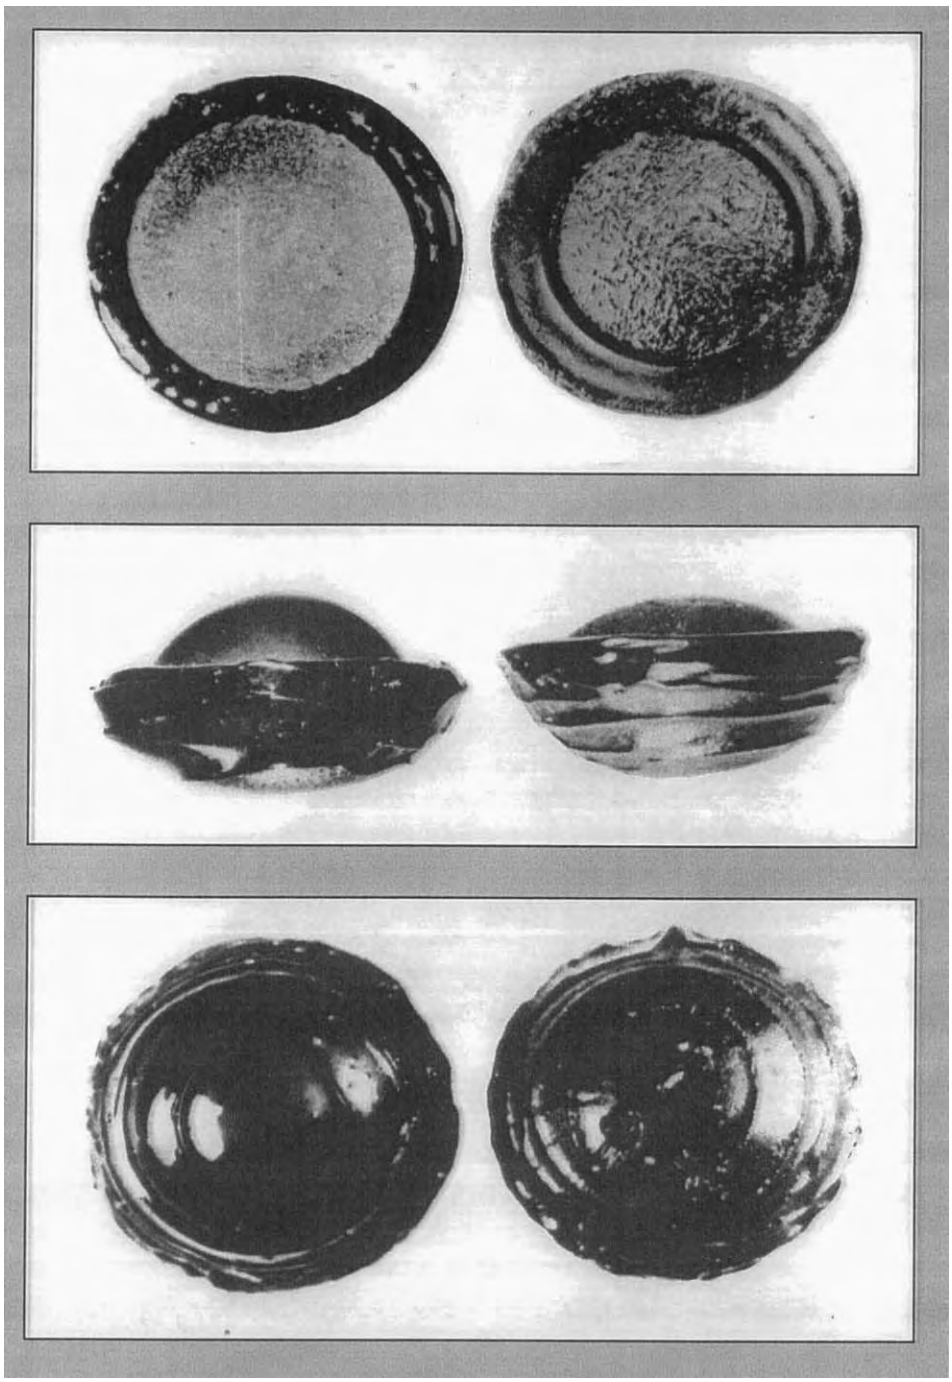

Figure 11 Comparison between a flanged australite from Port Campbell, Victoria (right) and an artificial product of a wind tunnel experiment (left) by DR Chapman and HK Larsen on tektite glass (NASA photograph, 1963). cores close to the impact melt layer associated with a chaotic formation within the structure. The forms resemble microtektites in size and shape (spheres, teardrops), but the chemistry is quite different (silica average, 45%).

Late Eocene Microspherules

A microspherule layer has been recognized just below the North American microtektite layer in Caribbean cores and in the Weddell Sea core. These

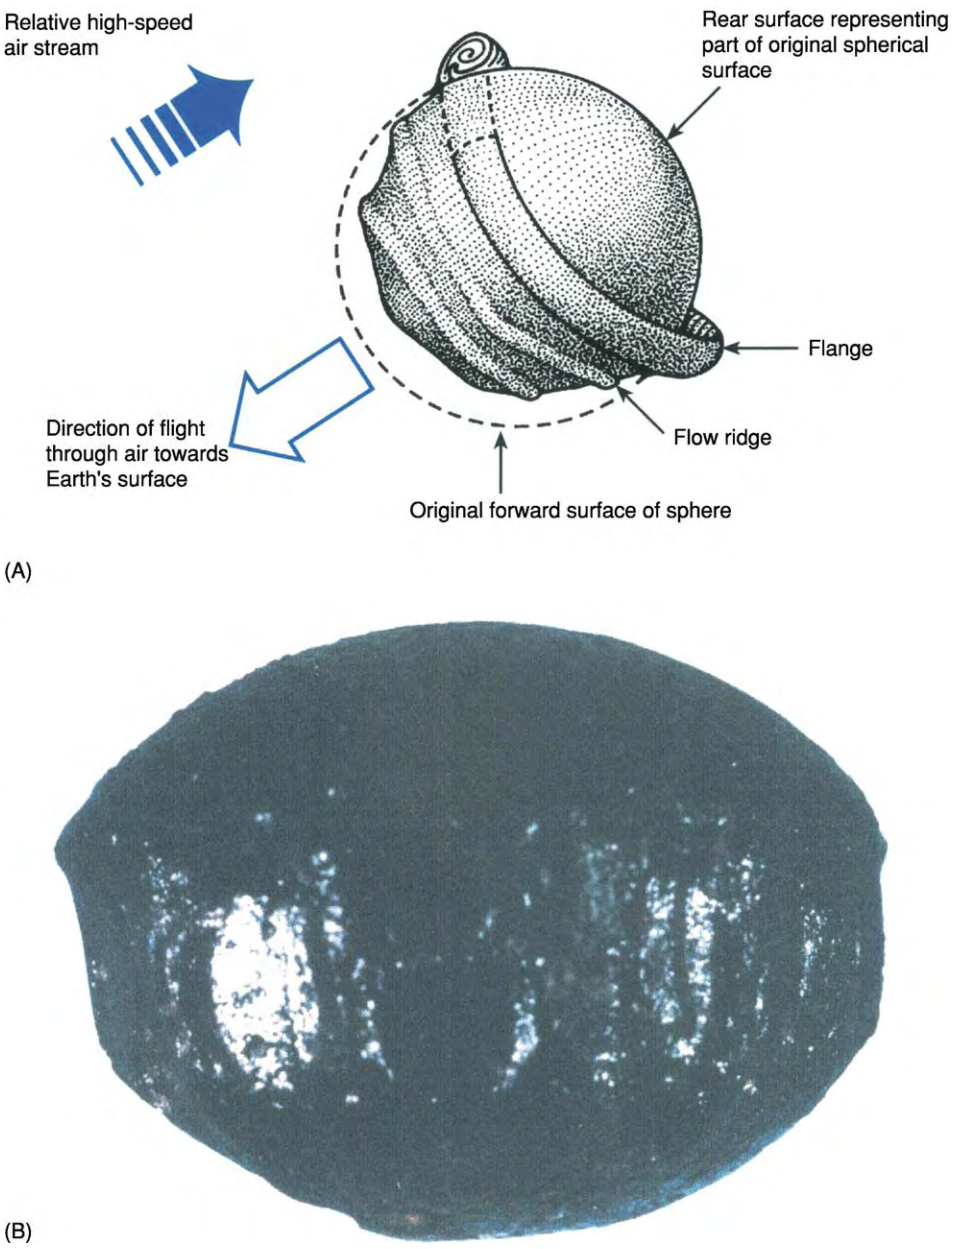

Figure 12 (A) Development of a spherical splash form australite during atmospheric ablation on descent. (B) The common 'core' form produced on separation of the flange, showing equatorial chatter marks where it has separated. spherules differ from the Eltanin glasses in that they show a palimpsest of microcrysts, as well as glass (Figure 10D), and the chemical composition is much more varied. The mineral in the microcrysts is sometimes preserved and X-ray diffraction has shown it to be pyroxene. This layer has been equated with the Popigai impact structure in North Russia and the impact layer reported from Massignano, Italy, and other European sites. The average silica content of 64% is lower than in any tektites and matches closely the Popigai impactite glasses.

K–T Boundary Glass Bodies

Carbonate sediments at the K–T boundary in Haiti (see Figure 2) contain tektite-like bodies of glass enveloped in smectite; the glass objects have the usual splash forms (spheres, ellipsoids, teardrops, and elongate and dumbbell shapes). The glass is vesicular and mostly crystal free. Similar bodies are reported from clastic sediments at Beloc, Mexico (Figure 2), where foraminifera indicate the K–T boundary (*see* **Mesozoic:** End Cretaceous Extinctions). Spheres and

dumbbells are represented. In both cases, removal of smectite coating reveals the sculpturing seen on the surface of microtektites. Compositions are very different compared to those of tektites or microtektites: silica contents are about 63%, similar to melt rocks of andesitic composition revealed at the favoured source impact site, the 170-km-diameter Chicxulub Crater impact structure on land and offshore of Yucatan, Mexico. The contrast to the tektite composition is consistent with the country rock makeup at Chicxulub, and these glass bodies, though not fitting strictly the common definition of tektites, are clearly a form of tektite *sensu lato*. Microspherules are reported from the K–T boundary at Petruccio, Italy, and there are many examples of shocked quartz with planar structures at the same boundary in the United States (*see* **Impact Structures**).

Late Devonian Glass Bodies

Microspherules have been reported from the Senzeilles Shale, Belgium, a quiet-water deposit of Late Devonian age and very close above the Frasnian–Famennian stage boundary, the site of another, smaller scale extinction. The horizon is at the top of the *Palmatolepis triangularis* conodont zone, at the bottom of which is the extinction boundary. The spherules, up to 1 mm in diameter, are wholly of glass; they have been preserved from devitrification perhaps because of the anhydrous nature of the glass. Most of the bodies are spheres, but elongate, teardrop, and dumbbell shapes are present. The silica content varies from 38 to 80% and the chemical composition is variable. There are several possible source impact structures, though the Siljan, Sweden, 55-km structure is favoured.

Similar spherules occur at Qidong in Hunan Province, South China, in the *Palmatolepsis crepida* conodont zone of the Famennian. They reach up to 0.160 mm in diameter and are mostly spheres, though teardrop and peardrop forms are recorded. Lechatelierite is present in them. The chemistry is variable and the silica content ranges from 62 to 99%. They have been tentatively related to a possible impact structure at Taihu, south-west of Shanghai, but little is known of this structure. As for the Senzeilles Shale microspherules, these spherules do not correspond exactly to the extinction horizon.

Archaean Spherules

Microspherules in which no glass is preserved are known from the Wittenoom Formation in Western Australia (dating to 2500–2600 Ma) and also from rocks of the Onverwacht and Fig Tree Groups (3100–3500 Ma) near Barberton, South Africa. These microspherules have been attributed to impact processes and are related to microtektites.

Research Directions

Many state-of-the art techniques have been applied to studies of tektites, resolving many of the early questions about these objects. Geochemical, geophysical, isotopic, and statistical analyses that have been applied to tektites in the past 50 years have resolved questions concerning their source, the manner of formation of their primary and secondary flanged shapes, and the age of the four events forming the strewn fields in which they are found. The connection between tektites and microtektites has also been established. However, there are still questions that have not been fully resolved. Further research may reveal the process of melting at the target, and ejection from the target; the reason for the restricted nature of the target rocks involved in generating tektites; the reason for the restriction of tektite associations to a handful to the ~170 terrestrial megaimpact sites known; the exact relationship of tektites to microtektites in the processes occurring at the target, in flight, and during transport and dispersion to the strewn field; and the source of the Australasian strewn field.

TERRANES OVERVIEW

L R M Cocks, The Natural History Museum, London, UK

Introduction

The word 'terrane' is used in a specialised sense by geologists, and should not be confused with the same-sounding 'terrain', which is used by many people, particularly the military, to denote characteristics of the countryside in a particular area. To a geologist, terrane is used for a discrete block of continental crust that is moving or has moved in relation to those blocks that surround it.

Definition

The Earth is today, and through geological time, made up of a number of moving plates (*see* **Plate Tectonics**). Each plate consists of heavier oceanic crust underlying lighter continental crust. Plates are constantly being enlarged through ocean-floor spreading, reduced by subduction or obduction, or displaced laterally by transform faulting, all of which processes affect both oceanic and continental crusts. However, because of its lighter density, continental crust tends to remain at the Earth's surface for far longer periods than does oceanic crust; consequently, very often the continental crust of an old plate remains at the surface today long after the oceanic crust on which it once rested has disappeared within Earth's interior, perhaps to be later remobilized into fresh crust. The oldest ocean crust known today in its original position is only about 160 million years old (Jurassic), whereas the continental crust includes rocks from modern times to more than 3 billion years ago, the oldest known. Terranes can be of varied size, ranging today from the vast Eurasian–African block down to the relatively small microplates found in the south-west Pacific within the East Indies. The difference between a 'continent' (as strictly defined) and a 'terrane' is that the former is invariably bounded by one or more oceans, whereas the latter is defined by its surrounding structural discontinuities. An accreted terrane is one that has been added to the margin of a larger one. Many areas may or may not have been real (i.e., separate) terranes in the past, and geological opinions can often differ widely as to their reality and status. When this uncertainty exists, the area is referred to as a 'suspect terrane'.

Boundaries of Terranes

The marginal boundaries of old terranes are termed 'sutures': when exposed, they are usually faults or fault systems, with the obvious characteristic that the rocks and stratigraphy are completely different on the opposite sides of the faults. Because movement of the crust is principally dominated by horizontal components, the suture faults are usually strike-slip or transform. For example, a major suture is the Tornquist–Teisseyre Line, or the Trans-European Suture Zone (TESZ), which stretches from the North Sea to the east of Aberdeen, through southern Denmark, north-eastern Germany, south-central Poland, Slovakia, Hungary, and Romania to the Black Sea. That suture represents what remains of the south-eastern margin of the old terrane of Baltica and separates that terrane from Avalonia (see later), Perunica (often termed Bohemia), and others to its south. The suture was originally formed during the Variscan Orogeny in Late Palaeozoic time, but movements along the TESZ area of crustal weakness have been reactivated during several subsequent geological periods and continue sporadically to the present day.

Principal Terranes

At two recognizable times in Earth history, at about 1000 Ma and 250 Ma, most of the continental

crust was together, forming vast supercontinents named Rodinia (*see* **Precambrian:** Overview) and Pangaea (*see* **Pangaea**), respectively. Prior to the aggregation of Rodinia, little is known of the preceding terranes, and so they are characterised and named only by the major earlier Precambrian shield areas, such as the Canadian Shield, and their positions relative to each other are currently poorly constrained and open to much scientific debate. However, after the breakup of Rodinia, which was well under away by 850 Ma, larger terranes have separate names, and the principal terranes were identified as follows:

- Gondwana. Easily the largest terrane (*see* **Gondwanaland and Gondwana**), comprising South America, Africa, India, Antarctica, and Australia, as well as a number of peripheral areas that formed parts of this huge terrane at different times.
- Siberia (otherwise known as Angara). An area that included only part of the modern political area of Siberia, but that was nevertheless very substantial.
- Laurentia. Most of North America and Greenland, and then adjacent areas, including Spitzbergen, northern Ireland, and Scotland. It was separated from Baltica and Gondwana by the Iapetus Ocean in the Lower Palaeozoic.
- Baltica. The northern part of mainland Europe eastward to the Ural Mountains and northward to include Novaya Zemlya and Franz Joseph Land in the Arctic. It was separated from Avalonia by the Tornquist Ocean and from Siberia by the Aegir Sea during the Lower Palaeozoic.
- Avalonia. An area including the western coast of the United States, the Maritime Provinces of Canada, Newfoundland, southern Ireland, Wales, England, and Belgium, which formed part of Gondwana until the Early Ordovician (about 490 Ma). It was a separate terrane only in the Ordovician. As Avalonia left Gondwana, the widening ocean between it and Gondwana is termed the Rheic Ocean.
- Laurussia. The terrane formed by the amalgamation of Laurentia, Baltica, and Avalonia during the Silurian, and which continued until the formation of Pangaea in the Late Palaeozoic. During the Upper Palaeozoic, Armorica, Perunica, the Rheno-Hercynian Terrane, and others drifted across the Rheic Ocean to become accreted to Laurussia, leaving a widening Neotethys Ocean behind them.
- Armorica-Iberia. This is sometimes termed the Armorican Terrane Assemblage (ATA); it consists of most of the western part of southern Europe, including Spain, Portugal, France, Sardinia, and parts of Germany. Some regard Perunica (Bohemia) as part of the ATA, but it moved independently of the ATA after its separation from Gondwana in the Ordovician.
- North China. The southern part of Siberia and the Korean Peninsula as well as northern China.
- South China. Most of southern China.
- Annamia. The Indochina Peninsula and adjacent areas.
- Sibumasu. The area running from eastern Burma (Myanmar) through Thailand, south-western China, and western Malaysia to Sumatra.

In addition to these named terranes, more than 50 additional terranes of variable size have been identified and named as existing during the Palaeozoic, as well as numerous discrete geological entities such as island arcs, which were independent units for differing geological times. Some of the many terranes that make up Eurasia today are shown in **Figure 1**. After the mutual accretion of the various terranes during the Palaeozoic, progressively forming Pangaea during the Upper Palaeozoic, the process of splitting and disintegration of Pangaea began in the Early Mesozoic to form the larger terranes that are known by their modern continental names today. The large area eastward of Pangaea was occupied first by the Neotethys Ocean and subsequently by the Tethys Ocean. The Mediterranean Sea can be considered as a remnant of the Tethys Ocean today. However, there are in addition many much smaller terranes; for example, it has been suggested that there are as many as 100 Early Mesozoic terranes in the collage that makes up the present-day Cordillera of North America.

Identifying the Positions of Old Terranes

To reconstruct the geography of Earth at different times in the geological past, it is necessary to locate the former position of the different terranes, and to understand how each moved with time. The ways of doing this using current knowledge are through evidence of ocean-floor magnetic stripes, movement over hotspots, palaeomagnetism, faunal provinces, distribution of sediments, and positioning of tectonic belts.

Ocean-floor magnetic stripes are studied by mapping out the modern ocean floor and its magnetic anomaly stripes, dating the stripes, and then progressively removing them so that it can be seen how the oceans have widened with time (*see* **Palaeomagnetism**). Magnetic field reversals and related issues such as the age of onset, the duration, and the frequency of superchrons (long periods of constant magnetic polarity) are now reasonably documented to the beginning of the Cretaceous. This is the only objective

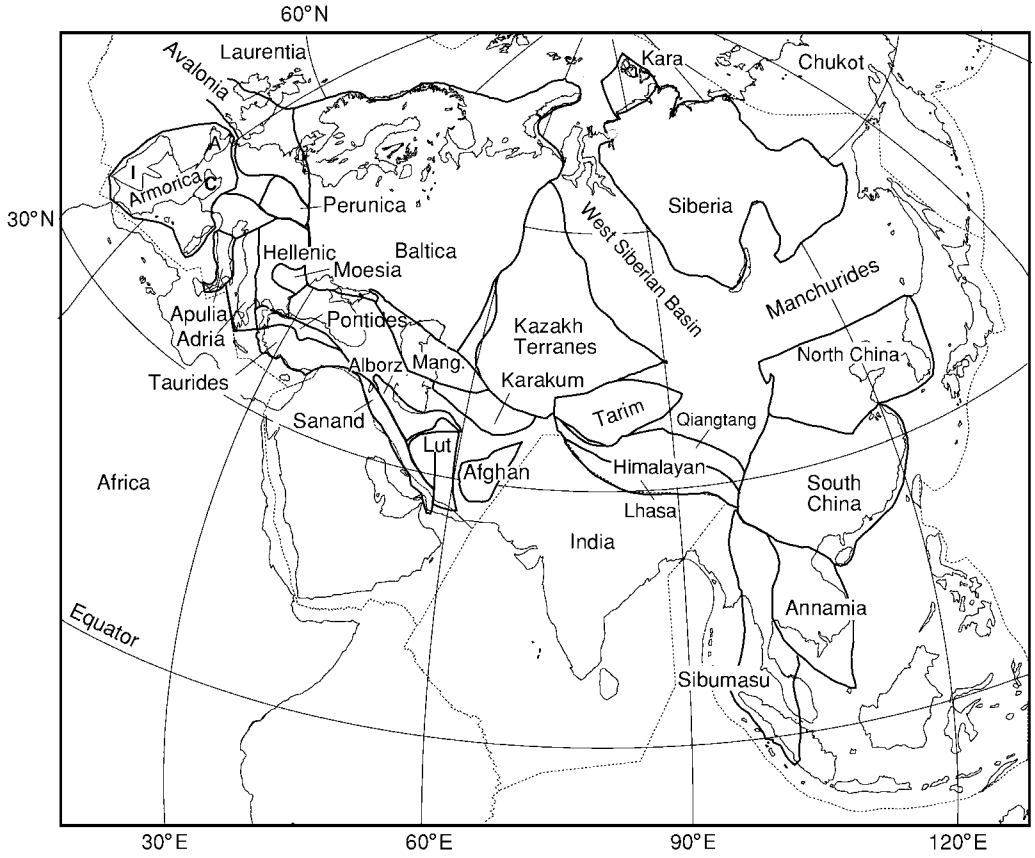

Figure 1 The boundaries of the major Palaeozoic terranes that have united to make up Eurasia today. C, Central France; I, Iberia; Mang., Mangyshlak Terrane. The large areas labelled West Siberian Basin and Manchurides are those occupied largely by continental crust that is post Palaeozoic in origin, as is the large area of south east Asia south eastwards of the Sibumasu and Annamia terranes. Thin dotted lines are modern plate boundaries. Modified by Trond Torsvik, Trondheim, from Torsvik and Cocks (2004).

method of discovering the previous position of terranes through time. Unfortunately, however, because the oldest ocean-floor crust known is of Jurassic age (and most of Earth's oceans floors are very much younger than that), this method is available only for determining terrane positioning in Tertiary and Late Mesozoic times.

Some terranes can be seen to have moved over hotspots with time, which thus gives progressive and definitive positioning of the terranes. This is unique in providing objective (as opposed to subjective) longitudinal control of terrane movement. Unfortunately, as with the plotting of the magnetic stripes, this method applies only to those few terranes that are drifting over active hotspots, and no consensus on results has been obtained for positions much older than the Tertiary. The only Mesozoic data are for the Tristan da Cunha and Great Meteor hotspots in the South Atlantic, which are traceable back to 130 Ma.

Palaeomagnetism occurs when an igneous rock is emplaced, then the magnetic (largely iron) constituents within it cool with their magnetic direction pointing towards the pole. This remnant magnetism is set after cooling, and so the study of an ancient igneous rock indicates the pole position at the time of deposition of the rock. Thus two things can be calculated: the palaeolatitude of the rock at the time of cooling and the subsequent rotation of the terrane. This is the best method of calculating the position of old terranes. There are, however, two drawbacks: first, there is no determination of the palaeolongitude of the terranes, and second, a great many igneous rocks have their original palaeomagnetism completely reset by subsequent tectonic events that involved enough heating to reset the magnetisation of the rock.

If the palaeoecology and the age of the fossils contained within an individual terrane are known, then some marine benthic or terrestrial fossils are found to be specific to one or more terranes, and quite different from those in other terranes that may be close to it today. These differences are often recognised as faunal provinces. The data from these fossil distributions provide terrane affiliations and positions that are reached completely independently of palaeomagnetic methods, and the two methods have

been used effectively together to discover where most of the terranes lay in Cambrian to Jurassic times. In addition, bioherms such as coral reefs are usually restricted to within 30° north and south of the equator, ancient or modern. Coals are most commonly found in two belts occurring in low temperate latitudes.

Distribution of sediments may be examined to locate the former position of the different terranes. Most clastic rocks give little indication of the climates within which they were deposited, but carbonates increase in abundance from high to low latitudes as the average surface temperature increases. Evaporites are seldom equatorial but are most common in two bands centring at about 20° north and south of the equator or palaeoequator. Glaciogenic sediments, such as tillites, are almost invariably found at high latitudes.

Positioning of tectonic belts may provide evidence of the position of old terranes. Some substantial mountain belts can be traced from one terrane to the adjoining one, but, in the past, several such correlations made by geologists have been shown to be incorrect. However, in the Precambrian, when there were no terrane-diagnostic fossils, mountain belts have proved to be the only indicators apart from palaeomagnetism.

In positioning old terranes, a key underlying precept must be kinematic continuity. This means that it must be remembered that terranes never leapt around the globe like sodium on water. Thus, if a certain terrane (for example, Baltica) appears to have been in one place, then 2000 km away 10 million years later, and then close to its original position 10 million years after that, it is probable that one or more of those postulated positions are not correct!

Ever since the acceptance of modern plate tectonic theory in the mid-1960s, geologists have realised that plates and their terranes have not been in a single position during geological time. Tuzo Wilson, in 1966, suggested that there was a substantially different terrane pattern and therefore geography before the supercontinent of Pangaea came together in the Late Palaeozoic. Since Wilson's observations,

Figure 2 The major terranes and Earth geography 400 Ma (the Early Devonian), assuming that Earth's magnetic field was a simple geocentric axial dipole. The dot dash line represents the margin of Gondwana. RH, Rheno Hercynian Terrane. Modified by Trond Torsvik, Trondheim, from Torsvik and Cocks (2004).

there have been many published models of where the various terranes lay through geological time. There is now considerable agreement on the identity, positions, and progression, through the Palaeozoic, of terranes surrounding what is today the North Atlantic area, around which the majority of academic geologists work. However, the many terranes that make up Central and South America, Africa, Asia, and Australasia are, in many cases, rather poorly defined and recognised, and their relative positioning through the Phanerozoic (let alone the Precambrian) is a matter for unresolved debate and geological argument. Figure 2 shows a possible terrane reconstruction for half the globe at about 400 Ma (the Early Devonian), at a time when Laurentia, Baltica, and Avalonia had fused to form Laurussia and when various terranes such as Armorica, Adria, the Pontides of Turkey, and the Hellenic Terrane (including Moesia) had all left the Gondwana superterrane following the opening of the Palaeotethys Ocean to their south. The other half of the globe, not shown in Figure 2, was largely occupied by the vast Panthalassic Ocean.

Paleocene

J J Hooker, The Natural History Museum, London, UK

Introduction

The Paleocene Epoch/Series is the first of the Cenozoic Era/Erathem. It is the first of five epochs in the Tertiary Period and the first of three in the Paleogene, which is treated either as a period in its own right or as a subdivision of the Tertiary. The Paleocene succeeds the Cretaceous Period/System and precedes the Eocene Epoch. The Paleocene lasted nearly 10 million years, from 65.5 till 55.8 Ma, and is divided approximately equally into three ages/stages (in order of decreasing age): the Danian, the Selandian, and the Thanetian (**Figure 1**). The naming of the Paleocene follows the earlier procedure of adding a prefix denoting degree of antiquity or modernity, in this case 'paleo', from the Greek *palaios*, meaning 'ancient', and 'cene', from the Greek *kainos*, meaning 'recent'. The Paleocene was the last of the Cenozoic epochs to be named, originally being proposed by Schimper in 1874. Schimper was a palaeobotanist and, in contrast to the definitions of the other Cenozoic epochs,

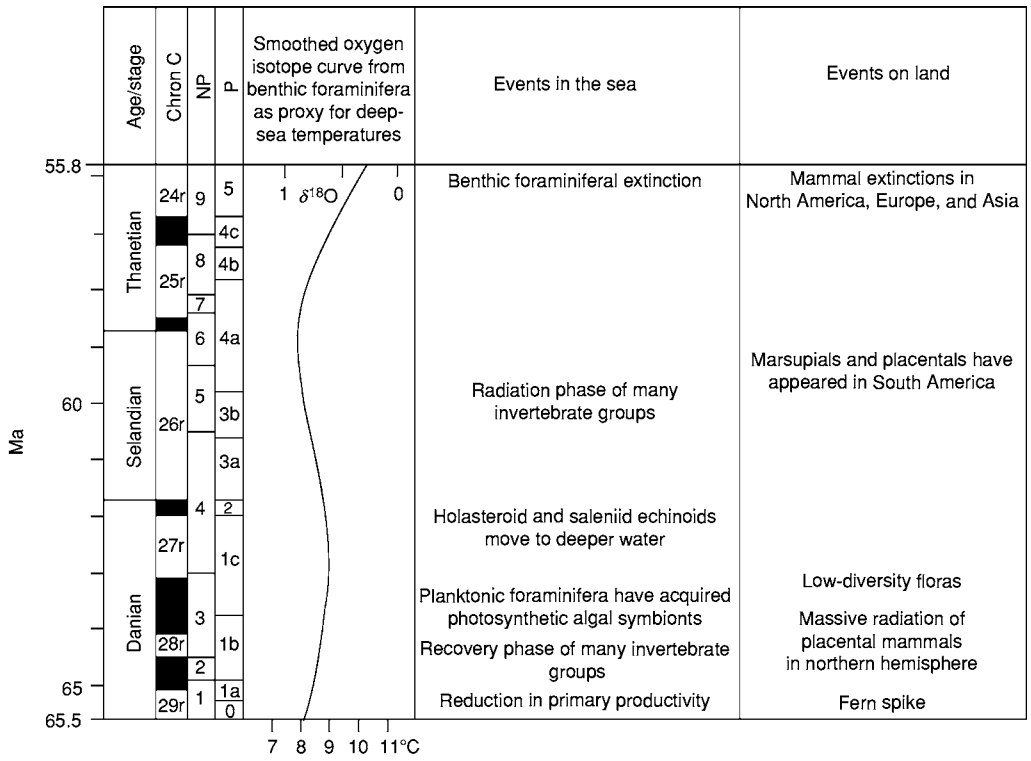

Figure 1 Time chart of the Paleocene, showing how it is divided up by ages/stages, magnetochrons (Chron C), global calcareous nannoplankton (NP), and planktonic foraminiferal (P) biozones. Also shown are an isotope proxied temperature curve and the main biotic and physical events in the sea and on land. Magnetochrons are divided into normal (black) and reversed (white) intervals; the normals, often composite, are younger than the reversals (r) that bear the same number. he based his concept of the Paleocene on floras. Thus, he noted the presence in the Paris Basin of distinctive assemblages of plants that occur in strata overlying the Cretaceous and underlying the Eocene.

Unfortunately, some of the strata Schimper regarded as Paleocene are now known to be contemporaneous with those he regarded as Eocene. Partly as a consequence of this confusion, the Paleocene nomenclature did not gain worldwide acceptance until nearly a century after Schimper's work. The Paleocene was largely ignored by marine workers, but since the early years of the twentieth century, it has been championed by vertebrate palaeontologists, especially in North America, where it was recognized to be characterized by highly distinctive faunas of land mammals (Figure 2). Over the decades, the concept of its time-span has changed considerably and has also meant different things to palaeontologists in different fields. In Schimper's time, the first Paleocene age/stage, the Danian, was regarded as latest Cretaceous, mainly because of the continuation in northwest Europe of the typically Cretaceous chalk facies (Figure 3). The Danian was moved into the Paleocene when it was realized that it postdated a major extinction event in the sea and on land, which is now taken to mark the end of the Cretaceous Period and indeed of the Mesozoic Era. The official Global Stratotype Section and Point (GSSP) for the beginning of the Paleocene is at El Kef, Tunisia. The end of the Paleocene was also the subject of much discussion until a decade ago, when a sharp anomaly in the carbon isotope curve, known as the carbon isotope excursion (CIE), was recognized in a borehole core from the Weddell Sea, Antarctica. This has been interpreted as a climatic warming event, known as the Paleocene–Eocene thermal maximum (PETM). The PETM had profound and widespread effects on marine benthos and land mammal faunas, and is now accepted to mark the boundary between the Paleocene and Eocene epochs.

Plate Tectonics and Other Physical Phenomena

In many ways, the Paleocene represents a continuation of processes begun in the Cretaceous. Thus, Pangaea continued to fragment. Falling sea-levels since the beginning of the Late Cretaceous appear to

Figure 2 Kutz Canyon area, San Juan Basin, New Mexico, USA., showing the thick sequence of non marine fluvial mudstones, spanning much of the Paleocene. This is the basin that originally yielded distinctive Paleocene mammal faunas.

Figure 3 Stevns Klint, Denmark, showing marine Danian chalk facies, with basal fish clay unit, resting on Maastrichtian (latest Cretaceous) chalk.

have reached a threshold in the Paleocene, draining the very extensive Late Cretaceous marine carbonate platforms and dramatically increasing the non-marine area of the globe. A phase of the North American Laramide Orogeny also took place during the epoch. This involved continued sliding of the Farallon Plate under the western margin of the North American continent to produce early phases of the Rocky Mountains uplift. As a result, the North American Western Interior Seaway, which in the Late Cretaceous had split the continent from north to south, almost completely filled with sediment shed from the rising Rocky Mountains. The remnant Paleocene elongate inlet that had only a southerly opening is known as the Cannonball Sea; and the series of basins that formed in the west of the area were non-marine. The marine area of the Gulf Coast and Florida continued to subside.

The Farallon Plate also continued to be subducted beneath the western margin of South America, resulting in early phases of the Andes uplift. North America and South America were slowly moving away from each other at this time, the intervening ocean allowing deep-water circulation between the Pacific and Atlantic. Subduction in the Pacific continued on the eastern side (Kula Plate) beneath Kamchatka and Sakhalin. A land bridge across the Bering Straits was also intermittently developed between North America and Asia in response to fluctuating sea-levels.

On the other side of the world, the Atlantic Basin was continuing to spread. This particularly involved an extension of rifting northwards between Labrador

and West Greenland and between East Greenland and Europe. A hotspot formed beneath Greenland, producing outpourings of lava that intensified at the end of the epoch as the East Greenland–Europe area drifted over the hotspot. Between Europe and Asia, the epicontinental West Siberian Sea, although more restricted than in either earlier or later times, extended southwards from the Arctic Ocean, reaching the northeastern part of the Tethys Ocean (known as the Peritethys) separating Asia from Europe near the end of the epoch.

Africa moved and rotated north, pushing Apulia (comprising Italy, the former Yugoslavia, and western Greece) towards the main European craton, and producing the initial phases of the Alpine Orogeny. Eastward extension of this structural belt through Asia Minor and southern Iran partially isolated the Peritethys. India was an island continent still moving north towards Asia. The massive outpourings of hotspot-related basaltic lava that occurred in the Deccan region of West India during the latest Cretaceous continued for a brief interval in the earliest Paleocene. The Aluk Plate in the South Pacific continued to be subducted beneath the western edge of the Antarctic Peninsula. Rifting occurred between Antarctica and Australasia, but the two continents did not separate. In fact, during the Paleocene, the three major elements of Gondwana (South America, Antarctica, and Australasia) remained in contact. At the opposite pole, the Arctic Ocean was, for most of the epoch, an enclosed water body, separated by land from the rest of the world's oceans.

Biota

After the End-Cretaceous extinctions (*see* **Mesozoic:** End Cretaceous Extinctions), the earliest Paleocene biota was notable for the absence of such major and formerly diverse groups as ammonites, belemnites, rudists, plesiosaurs, mosasaurs, and non-avian dinosaurs, as well as for the low abundance and diversity of brachiopods, bivalve and gastropod molluscs, and marine reptiles. There is generally low abundance and diversity of marine life at the beginning of the Paleocene. In fact, some groups (both in the sea and on land) show a low-diversity recovery phase followed by radiation. However, the pattern is different for other groups of organisms. Key biotic events are discussed below.

Marine Realm

Calcareous nannoplankton Few members of the calcareous nannoplankton, a group of microscopic calcifying algae (coccolithophores and their possible relatives), survived the end of the Cretaceous. Paleocene nannofloras comprise these relict survivors plus an array of rapidly radiating new taxa (24 genera in the course of the epoch). By the end of the Paleocene, another major turnover resulted in over half of the Cretaceous relict species, and nearly a third of the newly evolved genera, becoming extinct. The rapidity of this evolutionary turnover and the widespread occurrence of these fossils in marine strata have resulted in the establishment of nine globally recognized Paleocene biozones (**Figure 1**).

Dinoflagellates The dinoflagellates, a group of cyst-forming unicellular algae, exhibit a stepwise origination pattern in the Early Paleocene. Nevertheless, rapid evolution and widespread occurrence make dinoflagellates important zone fossils. In particular, the biostratigraphically important genus *Apectodinium* originates during this epoch. A nearly worldwide acme of the genus occurs at the very beginning of the succeeding Eocene and this is one of the primary markers used for recognizing the boundary between the two epochs.

Foraminifera Rapid radiation of planktonic foraminifera typical of the Cenozoic continued in the earliest Paleocene from its beginnings in the last few hundred thousand years of the Cretaceous. The result was almost complete replacement of latest Cretaceous species by Cenozoic ones in an interval of less than 1.5 million years. It is thought that some planktonic foraminiferal species acquired photosynthetic algal symbionts during the Paleocene, which may have allowed them to spread into oligotrophic environments. Benthic foraminifera fared better than did the planktonics, and low-oxygen-tolerant species increased to dominate early in the epoch. Notable newcomers were the textulariids among the agglutinated-shelled forms and the nummulitids among the calcareous-shelled forms, these latter representing one of the best known groups of larger benthic foraminifera of the Cenozoic. A major extinction, the benthic foraminiferal extinction (BFE), affected benthic foraminifera at the end of the Paleocene. The evolutionary and cosmopolitan attributes of planktonic foraminifera, like those of the calcareous nannoplankton, have resulted in planktonic foraminifera being used to divide the Paleocene into eight global biozones (**Figure 1**).

Coelenterata and bryozoans The millepore hydrozoans made their appearance during the Paleocene, as did two families of octocorals. There were no innovations at family level within the scleractinian corals. However, this group does show a marked low in terms of diversity. Based on gross morphology, there is no

evidence that algal symbiosis collapsed at the end of the Cretaceous. Although the Paleocene reef recovery does not involve a return to Mesozoic levels of diversity, it does mark the first appearance of microbially cemented reefs since the Jurassic Period. This suggests that the Paleocene marks the emergence of modern coral reef communities, rather than a recovery from a eutrophically driven collapse. The Paleocene radiation of cheilostome and ascophoran bryozoans increased its pace; especially the cheilostomes, the family diversity of which increased exponentially.

Molluscs Cephalopods scarcely recovered from the end-Cretaceous extinctions, which eliminated ammonites and belemnites, although a new family of nautiloids, the Aturiidae, arose at the beginning of the Paleocene. Bivalve and gastropod recovery was more dramatic. Typically, the initial recovery phase in which diversity remained low varied in length and was followed by several pulses of increasing diversity separated by lows (initial radiation phase). Several families (Ostreidae, Carditidae, and Turritellidae), however, show a different pattern. In these cases, diversity increased or remained high at the beginning of the epoch, then suffered a decline. This means that these families formed a much higher percentage of the mollusc faunas early on than later in the epoch. The speciose nature of these families and their mixture of planktotrophic and brooding larval development mechanisms may have enhanced the Paleocene survival and early success of these opportunists. Once new forms arose later in the Paleocene, however, their competitiveness was low. Survival of Mesozoic taxa was more marked in high northern and southern latitudes than elsewhere.

Echinoids The end-Cretaceous extinctions resulted in a drop in diversity in the Early Paleocene and a change from roughly equal representation of regular and irregular groups to dominance by irregular echinoids. Irregular forms were also affected at the end of the Cretaceous, with holasteroids being decimated and survivors moving from shelf to deep-water environments as the Danian chalk facies disappeared. The regular family Saleniidae also shifted into deeper waters at the same time.

Vertebrates Marine fishes appear to have suffered little at the Cretaceous–Tertiary boundary. Among the cartilaginous elasmobranchs (sharks and rays), one family (the Torpedinidae) originated at the beginning of the Paleocene and four more (the Lamnidae, Otodontidae, Carcharinidae, and Mobulidae) first appear later in the epoch. Six teleost families appeared at the beginning of the Paleocene and a further 10 families appeared later in the epoch. Despite a patchy record, the Paleocene appears to mark the meagre beginning of a major Cenozoic radiation. In contrast, the only marine reptiles to survive into the Paleocene were turtles and dyrosaurid crocodilians.

Continental Realm

Land plants Schimper, when basing his Paleocene on distinctive floras, was aware that what he was observing might only be a local phenomenon of north-western Europe. In fact, Paleocene seed plant taxa and floral composition seem to represent a segment of a modernization trend, the origins of which lay in the latest Cretaceous, when angiosperms (flowering plants) became dominant over gymnosperms (broadly, conifers and cycads). There was turnover of seed plant taxa across the Cretaceous–Tertiary boundary and low-diversity opportunistic floras (particularly ferns) suggestive of abrupt ecological disruption in the very earliest Paleocene in western North America and probably elsewhere. Diversity, however, increased later in the epoch. Angiosperm fruits in the Paleocene were mainly small and dry.

Invertebrates Non-marine (mainly pulmonate) gastropods show no particular effect from end-Cretaceous events and the Paleocene saw essentially the beginning of a Cenozoic radiation of terrestrial families. For insects, there is little evidence of extinction, at least at family level, at the end of the Cretaceous, although there are few Paleocene sites yielding members of this group. Nevertheless, diversification that began in the Cretaceous seems to have increased in the Paleocene. Evidence from leaf damage by herbivorous insects suggests that early Paleocene insect herbivores were generalists. A recovery phase is lacking for at least the first million years of the Paleocene.

Vertebrates The pattern of events from freshwater teleost fishes is similar to that of the marine pattern. Five families have first records at the beginning of the Paleocene and a further 10 occur later in the epoch. Similarly, there appears to have been little effect of end-Cretaceous events on Paleocene amphibians, lizards, snakes, crocodilians, or turtles. The freshwater champsosaurs also survived into the Paleocene. The record of birds is sparse, but there is as yet no evidence of a major turnover at the end of the Cretaceous and no undoubted appearances of modern bird families in the Paleocene. There was, in contrast, a major change in mammals between the Cretaceous and the Paleocene. Although a boundary sequence exists only in western North America, Paleocene mammals differ radically from latest Cretaceous

ones in every continent where they are known. This implies a major turnover at or near the boundary. In North America, the Cretaceous marsupial versus placental-dominated fauna was replaced in the Paleocene by an almost exclusively placental fauna (*see* **Fossil Vertebrates:** Placental Mammals). In Europe (poorly known in the Late Cretaceous) and Asia, the Paleocene faunas are also dominated by placentals, but the closeness of their phylogenetic relationships with Late Cretaceous placental groups is disputed. The greatest difference is in South America, where primitive non-therian mammals are replaced by a diversity of marsupials and placentals. Prominent features of Paleocene mammal faunas are (1) their dominance by archaic types not closely related to modern orders and (2) their strong, continent-specific endemism. Nevertheless, the following modern orders do have their first fossil appearances during the Paleocene: carnivorans, edentates, rodents, and probably also lipotyphlans (typical insectivorans) and macroscelideans (elephant shrews). Mammals underwent rapid recovery and massive radiation following the end-Cretaceous extinction. Extinction of many of these archaic types took place at the end of the Paleocene in the northern hemisphere continents when major dispersal of more modern types displaced them. Various endemic groups, however, evolved in South America, which became isolated, first from North America and later from Antarctica. These groups survived long after the Paleocene.

Climate and Environments

After the end of the Cretaceous, oxygen isotopic records from benthic foraminiferal tests document a gradual warming of the world's oceans during the first third of the Paleocene. This warming reversed the overall but fluctuating cooling trend of the latest Cretaceous (Maastrichtian), but was minor compared to the brief warming event near the end of the Maastrichtian. A cooling in the Late Paleocene was followed by a major warming, punctuated at the very end of the epoch by the beginning of a brief intense warming episode that marks the onset of the Eocene (Figure 1). During the Paleocene, there was likely to have been little or no polar ice. The impact of climate and other factors on Paleocene environments are examined in the following sections.

Marine Environments

Following the end of the Cretaceous, it has been suggested that primary productivity in the oceans was strongly reduced. This is thought to explain the general change from infaunal to epifaunal dominance among benthic foraminiferal communities at the Cretaceous–Tertiary boundary. In some deep-water sites, the change was briefly delayed at the very beginning of the Paleocene by an opportunistic low-diversity infaunal assemblage that may have been responding to a large but short-term flux of organic matter to the seafloor, from the mass mortality of microplankton. Moreover, radiolarians and associated biosiliceous oozes, which infer high oceanic productivity, are generally rare across the Cretaceous–Tertiary transition. However, evidence of rich radiolarian assemblages across the boundary in New Zealand suggest that enhanced upwelling caused by climatic cooling characterized this southern high-latitude area at the beginning of the Paleocene. Carbon isotope studies of foraminifera also indicate stability of surface productivity at high, in contrast to low, latitudes, with resultant lower extinction levels. Another phenomenon is the apparent enhanced survival of both mollusc and ostracod taxa from the Cretaceous at high, compared to low, latitudes, with subsequent spread of the ostracods to lower latitudes later in the Paleocene.

Later Paleocene oceans had more normal higher primary productivity according to their greater diversity of planktonic microbiota. They are also likely to have had modern rates of thermohaline circulation and thus of nutrient flux from subsurface to surface waters. Major warming at the end of the epoch caused a slowing of the thermohaline circulation, with resultant reduction in rate of nutrient flux, which in turn expanded the geographic range of oligotrophic habitats. This trend eventually involved a selective warming of the deep ocean by 4°–6°C due to changed circulation and a much reduced pole-to-equator temperature gradient, resulting in reduced wind intensity. The sudden warming at the Paleocene–Eocene boundary is attributed to a massive injection of CO_2 into the oceans and atmosphere by thermal dissociation of methane hydrates and their release from marine sediments. This event is judged to be the cause of the contemporaneous major extinction of benthic organisms, mainly foraminifera (BFE) and ostracods.

Continental Realm

Leaf physiognomy climate proxies produce a land-based climate curve resembling that for the marine realm. Vegetation shows a shift from open-canopy broad-leaved evergreen woodland in the Late Cretaceous to rainforest in the Early Paleocene. This marks the first appearance of such a vegetation type, which extended to higher latitudes than the present day because of the absence or near absence of polar ice. The highest (polar) latitudes were occupied by

broad-leaved deciduous forests. Despite the enhanced equability, these floras had to survive extended winter darkness. Accordingly, their structure was open and their diversity low. The very beginning of the Paleocene is also locally marked by a dominance of the spores of ferns. This phenomenon, known as the 'fern spike', is recorded from regions as far apart as western North America and New Zealand and suggests that these plants were the first colonizers of a denuded landscape.

The mammals that lived in these Paleocene habitats were mainly small. Their Cretaceous ancestors had been mainly insectivorous and to a certain extent carnivorous, and they were only now expanding their dietary spectrum to include fruit. Larger size, which went hand in hand with leaf eating, was rare and began to be evolved late in the epoch. The ecological composition of most well-known faunas supports the presence of widespread forested environments. Land connections between continents, even if fleeting during times of low sea-level, allowed marsupials and placentals to disperse from North America to South America around the end of the Cretaceous or the beginning of the Paleocene. The marsupials went on to colonize Australasia via Antarctica before Australasia finally broke free.

Eocene

J J Hooker, The Natural History Museum, London, UK

Introduction

The Eocene epoch/series is the oldest of the four original subdivisions of the Tertiary period/system proposed in 1833 by Sir Charles Lyell in his *Principles of Geology*. The name derives from the Greek '*eos*', meaning dawn, and '*kainos*', meaning recent. This is "... because the very small proportion of living species contained in those strata indicates what may be considered the first commencement, or *dawn*, of the existing state of the animate creation" (vol. 3, p. 55). The time covered by Lyell's 'existing state' is what we now understand to be the Cenozoic era/erathem, which itself is broadly divided into either Tertiary and Quaternary or Paleogene and Neogene periods. Lyell subdivided the Tertiary into four epochs based on the proportions of living and extinct species of shelled organisms (molluscs and foraminifera) encountered as fossils in different strata. He recognized 1238 Eocene species, of which he considered only 42 (or 3.5%) remain alive today. Lyell's species are about equivalent to what modern marine biologists would rank as genera or even subfamilies. For this reason, no modern species of mollusc or foraminifer is currently recognized as occurring as far back as the Eocene.

The Eocene as recognized today has changed considerably in its definition and time-span since 1833. Its earliest parts have become the Paleocene and its later parts the Oligocene, both epochs that were described after 1833. The Eocene thus succeeds the Paleocene and precedes the Oligocene. It is currently estimated to have lasted nearly 22 million years, from 55.8 to 33.9 Ma. The Eocene itself is divided into four ages/stages (in order of decreasing age): the Ypresian, the Lutetian, the Bartonian, and the Priabonian (Figures 1 and 2). The beginning and end of the Eocene have only recently been stabilized by the Paleogene Subcommission of the International Union of Geological Sciences (IUGS). Its beginning is marked by a sharp dip in the carbon isotope curve, named the Carbon Isotope Excursion (CIE), interpreted as a global warming event, the Paleocene–Eocene Thermal Maximum (PETM). This climate event sparked major changes in both marine and continental biotas. The Global Stratotype Section and Point (GSSP) for the beginning of the Eocene is placed at Dababiya, Egypt. This geological section is the best available for demonstrating the boundary criteria and acts as a global reference. The end of the Eocene is marked by extinction of the planktonic foraminiferal family Hantkeninidae, representing the last in a cumulative series of extinctions caused by long-term global cooling. The GSSP for the Eocene–Oligocene boundary is at Massignano, Italy.

Plate Tectonics and Other Physical Phenomena

The processes of subduction around the Pacific rim continued from the Paleocene, with the Kula Plate disappearing beneath the Aleutian Arc of Alaska. In North America, the remnants of the Late Cretaceous Western Interior Seaway, still present in the Paleocene, disappeared completely. Caribbean, deep-water circulation between the Pacific and Atlantic began to be cut off late in the Eocene as the Central American Isthmus formed a structural unit, but remained submerged.

Seafloor spreading in the Atlantic continued to migrate northwards on either side of Greenland. Thus, a seaway formed early in the Eocene between Greenland and Europe, linking the earlier landlocked Arctic Ocean once again with the Atlantic. At the same time, the maximum outpourings of lava associated with the Iceland hotspot occurred in East Greenland and the then adjacent Hebridean Province. The Labrador Seaway between Greenland and North America also widened and the land connection between Europe and North America via Greenland finally severed. A land bridge developed intermittently between North America and Asia across the Bering Straits as a result of sea-level changes.

For the entire epoch, the epicontinental West Siberian Seaway linked the Arctic Ocean with the Peritethys, maintaining the isolation of Europe from Asia. This seaway narrowed at its southern end to form the Turgai Straits, which may occasionally have dried out at times of low sea-level. In fact, except for the first million or so years of the epoch, when Europe was connected to North America via Greenland, Eocene Europe comprised several island masses isolated from the rest of the world's continents. The Peritethys continued to be partially separated from the main mass of the Tethys Ocean by the narrow orogenic belt stretching intermittently from Italy through Asia Minor to southern Iran. In this complex area of the ancient Mediterranean, the islands of Corsica, Sardinia, and the Balearics were still part of the Iberian Peninsula. During the course of the Eocene,

Figure 2 Coastal section in Alum Bay, Isle of Wight, UK, showing strata spanning almost the entire Eocene. Oldest is to the right, youngest to the left. The red and brown are Ypresian, the yellow with dark intercalations is Lutetian, the grey below the house is Bartonian (all vertical), and the white (mainly horizontal) is Priabonian.

anticlockwise rotation of Iberia resulted in initial uplift of the Pyrenees.

Further south, India completed its northward drift and docked with Asia in the Early Eocene, laying the foundations for the Himalayan uplift. Rifting between Australasia and Antarctica widened and developed into an (at first) narrow Tasman Sea. Australasia began its 50-million-year-long trek to lower latitudes at this time. Subduction beneath the west side of the Antarctic Peninsula led to its uplift and shallowing of the back-arc basin to the east. South America remained connected to the Antarctic Peninsula for most of the epoch. However, development of the Scotia Arc and formation of the Scotia Sea (Drake Passage) meant that, by the end of the Eocene, all major elements of Gondwana had separated and the modern arrangement of the continents was essentially in place.

Two important impact-ejecta strewn fields have also been recognized within Late Eocene sediments. It has been suggested that two large impact craters, Popigai in Siberia and Chesapeake Bay in the USA, were the sources for these (Figure 1).

Biota

The Eocene biota is characteristically diverse and abundant. Most surviving groups had recovered from the Early Paleocene diversity low by this time and had undergone or were undergoing radiation. Marine groups, such as molluscs, crustaceans, and echinoids, had a familiar modern appearance. On land, the same was true of many reptile and amphibian groups, but Eocene mammals differed radically from their living relatives. Key biotic events are discussed below.

Marine Realm

Calcareous nannoplankton An important turnover in this group of microscopic algae occurred during the first million years of the Eocene with the origination of many new taxa. The genera that had radiated and dominated in the Paleocene became extinct. Survivors were the previously low-diversity genera of modern aspect. This turnover is attributed to the PETM (see below). Later in the Eocene, diversity reduced regionally and deeper water habitats were vacated because of progressive cooling. New taxa evolved in response to the temperature changes and increased eutrophication. The rapid evolution and widespread occurrence of nannoplankton at this time have enabled the Eocene to be divided into 12 global biozones (Figure 1).

Dinoflagellates The PETM resulted in a near-global spread of dinoflagellate species belonging to the genus *Apectodinium* through middle and high latitudes. This event, known as the *Apectodinium* acme, is an important biostratigraphical marker for the Paleocene–Eocene boundary. Continued radiation produced increasingly diverse cyst assemblages during the Early and Middle Eocene, especially of the genus *Wetzeliella* and its relatives. Diversity remained high for most of the Eocene, despite the later cooling of sea surface temperatures. The very end of the epoch, though, bears witness to a reduction in abundance of low-latitude taxa, as well as the invasion of these areas by formerly higher latitude groups.

Foraminifera The initial Eocene turnover in planktonic foraminifera at the PETM was minor. Radiation continued from the Paleocene to reach a diversity maximum in the Middle Eocene. Then, deteriorating temperatures caused long-term stepwise extinctions, of which the most intense was at the end of the Middle Eocene (Bartonian). Surface-dwelling species were gradually replaced by cold-tolerant, subsurface species. Benthic foraminifera fared much worse at the PETM, suffering 30–50% extinctions for middle bathyal through abyssal forms. This is known as the Benthic Foraminiferal Extinction (BFE). Shallower water taxa fared better. The latter include the best-known Eocene calcareous foraminifera, some of which (e.g., the nummulites) became important rock formers and reached maximum diameters of 10 cm. Benthic foraminifera, like the planktonics, underwent stepwise extinctions throughout the Middle and Late Eocene. The evolutionary and cosmopolitan attributes of planktonic foraminifera, like those of the calcareous nannoplankton, have resulted in their use for dividing the Eocene into 13 global biozones (Figure 1).

Coelenterates and bryozoans Two families of octocorals originated at the beginning of the Eocene. Radiation of scleractinian corals occurred, with increasing species numbers throughout the epoch. Interestingly, there was no reduction in diversity when climates cooled in the Middle and Late Eocene. Amongst the bryozoans, the rapid diversification of cheilostome families in the Paleocene continued into the Eocene, but then began to slow, although there was a peak diversity of species in the Priabonian.

Molluscs After the terminal Cretaceous extinctions of ammonites and belemnites, the surviving coleoids (squids and cuttle fishes) were slow to recover and have left little fossil evidence in the Paleocene. Their appearance in the Eocene is therefore virtually as 'Lazarus' taxa. Most of the spirulid, and all of the sepiid, radiation took place in this epoch, with several new families appearing. Diversification in bivalves and gastropods continued from the Paleocene into the Eocene. A study in the Gulf Coast, USA, has shown that species numbers reached a peak in the Bartonian, when climates were already beginning to deteriorate, and plummeted during the Priabonian. The origination of many new families in the epoch gave these faunas a more modern aspect.

Echinoids The main Eocene evolutionary events surround the irregular group. This epoch saw a decline in cassiduloids and a corresponding rise in diversity of clypeasteroids, with five new families appearing. Clypeasteroids were the last group to evolve non-planktotrophic lecithotrophic or brooding development for their larvae, and this development occurred in the Eocene. Although this adaptation resulted in reduced dispersal ability, it is thought to have enhanced resistance to the rigours of increased seasonality associated with the deteriorating Middle and Late Eocene climate.

Vertebrates Amongst cartilaginous fishes (Elasmobranchii), there was a significant increase in rays (Rajiformes), with three new families making their first appearance at the beginning of the epoch. Eocene marine teleosts are characterized by a continuation of their Cenozoic radiation, particularly in tarpon and eels (Elopomorpha) and massively in spiny-ray fishes (Acanthomorpha). A caveat, however, is provided by the breadth of diversity of the many newly appearing acanthomorph families, implying an earlier record of these, which we have yet to discover.

Marine mammals are first recorded from the Eocene in the form of primitive whales (Cetacea) and sea cows (Sirenia). These represent the first marine tetrapod evolutionary innovation since the extinction of plesiosaurs and mosasaurs at the end of the Cretaceous. The earliest known cetaceans are from the Ypresian of Pakistan. These early members retained well-developed walking limbs, both fore and hind, and are interpreted to have been amphibious inhabitants of both freshwater and marine habitats. Limb structure demonstrates a close relationship with the entirely land-based artiodactyls (cloven-hoofed mammals) which appeared at about the same time.

Continental Realm

Land plants In the Eocene, angiosperms (flowering plants) diversified and became more modern in appearance. Many modern genera (although no modern species) can be recognized within families that are well represented today. Examples are magnolias (Magnoliaceae), grape vines (Vitaceae), citrus and allies (Rutaceae), spurges (Euphorbiaceae), dogwoods (Cornaceae), custard apples (Anonaceae), laurels (Lauraceae), moonseeds (Menispermaceae), icacinas (Icacinaceae), and palms (Arecaceae). Grasses, on the other hand, were notably rare.

Invertebrates Land gastropods underwent a major Eocene radiation with two new prosobranch and 16 new pulmonate families appearing. This gave a more modern aspect to land snail and slug faunas. The poor Paleocene record of insects makes it difficult to judge specific Eocene innovations. By the end of the Eocene, though, 223 families had appeared since the Cretaceous. In particular, there is a surge in origination of dragonflies (Odonata), flies (Diptera), butterflies and moths (Lepidoptera), and beetles (Coleoptera). Compared with the Paleocene, leaf damage indicative of insect herbivory shows an overall increase in abundance and diversity, which is expressed particularly by more specialist damage types, such as leaf mines and leaf galls.

Vertebrates Eight families of freshwater teleost fishes have their first records in the Eocene. These include such well-known families as carp (Cyprinidae), salmon (Salmonidae), and perch (Percidae). Five modern families of freshwater and terrestrial turtles appeared in the epoch. These included the well-known terrapins (Emydidae) and tortoises (Testudinidae). Nine modern families of birds have their first records in the Eocene, with doubtful records of a further 14. The undoubted records include parrots (Psittacidae), owls (Strigidae), nightjars (Caprimulgidae), swifts (Apodidae), colies (Coliidae), and rollers (Coraciidae). None, however, belong to the passerines, which were either very rare at this time or had not yet evolved.

Land mammals underwent their greatest innovation of the Cenozoic in the Eocene. Most modern

placental orders appeared at the beginning of the epoch in the northern hemisphere in what is known as the Mammalian Dispersal Event (MDE). The sudden appearance of so many specialized morphotypes implies an earlier evolution extending back into the Paleocene, of which we have no record. These newcomers were bats (Chiroptera), primates (Primates), cloven-hoofed mammals (Artiodactyla), odd-toed ungulates (Perissodactyla), and elephants (Proboscidea). Other modern orders appeared later in the Eocene, including hyraxes (Hyracoidea), pangolins (Pholidota), and tree-shrews (Scandentia). Many early members of these groups were small. Moreover, few hoofed plant-eaters developed a large size or an exclusively leaf-eating diet until relatively late in the epoch.

Climate and Environments

Eocene climates include the warmest of the entire Cenozoic era (early in the epoch), deteriorating later to lead eventually to the first Cenozoic ice build-up in Antarctica (Figure 1). Carbon and oxygen isotope records based on the analysis of foraminiferal tests, mammalian dental enamel, soil carbonates (Figure 3), and lignites all show a short, sharp, 200 000-year-long, negative anomaly (CIE) at the very beginning of the Eocene. This indicates an extreme warming perturbation (PETM), when deep-sea temperatures rose by 4–6°C. This spike was superimposed on a long-term warming trend that began in the Late Paleocene and culminated late in the Ypresian with a comparable, but longer duration, warming peak, known as the Early Eocene Climatic Optimum (EECO). During the PETM and EECO, there was probably no polar ice, pole to equator temperature gradients were much reduced, and overall wind circulation slowed. Subsequently, temperatures declined, with small warming interruptions near the end of the Lutetian and in the Priabonian (Late Eocene). Significant amounts of ice-rafted debris, indicative of glacial activity, first occur in southern high-latitude sediments at the end of the Bartonian.

Figure 3 Polecat Bench, Wyoming, USA, showing a thick sequence of latest Paleocene and earliest Eocene fluvial mudstones and palaeosols. The base of the Carbon Isotope Excursion (CIE) is recorded from mammalian dental enamel and soil nodules at a point intermediate between the two distinct red bands. The upper red band records the Mammalian Dispersal Event (MDE).

Marine Environments

The PETM perturbation is thought to have been caused by a massive injection of CO_2 into the oceans and atmosphere by the thermal dissociation of methane hydrates and their release from marine sediments. This event, in turn, caused a slowing of the thermohaline circulation with a resultant reduction in the rate of vertical marine nutrient flux and an expansion in the geographical range of oligotrophic habitats. The major rapid extinction of benthic foraminifera (BFE) and ostracods that resulted (*see* **Tertiary To Present:** Paleocene) meant low diversity for such organisms in bathyal and abyssal regions early in the Eocene. Post-extinction benthic foraminiferal faunas vary widely with geography compared with pre-extinction faunas. This is thought to be a phenomenon of highly perturbed communities. Early Eocene planktonic foraminiferal communities also show a greater diversity of oligotrophic forms than do those of the Late Paleocene. This is consistent with the proposed model of a uniformly warm Early Eocene ocean with reduced rates of circulation. Widespread deep-water anoxia, with associated calcium carbonate dissolution at the PETM, appears to have favoured the latitudinal spread of dinoflagellates of the genus *Apectodinium* (the *Apectodinium* acme) as far north as the Barents Sea and as far south as New Zealand. *Apectodinium* is thought to have been partially or fully holozoic and replaced earlier dominant photosynthetic dinoflagellate communities.

This period of warming and equability promoted high taxonomic diversity for many groups of organisms at much higher latitudes than today. Thus, tropical-type molluscs, zooxanthellate-like corals, and giant nummulites are well represented in northern Europe, a fact that impressed Lyell as long ago as 1833. The subsequent cooling reversed processes that took place early in the epoch. Thermohaline circulation rates accelerated, ocean mixing increased, low-nutrient, surface water habitats were reduced, and instability was created in high-nutrient, surface water areas through seasonal production. This

increase in seasonality, documented from oxygen isotopes in mollusc shells and fish otoliths (ear stones), is considered to be an important feature of the Late Eocene cooling. Extensive investigation of the two Late Eocene impacts has found no important, associated biotic extinctions. However, carbon and oxygen isotope analyses and microfossil assemblage composition from strata overlying the ejecta layers suggest that a minor, but prolonged, cooling followed at least one of these impact events. This prolongation of the environmental effect may have been caused by an increase in the Earth's albedo from ice-sheets that were extended in response to the cooling.

Continental Environments

Leaf physiognomy climate proxies give a land-based climate curve that, like the marine curve, shows cooling from an Early Eocene maximum, but declines in more widely fluctuating steps. Moreover, the study of leaf floras across the Paleocene–Eocene transition in the Bighorn Basin, Wyoming, USA, indicates an initial warming (PETM), followed by a cooling, and then renewed warming up to the EECO. The long-term warming phase that began in the latest Paleocene and culminated in the EECO had important effects on vegetation. During its later stages, highly diverse, multistratal rainforest with many lianas extended to latitudes of 55° or 60° north and south. This was accompanied by coastal mangrove vegetation, often dominated by the mangrove palm *Nypa*. These widespread rainforests were similar to those of south-east Asia today. They appear to have differed, however, in lacking epiphytic flowering plants and in having only very rare representatives of some taxa (e.g., dipterocarps) that are highly significant in modern south-east Asian forests. In addition to the multistratal nature of these Early Eocene forests, the plants differed from those of the Paleocene in their fruiting strategies. In the Paleocene, fruits were mainly small and dry with some drupes and nutlets. Fleshy fruits were rare. In contrast, in Eocene forests, fleshy fruits were abundant and larger nuts were also present. This change represents the beginning of the co-evolution of fleshy fruits with fruit-eating primates and of nuts with scatterhoarding rodents, that facilitates plant dispersal. At higher, polar latitudes, these rainforests were replaced by broad-leaved deciduous forests. There is no evidence in the Eocene for the coniferous forests that today clothe Earth's boreal regions. The later Eocene cooling is tracked by a shift to less diverse, more open, deciduous broad-leaved forests in middle and high latitudes, with the loss of many of the tropical taxa that dominated earlier in the epoch. Despite the development of more open vegetation, this did not include grassland, grasses being virtually absent from all Eocene floras.

The MDE that introduced many new mammals into the northern hemisphere continents at the time of the CIE (Figure 3) is partly attributed to the warm temperatures. These may have facilitated the well-documented dispersals through northern high latitudes (across the Greenland and Bering land bridges) through the extension of vegetation zones. However, minor dispersal also appears to have taken place across the Turgai Straits at lower latitudes. Low sea-levels in the vicinity of the Paleocene–Eocene boundary are also likely to have had a strong influence on dispersal. Mammal communities in the Early Eocene were dominated by small animals, many of which fed on insects and fruit and were adapted for life in the trees. Their patterns of ecological diversity resemble those of south-east Asian evergreen forests and thus support the plant evidence for the nature of the Eocene vegetation. As climates cooled later in the epoch, fruit-eating and climbing mammals diminished and larger ground-dwelling herbivores evolved. The patterns of ecological diversity that characterize these later faunas fit closely with more open wooded habitats as the plant fossils indicate. The structure and wear patterns of the teeth of these later Eocene herbivorous mammals indicate that they were browsers not grazers.

Oligocene

D R Prothero, Occidental College, Los Angeles, USA

Introduction

The Oligocene Epoch was defined by Heinrich Ernst von Beyrich in 1854. This interval of geological time was based on marine strata in Belgium and Germany, thought to be younger than the Lyell's classic upper Eocene (*see* **Tertiary To Present:** Eocene) strata of the Paris Basin, but older than Lyell's (*see* **Famous Geologists:** Lyell) concept of Miocene rocks. Von Beyrich's original list of 'Oligocene' rocks contained a wide spectrum of units of varying ages, including those that are now clearly referable to the Eocene or Miocene. For example, one unit (the bone sand of Eppelsheim) produced a Late Miocene *Hipparion* fauna. In addition, the type strata of von Beyrich's Oligocene in Belgium and Germany do not overlie the type strata of the Paris Basin or Italian Eocene, so the Eocene–Oligocene boundary cannot be recognised in either area. As is true of the rest of the European Cenozoic, the type sections of the stages within the Oligocene are shallow-water deposits bounded by unconformities, and represent only a small portion of its duration.

For 130 years after von Beyrich's establishment of the Oligocene, there was considerable confusion over what was Eocene and what was Oligocene, not only in the western European type areas, but especially in other regions which could only be correlated indirectly to the stratotypes. For example, in North America, the Duchesnean land mammal age was thought to be late Eocene or Oligocene (it is now considered middle Eocene), the Chadronian land mammal age was correlated with the Early Oligocene (it is now known to be Late Eocene in age), and the Orellan and Whitneyan land mammal ages were thought to be Middle and Late Oligocene (they are now both regarded as Early Oligocene in age). Although these problems made the type Oligocene stages hard to correlate to other regions, the use of planktonic microfossils and magnetic stratigraphy has allowed geologists to correlate the classic shallow-marine European stratotypes and terrestrial sections to the global deep-marine standard (**Figure 1**). As a result, the Oligocene is now securely correlated around the world.

In 1989, the Eocene–Oligocene boundary was formally established at the last appearance of the spiny planktonic foraminiferal genus *Hantkenina* in a quarry section near Massignano, Italy. However, later work has since shown that part of the type upper Eocene Priabonian Stage is Early Oligocene by this definition, so there are still problems with this criterion. Most of the important climatic events that many scientists believe should mark the beginning of the Oligocene (e.g., the global oxygen isotope shift indicating the expansion of Antarctic glaciers, and related events such as the cooling on North America) are earliest Oligocene (magnetic Chron C13N, about 33 million years ago) using the hantkeninid criterion. Thus, there are grounds for revising

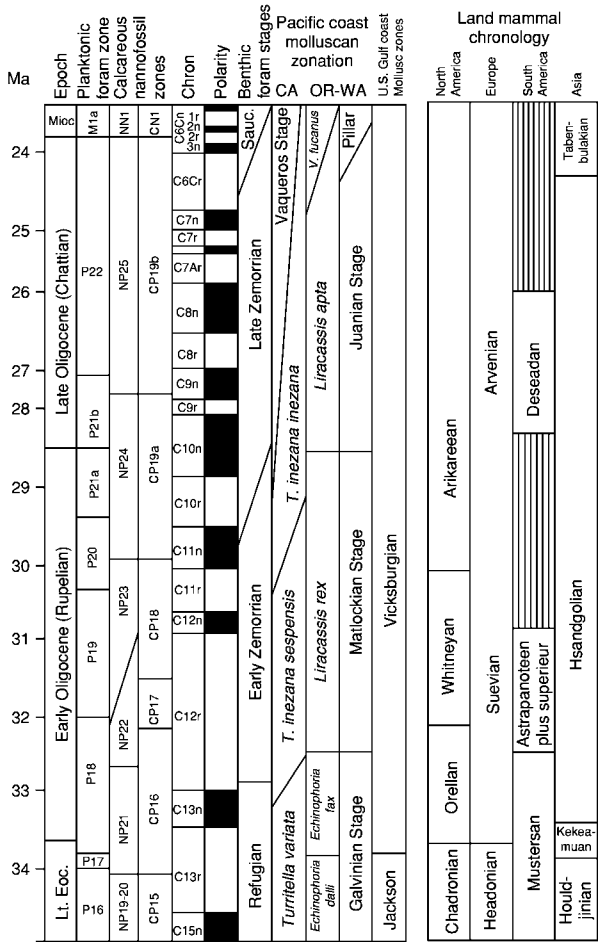

Figure 1 Correlation of various Oligocene biostratigraphic units to the global time scale (left) and magnetic polarity time scale (middle). Global time scale and planktonic zonation (after Berggren *et al.* (1995)). Pacific Coast marine zonation after Prothero (2001). US Gulf Coast molluscan zonation (after Prothero *et al.* (2003)). North American land mammal chronology (after Prothero and Emry (1996)). Asian land mammal chronology (after Meng and McKenna (1998)). European land mammal chronology (after Barbera *et al.* (2001)).

the 1989 definition to a more 'natural' boundary. This would also place the beginning of the Oligocene after the end of the type Late Eocene (Priabonian Stage). However, no such revision has been formally proposed to date.

Only two stages are recognized in the 11-million-year (34–23 Ma) span of the Oligocene. The Early Oligocene Rupelian Stage includes the interval from 34–28.5 Ma. The Late Oligocene Chattian Stage is dated between 28.5–23.8 Ma. There is no formally recognized Middle Oligocene.

Oligocene Climate

The 11 million years of the Oligocene marked an important climatic transition in Earth history. The latest Paleocene and Early Eocene (55–50 million years ago) was the peak of global warming, a 'greenhouse' climate that exhibited the warmest global conditions since the Late Cretaceous. Climates were so warm and mild that crocodilians and temperate plants lived above the Arctic Circle in regions that experienced six months of darkness. Beginning in the Middle Eocene, though, this balmy climate began to transform, with the greenhouse climate gradually changing to a colder, more extreme climate. The end of the Middle Eocene (37 Ma) was marked by a major cooling event, which caused the extinction of many marine organisms adapted to warm, tropical waters.

During the three million years of the Late Eocene (37–33 Ma), there was a slight warming and recovery from the long-term cooling trend. At least three major comet or asteroid impacts struck the Earth in the Middle of the Late Eocene (35.5–36.0 Ma), but these caused no significant changes in climate, nor extinction of any importance. As noted above, the Eocene–Oligocene boundary is now formally recognized by the extinction of hantkeninid foraminifera, although no other major climatic or extinction events occurred at this time. (Note that this invalidates an old idea from the 1970s and 1980s that a 'Terminal Eocene Event' – comparable to the event that ended the Cretaceous – also marked the end of the Eocene).

The most significant climatic event of this interval occurred in the earliest Oligocene (as currently defined, using the hantkeninid criterion), at about 33 Ma. This is now known as the Oi1 event. In the marine record, both benthic and planktonic foraminiferal oxygen isotopic ratios show about a 1.3 per mil increase (Figure 2). It was calculated that about 0.3–0.4 per mil of the change was due to a major expansion of Antarctic ice-sheets that lowered global sea-level by at least 30 m. The remaining 0.9–1.0 per mil is explained by about 5–6°C global cooling, which lowered global mean temperature from as high as 13°C in the Early Eocene and 7°C in the latest Eocene to values just a few degrees above freezing (as a global average – the poles were well below freezing for the first time, while the tropics remains relatively unchanged).

Abundant data suggests that this global cooling event was due largely to the growth of the first major Antarctic ice-sheet since the Permian (over 250 Ma). Drilling on the margin of the Antarctic continent and in oceanic plateaus in the Southern Ocean (e.g., Maud Rise and the Kerguelen Plateau) have produced unmistakable evidence of ice-sheet growth. Not only do the isotopic records show its effect, but many of the sediments drilled from the

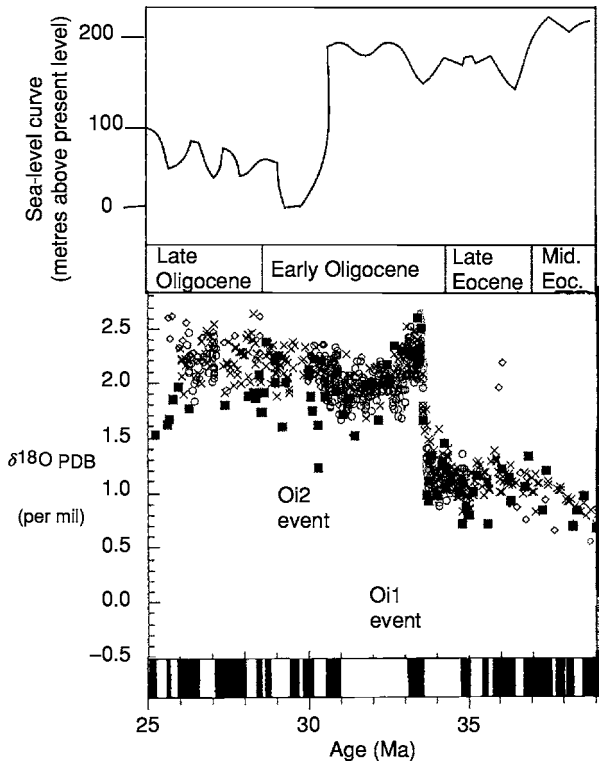

Figure 2 Details of oxygen isotope and sea level record in the Oligocene (modified from Prothero and Dott, 2003, and Zachos *et al.*, 1999).

Antarctic margin are glacial in origin. In addition, there are even observations of sediments dropped by melting icebergs well out into the Southern Ocean.

What caused this global cooling and the extinctions in the Early Oligocene? A few geologists have suggested that the Late Eocene impact events, or major volcanic eruptions in the Ethiopian Plateau, might have been responsible, but these ideas are challenged by the stratigraphical sequence of events. As noted above, the impacts occurred in the Middle of the Late Eocene, about two million years before the Early Oligocene cooling and two million years after the End–Middle Eocene cooling. Likewise, the volcanic eruptions that formed the Ethiopian traps are now dated in the Late Oligocene, when no significant extinctions are recorded. For more than 30 years, the primary mechanism responsible for the Early Oligocene cooling has been identified as the development of the Circum-Antarctic current. Today, this current circulates in a clockwise direction around the Antarctic continent, forming a 'refrigerator door' that locks the cold temperatures formed on the poles. This current is one of the largest in the ocean, moving as fast as 25 cm sec. The volume of water that passes between Antarctica and Australia is about 233 million cubic metres per second, or more than 1000 times the flow of the largest river on Earth, the Amazon. The 'refrigerator door' also separates the polar currents from subpolar and temperate currents, so that each is isolated from the other. By contrast, in the Early Eocene tropical waters in the Atlantic and Pacific mixed all the way to the poles, decreasing the difference in temperature between the poles and the equator.

As these cold waters circulate around the poles, they sink, generating the Antarctic bottom waters. These cold, oxygenated waters then flow along the bottoms of the world's oceans, all the way to the northern hemisphere. The effect of this on global oceanic circulation and climate is enormous. Antarctic bottom waters contain up to 59% of the world's marine water, and transport this cold water all over the bottom of the ocean. This, in turn, increases the stratification of shallow- and mid-level currents in the ocean, further accentuating the climatic differences between pole and equator.

So what triggered the development of the Circum-Antarctic current? The most obvious factor is plate Tectonics (*see* **Plate Tectonics**). In the Late Cretaceous, Australia and South America were still attached to Antarctica as remnants of the ancient Gondwana supercontinent. As noted above, this caused the tropical currents to mix with polar currents along a much broader front since there were barriers between the Atlantic, Indian, and Pacific oceans, and no southern ocean. The climatic effect was expressed by moderate global temperatures. Geophysical evidence shows that these three southern continents began their separation in the latest Cretaceous, but they were not far apart enough to allow deep-ocean currents to pass through until the latest Eocene or Early Oligocene. By the Early Oligocene, deep-sea cores south of New Zealand reveal a blast of cold water was passing between Australia and East Antarctica. As the Oligocene progressed, the between-continent separation grew wider, resulting in the development of larger and more powerful cold-water currents. Originally, geologists thought that the separation between the tip of South America and the Antarctic Peninsula did not occur until the end of the Oligocene, but recent evidence has suggested that this passage also opened in the Early Oligocene. This implies that the entire Circum-Antarctic current developed in a relatively short period of geological time.

In addition to these important currents, it is also thought that another body of water, the North Atlantic Deep Water, which flows out of the Arctic Ocean past Greenland into the bottom of the North Atlantic, originated some time in the Oligocene. Thus, the

global 'icehouse' conditions of the Oligocene can be largely attributed to the development of modern oceanic stratification and circulation patterns.

It has been suggested that a decline in greenhouse gases – especially CO_2 – might be a more important factor than the effects of oceanic circulation changes in steepening Oligocene climatic gradients. This interpretation is based on global circulation models of the atmosphere and oceans, coupled with simulation experiments in which the amount of atmospheric CO_2 was varied in the computer models. Certainly, there must have been a decline in CO_2 from the greenhouse world of the Cretaceous through Early Eocene to the icehouse of the Oligocene. But important questions have not yet been answered. Where is the global reservoir for all this carbon? There were no great bodies of unoxidized carbon locked up in coal deposits such as the one that terminated the Mid-Paleozoic greenhouse. Nor are there extensive Oligocene carbonates that might have locked up atmospheric CO_2. Those who favour this hypothesis suggest that the carbon was locked up in frozen methane hydrates on the sea-floor. Since the evidence of this frozen hydrate might not be preserved in the stratigraphical record, it is difficult to test this idea directly. Several other empirical studies also contradict this computer model. Chemical analyses of foraminifera suggests that Eocene CO_2 concentrations were not much higher than they are today. The number of stomata on the bottom of a leaf is strongly correlated with atmospheric CO_2 concentration, and it is observed that there is no evidence of higher CO_2 levels in Eocene leaf data. It has been argued that methane (CH_4), rather than CO_2, might have been the greenhouse gas responsible for Eocene warming. Given the clear evidence of oceanic circulation changes directly tied to sedimentological changes on Antarctica, and isotopic changes in the oceanic waters, there must have been a significant effect from the opening oceanic gateways and circulation changes.

The effects of these oceanic temperature changes are critical, not only to marine climates and organisms, but also to terrestrial climates as well. The most complete land-based record comes from North America, where palaeobotanical records show that mean annual terrestrial temperatures dropped 7–11°C in the earliest Oligocene. This is true of palaeofloral records all the way from Alaska and the Pacific North-west to the Gulf Coast. In addition to this rapid cooling, the record of ancient plants and soils also suggests that the continent underwent significant drying, with the establishment of much more seasonal, drought-prone climates. In the Big Badlands of South Dakota, Upper Eocene palaeosols (*see* **Soils:** Palaeosols) suggest over a metre of annual rainfall, supporting a dense forest. By contrast, in the Early Oligocene, mean annual rainfall was less than half a metre, and the vegetation was patchy scrubland with limited riparian forests. The land snails from the Badlands also change, from Late Eocene forms like those found today in tropical Central America, to Early Oligocene forms that are smaller and more drought-tolerant, and found today in Baja, California. In addition, the Late Eocene reptilian fauna that was dominated by crocodilians and pond turtles was replaced by dry land tortoises in the Early Oligocene.

Once the Early Oligocene climatic deterioration was completed, the Earth remained in this icehouse mode through the remainder of the Oligocene. The other significant Oligocene climatic event was several pulses of glaciation that occurred during the middle part of the Oligocene, about 30 Ma (the Oi2 event). Thick, extensive Mid-Oligocene glacial deposits are found throughout the Antarctic region, and benthic foraminiferal oxygen isotopes shifted by 1.6 per mil, suggesting another increase in ice volume and drop in global temperatures (**Figure 2**). As these ice-sheets grew, they pulled water out of the oceans, resulting in the largest drop in sea-level in the past 100 million years. Originally, it was suggested that sea-level dropped by almost 150 m, although more recent estimates suggest it was only half that amount (**Figure 2**). Whatever its magnitude, the Mid-Oligocene regression had a major effect on the shallow-marine realm, causing the continental shelves to become deeply incised once they were exposed to the subaerial erosion, and producing huge Mid-Oligocene unconformities in most marine rocks around the world.

The effect of the cooling and regression in the Middle Oligocene on land climates was less obvious. Sensitive tropical floral elements were already gone by the Mid-Oligocene, so the land plant record shows only minor cooling effects. The record of ancient soils from the Big Badlands of South Dakota shows that the climate became cooler and much drier, so that sand dune deposits became common in the Mid-west in the late Oligocene. These same soils suggest that vegetation was a mixture of scrublands and grasses, with few trees, by the Late Oligocene.

Oligocene Life

As the Eocene–Oligocene climatic deterioration began, the total diversity of land animals and both marine organisms decreased significantly from Eocene levels, reaching a Phanerozoic low in the Late Oligocene. The forests and jungles of the Early

Eocene were rapidly disappearing by the Late Eocene, so that by the Oligocene most of the temperate latitudes were covered by a mixture of forest and scrubland vegetation. This change in vegetation triggered by this cooling and drying was a major change in many of the land organisms. The Oligocene land-mammal fauna was dominated by primitive members of most living families. These included three-toed horses (which began to radiate into multiple lineages by the Late Oligocene), three different lineages of rhinoceroses, early camels, deer, and peccaries, as well as a handful of archaic land-mammal groups left over from the Eocene. Numerous modern carnivoran groups (especially early dogs, and the cat-like nimravids, as well as primitive members of the bear, weasel, and raccoon families) became the dominant predators as the last of the archaic carnivorous mammals (*see* **Fossil Vertebrates:** Placental Mammals), the creodonts, straggled on. On all the northern continents and Africa, rodents and rabbits both underwent a huge diversification as the niches for ground-dwelling seed-eaters increased, and the habitat for squirrel-like nut and fruit eaters diminished.

In Eurasia, many of the same trends were apparent. In the Early Oligocene, the Turgai Strait across the Obik Sea between Europe and Asia opened up, allowing Asian mammals (such as rhinoceroses and ruminants) to immigrate to Europe and drive many of the endemic natives to extinction. This Early Oligocene event is known as the Grande Coupure. However, there was only limited migration between Asia and North America via the Bering Strait. In Eurasia, the Oligocene saw a similar diversification of rhinoceroses (including one group, the giant indricotheres found in Mongolia and Pakistan, which reached 6 m at the shoulder and weighed 20 tonnes), plus some of the earliest members of the deer, giraffe, pig, and cattle families. Tree-dwelling mammals became much less common and vanished from many continents. For example, primates once flourished on all the northern continents during the Early and Middle Eocene. By the Oligocene, though, they became restricted to Africa and South America, where they evolved into Old World and New World monkeys, respectively. The remainder of the African fauna was also endemic to this island continent, which was not connected to Eurasia at the Arabian Peninsula until the Early Miocene. Instead, the African fauna was populated by archaic mastodonts, a wide diversity of hyraxes, and other peculiar endemic forms, such as the horned arsinoitheres. South America and Australia were also island continents, unconnected to the rest of the world, and each developed their own endemic faunas.

In the marine realm, the Early Oligocene extinctions triggered by global cooling were severe, causing major extinction in the planktonic and benthic foraminifera, and even in the planktonic algae (*see* **Fossil Plants:** Calcareous Algae) such as diatoms and coccolithophores. In the Gulf Coast of the US, 97% of the marine snail species and 89% of the clam species found in the Late Eocene did not survive into the late Early Oligocene, and over 50% of the sea urchins and sand dollars also became extinct. However, the overall taxonomic composition of the marine fauna remained essentially the same, with new species of clams, snails, and sea urchins replacing the extinct species (but at lower diversity), and making up the bulk of the fossilisable organisms in the Oligocene. By the end of the Early Oligocene, diversity was at an all-time low. Marine faunas were composed of groups tolerant of the cooler waters that began in the Oligocene. This is true especially in the molluscs (*see* **Fossil Invertebrates:** Molluscs Overview) of the Pacific Rim, which are mostly cold-water tolerant forms that migrated south to California from Alaska and Siberia during the Oligocene. Planktonic organisms were not only low in diversity, but occupied relatively few, simple biogeographic realms (since the area of the tropics had decreased), and evolved relatively slowly during the Oligocene.

Palaeogeography

With the Eocene separation of Australia from Antarctica and the collision of India with Asia, by the Oligocene most of the continents were approaching their present configuration. South America, however, would not finally separate from Antarctica until the beginning of the Oligocene, completing the breakup of Gondwana and opening the gateway for the full development of the Circum-Antarctic current. As discussed above, these continental movements brought about major changes in oceanic circulation, with the Circum-Antarctic current locking in cold conditions over Antarctica, initiating the first Antarctic ice-sheets, and also stimulating the flow of cold Antarctic bottom waters, which today control much of the world's oceanic circulation.

The growth of Antarctic glaciers meant that the high sea-levels of the Eocene greenhouse world were gone, and much of the seawater locked up in ice. The Late Oligocene regression turned the drowned coastal plains of the Atlantic and Gulf coast of North America into emergent floodplains, and the European archipelago largely dried up. This regression also dried up the Obik Sea and ended the separation of Europe and Asia. The Tethys Seaway was already partially disrupted by the collision of India

with Asia, but global regression destroyed the remaining vestiges of this seaway and its unique tropical biota.

On land, the Himalayas continued to develop, and the Alps began to rise rapidly as Africa began to collide with Europe and close the Mediterranean. The Andes began to erupt huge volumes of volcanic rocks, forming a mountain chain for the first time. In North America, the Rocky Mountains were no longer rising, but they continued to soar high above the western part of North America. The basins between the ranges began to fill up with sediments and volcanic debris erupted from the arc volcanoes to the west. Volcanic activity on the western edge of the continent, which had ceased when the Laramide Orogeny shut off the Sierran-Sevier arc, resumed in the Oligocene. The new arc was much further east than the previous arc, running in an irregular belt from central Mexico to New Mexico (the Mogollon-Datil volcanics) to south-west Colorado (the San Juan volcanics), Utah, and Nevada, and then up through Oregon and Washington (the ancestral Cascades), and British Columbia. These explosive volcanic centres erupted huge amounts of ash, much of which blew east and helped bury the Laramide uplifts of the Rocky Mountains. Much of this ash and sediment also spilled over onto the High Plains, forming the thick Oligocene deposits of the White River and Arikaree Groups (entombing their excellent record of fossils (*see* **Fossil Invertebrates:** Echinoderms (Other Than Echinoids)) and climates (*see* **Palaeoclimates**) in the Big Badlands of South Dakota and adjacent states. At about 30 Ma, the corner of the Pacific Plate was subducted under California, so the San Andreas transform fault began its activity. This, in turn, set off a wide variety of geologic events, including the beginning of the spreading of the Basin and Range Province in Arizona, Utah, and Nevada; the end of the eruptions in Nevada and California; the clockwise rotation of the Sierra-Cascade arc to the south-west by over 400 km; and the clockwise rotation of many tectonic blocks, including the Transverse Ranges of California. By the Miocene, all of these regional events (Basin and Range extension, Sierran rotation; cessation of southern volcanism; and Transverse Ranges rotation) were well developed and approaching their modern condition.

Miocene

J M Theodor, Illinois State Museum, Springfield, IL, USA

Introduction

The Miocene (23.8–5.3 Ma) is the interval during which the world began to assume much of the configuration and topography we know today. Major tectonic changes in North America uplifted the Coast Ranges, formed the Basin and Range, and saw the evolution of the San Andreas Fault Zone. In Eurasia, the ongoing collision of India and Asia elevated the Tibetan Plateau, drastically altering global atmospheric circulation patterns. In South America, global atmospheric and oceanic circulation were greatly affected by the uplift of the Andes and the closure of the Panamanian seaway, in ways that persist to this day. The Miocene separation of Australia and Antarctica altered oceanic circulation patterns, changing the prevailing currents off Europe. In Africa, the development of the Great Rift Valley formed the environments that were home to the early hominids (*see* **Fossil Vertebrates:** Hominids). Much of the flora and fauna of the Miocene belong to groups that are still living today, but several groups experienced large radiations during this time interval, such as the whales and the snakes. Two major ecosystems – grasslands and kelp forests – evolved during the Miocene. These changes form the foundation for modern conditions.

The Miocene Epoch is the fourth subdivision of the Tertiary Period. In 1828, Sir Charles Lyell (*see* **Famous Geologists:** Lyell) noticed that different layers of rock in Europe contained different proportions of living and extinct species of marine molluscs. Concluding that the variation in this proportion indicated that the rock layers were formed at differing times, and assuming that the higher the proportion of living to extinct species, the more recently the layer was laid down, he defined three epochs – the Eocene (Dawn Recent), Miocene (Middle Recent), and Pliocene (More Recent), where the transitions between epochs were specified as a given percentage of living to extinct species.

Because the species composition of a rock layer can vary depending on the type of depositional environment, geologists no longer use this definition, and rely on other methods. Two specific, internationally recognized localities (also known as stratotypes) are currently designated as being the boundaries of the Miocene for international correlation. The base, or start, of the Miocene is defined at the Lemme Carrosio section in the upper part of the Rigoroso Formation in northern Italy. The base of the Pliocene – which is also, by definition, the end of the Miocene – is defined at the base of the Trubi Formation in the Evaclea Minoa section, on the southern coast of Sicily (*see* **Tertiary To Present:** Pliocene).

Geochronology

The European Miocene is generally divided into six marine stages (oldest to youngest): the Aquitanian, Burdigalian, Langhian, Serravallian, Tortonian, and Messinian (Figure 1). Terrestrial fossils in Europe have generally been associated with these marine stages as European marine rocks interfinger with terrestrial deposits, thus allowing a clear correlation between terrestrial and marine units. However, a number of more isolated fissure-fill localities are more difficult to correlate. As a result, two other systems based exclusively on terrestrial mammals have been developed, the European Land Mammal Ages (ELMAs) and the Mammalian Neogene Reference Level system (MN Zones).

In North America, there are fewer localities with interfingered marine and non-marine beds, but many units are associated with strata that can be radioisotopically dated. The majority of these deposits are correlated using mammalian biostratigraphic units. The North American Land Mammal Ages in use for the Miocene include the Arikareean, Hemingfordian, Barstovian, Clarendonian, and the Hemphillian. Most of these are well associated with radioisotopic dates and/or paleomagnetic assessments.

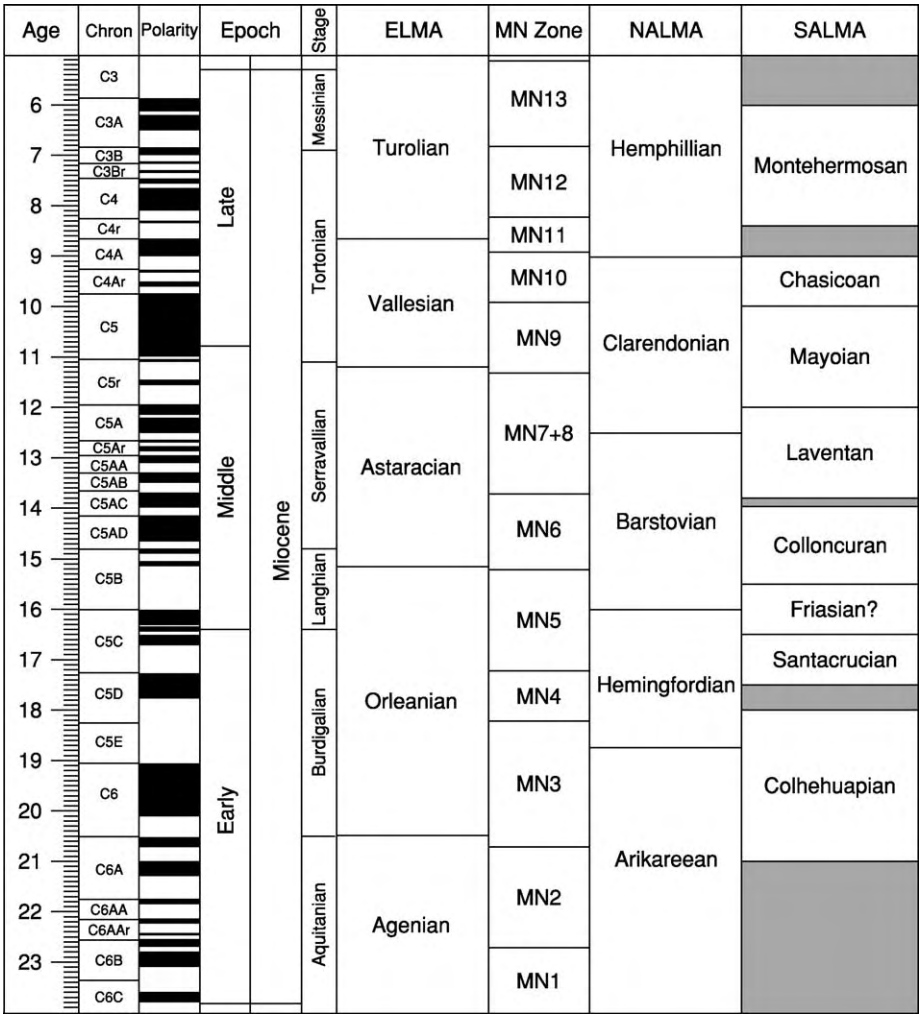

Figure 1 Chronostratigraphical correlation chart for the Miocene. ELMA European Land Mammal Age, MN Mammalian Neogene Reference Level Age, NALMA North American Land Mammal Age, SALMA South American Land Mammal Age.

Many regions are not as well described as Europe and North America. The South American Miocene Land Mammal Ages include the Colhehuapian, Santacrucian, Colloncuran, Friasian, Laventan, Mayoan, Chasicoan, Huayquerian, and Montehermosan. Some of these intervals are poorly constrained in terms of absolute ages. Asian and African faunas do not yet have a well-established system of named ages in use, but much work is being done to establish such a framework. The Australian Miocene can be correlated to the other continents using pollen and marine fossils, but the mammals are so different from those on other continents that they are not used in correlation outside of that continent.

Tectonics

Continental position During the Miocene, the continents moved into positions very close to their modern configuration (Figure 2). By the mid-Miocene, as Australia moved away from Antarctica, the modern oceanic circulation pattern was established. Miocene tectonic changes resulted in the creation of numerous important features of modern continental topography.

North America

North America underwent a complex sequence of tectonic events throughout the Cenozoic. A number of events occurred during the Miocene which combined to shape much of the landscape familiar to us today.

East Pacific Rise Spreading at the East Pacific Rise continued during the Oligocene, causing the complete subduction of the Farallon Plate near Los Angeles by 30.0 Ma, leaving two remnants to the north and south still undergoing subduction. By the Early

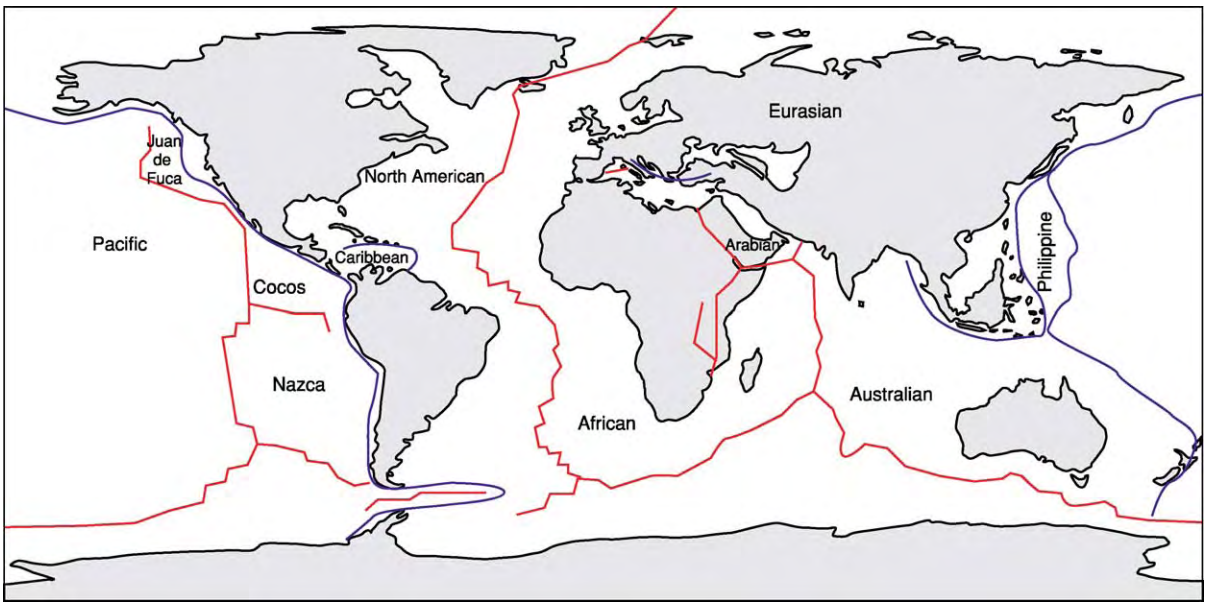

Figure 2 Palaeogeographical reconstruction of Miocene plate configurations and continent dispersions.

Miocene, most of the remaining Farallon Plate had been subducted under the North American Plate, bringing the Pacific Plate into contact with the North American Plate in southern California. The remaining two sections could no longer be considered a single plate by this time, and are henceforth regarded as independent plates with unique motions. The Juan de Fuca Plate is found to the north off the coast of Oregon and Washington and the Cocos Plate to the south off the coast of Mexico. Both continue to be subducted under the North American Plate. The contact of the Pacific, North American, and Juan de Fuca plates formed a triple junction at Mendocino, California by 20.0 Ma. During this transition, the subducting plate margin disappeared and the contact between the Pacific and North American plates developed into a transform fault system because the Pacific Plate is moving to the north, while the subducting Farallon Plate was moving more directly eastward. This transform fault system, which separates Baja California from the rest of California, runs under the continent between San Francisco and Los Angeles. The transform faulting formed along the Central Valley of California is known today as the San Andreas Fault Zone, and was in place by about 10.0 Ma.

Rocky Mountains The subduction of both the Farallon Plate and the more northerly Kula Plate are partially responsible for the character of the Rocky Mountains, which began their final uplift phase during the Miocene. The Farallon Plate was subducted under the North American Plate at an unusually shallow angle. This caused uplift of the Rockies in the western US and Mexico by compression, and probably caused some extension in the crust as the slab sank. By contrast, the Juan de Fuca and Kula plates were subducted at a much steeper angle (closer to 45°), resulting in more typical thrusted sedimentary sheets through the Canadian Rockies.

Basin and Range Changes in the continental crust to the west of the developing Rocky Mountains are poorly understood, but the thin crust in this region is evidence that this area became extended between 15.0 and 8.0 Ma. Crustal extension resulted in a series of faults that trend north–south, with dropped fault blocks (grabens) forming flat valley floors in between raised blocks (horsts). Erosion of the nearly 400 alternating mountain blocks formed the characteristic basin and range topography of the modern western United States.

Columbia River Flood Basalts From 17.0 to 15.5 Ma, a tremendous volume of volcanic rock was deposited in north-eastern Oregon, south-eastern Washington, and western Idaho, from at least 300 lava flows, some of which reached as far as the Pacific Ocean. The Columbia River Flood Basalts cover 164 000 km^2 and are situated between the Rocky Mountain and Cascade Ranges. The cause of these volcanic eruptions is complex and is tied to: (i) extension and thinning of the crust; (ii) formation of the Cascade Range; and (iii) the position of the Yellowstone hotspot (a mantle plume). Most flood basalt provinces are directly tied to a mantle hotspot, but the Yellowstone

hotspot was 300–400 km south of the flood basalt vents, and the basalt composition differs from classic hotspot flood basalts, indicating a more complex tectonic origin. The numerous basalt beds allow for precise radioisotopic age assessments for this area during the Middle Miocene.

Cascade and Sierra Nevada Ranges There is some evidence that these volcanic mountain ranges experienced a pulse of uplift beginning in the Late Miocene. Because there is also some evidence of uplift in the Coast Ranges at this time, it is possible that there was uplift of the entire north-western Cordilleran coast range. This uplift might have been a result of changes in plate motion, or of plate delamination and subsequent crustal rebound.

Central and South America

Two major events affected the topography of Central and South America during the Miocene, both of which had profound climatic and biogeographic effects: the beginning of closure of Panamanian seaway and the uplift of the Andes.

Isthmus of Panama The closure of the Panamanian seaway began at almost 13.0 Ma, with the gradual emergence of the Isthmus of Panama as a result of ongoing changes in tectonics and sea-level. The emergence of the isthmus resulted in separation of North and South America, and resulted in profound changes in Caribbean oceanic circulation in the Pliocene, cutting off circulation between the Atlantic and Pacific oceans. These drastic changes in oceanic circulation resulted in massive changes in oceanic heat transfer. The isolation of the Atlantic Ocean also helped produce the warm Gulf Stream current that today maintains warmer temperatures in northern Europe relative to other locations at the same latitude. It is probable that this change also affected northern-hemisphere glaciation.

Andes The major topographic feature of South America is the Andes Range, which provides a barrier to atmospheric circulation and creates a large rain shadow desert on its eastern margin. The Andes are unique because they formed at a non-collisional plate boundary. Crustal compression of the Andes region began in the Triassic, but by in the Early Miocene (~20.0 Ma) the majority of the range had reached only 25% of current elevation. By the later Miocene, the range had reached ~50% of the modern elevation, and uplift continued. The tectonic history of the Andes is complex and not yet well understood (*see* **Andes**).

Eurasia

The tectonic history of Eurasia is somewhat less complex than that of North America. Nevertheless there were several important Eurasian tectonic events that occurred during the Miocene.

Himalayas and the Tibetan Plateau Earlier in the Cenozoic, the northward plate motion of India brought that continental plate into contact with Eurasia (*see* **Indian Subcontinent**). The resulting continent-continent collision continued through the Miocene, causing uplift of the Himalayas, and, beginning in the Early–Middle Miocene, resulted in uplift of the Tibetan Plateau. This uplift exposed a considerable volume of carbonate rock to weathering, which is thought have affected global atmospheric CO_2 levels.

Messinian salinity crisis Considerable evidence from thick deposits of halite and anhydrite beneath the Mediterranean Sea indicate that, beginning at 5.96 Ma, the Mediterranean basin was repeatedly cut off from oceanic input and became a drying salt lake (Lago Mare) system. This dry-Mediterranean interval is termed the Messinian Salinity Crisis. It continued until 5.33 Ma, when the modern opening at the Strait of Gibraltar restored marine conditions. The cause of this Messinian Salinity Crisis is unclear. The likely major causes include several tectonic changes and a global decline in sea level of ~60 m as a result of glaciation. The most recent data favour a tectonic explanation, in which changes in the subduction of oceanic lithosphere of the Tethyan Ocean caused upwelling in the asthenosphere, resulting in uplift and consequent isolation of the Mediterranean Basin (*see* **Europe:** Mediterranean Tectonics).

Africa

During the Miocene, Africa, which had previously been relatively tectonically stable, underwent a series of tectonic changes as a result of the formation of a new spreading ridge running through the eastern edge of that continent. In the early part of the Miocene, the Afro-Arabian Plate moved north, contacting the Eurasian Plate. This contact reduced the size of the Mediterranean and may have contributed to the Messinian Salinity Crisis by reducing the amount of water available for rainfall and thus increasing aridity.

By the Early Miocene, uplift had begun in southern and eastern Africa, creating a rain shadow over eastern Africa. Around 18.0 Ma crustal extension from the spreading ridge began to take place along the East African Rift Valley, which forms one arm of the Afar Triple Junction – the other arms being the Gulf of

Aden and the Red Sea. Extension caused faulting and the formation of a horst-graben topography in the rift valley. This process fragmented the habitats of the rift valley, breaking up forest, increasing the diversity of the terrain and vegetation, and leading to the formation of numerous lakes along the valley floor. These lakes, such as Lake Turkana, provided drinking water and habitat for the early ancestors of humans. The lakes also provided better opportunities for preservation in the fossil record, which is much less likely in densely vegetated forest.

Climate

Sea-level Miocene sea-levels were generally higher than those of the modern day, and are tied to glaciations in Antarctica. During the Miocene, oceanic circulation patterns were strongly affected by the evolution of the circum-Antarctic current as Antarctica separated from Australia. This separation thermally isolated Antarctica and drastically altered global marine and atmospheric circulation.

In North America, much of the south-eastern United States was covered by shallow seas. The Early Miocene saw three major episodes of deposition of oceanic phosphorus, especially in eastern North America, when much of the eastern coast was underwater. These periods (21.0 to 20.0, 19.0 to 18.0, and 17.0 to 16.0 Ma) are likely to have been responses to global changes in sea-level, oceanic upwelling, and deep water currents, and may be related to the ongoing uplift and erosion of the Tibetan Plateau. Later in the Miocene (~6.0 Ma) sea levels dropped as much as 60 m because of glaciation, a drop which probably contributed to the Messinian Salinity Crisis.

Atmospheric CO_2 Early models of atmospheric CO_2 indicated that levels in the earlier Miocene were roughly double those of modern, pre-industrial times. However, more recent measurements of geochemical signatures (e.g., boron isotopes, plant alkenones) from marine sediments indicate that Early Miocene CO_2 levels were much lower. This is important because the hypothesised decline in the middle Miocene CO_2 levels have been thought responsible for the rapid spread of grasses that use the C4 photosynthetic pathway at that time. Plants that use only one enzyme to bind CO_2 in the chemical reactions of photosynthesis are termed 'C3' plants. However, this enzyme will also bind O_2, forming a compound that is harmful to the plant. At low concentrations of atmospheric oxygen this is not a significant disadvantage to C3 plants. The C4 pathway prevents these compounds from forming, but produces slightly less energy for the plant. At lower CO_2 levels, the C4 photosynthetic pathway is favoured, and it is generally assumed that the C4 pathway would only have evolved in intervals with lowered CO_2. The evolution of the C4 pathway allowed grasses to spread greatly during the Miocene, forming extensive grassland ecosystems for the first time.

Atmospheric CO_2 is a product of a number of different factors. One factor that is hypothesised to have affected global Miocene CO_2 levels is the uplift and subsequent erosion of the Tibetan Plateau, which is thought to have consumed massive amounts of atmospheric CO_2 as a result of limestone weathering.

Temperature and seasonality Global temperatures and seasonality are inferred from three sources: the ratio of oxygen and carbon isotopes measured in the skeletal fossils of benthic and microscopic planktonic organisms living in the ocean, and from the types of land plant fossils and the shapes of their leaves. Ice-rafted debris in the South Pacific indicates that Antarctic glaciation intensified at ~24.0 Ma. This was followed by a long warming interval, reaching a climax (Mid-Miocene Climatic Optimum) at ~15.0 Ma, with some brief episodes of glaciation in Antarctica. The warm interval was generally a continuation of Oligocene warm, temperate to sub-tropical conditions. Evidence from terrestrial floras indicates a mean annual temperature range from 11°C to 17°C in the northern United States during the Climatic Optimum, with the first grass macrofossils being found in the Great Plains. Following the Climatic Optimum, global temperatures decreased as the Antarctic ice sheets returned, and aridity increased in terrestrial ecosystems. In North America, temperatures warmed again ~8.0 Ma. A major glacial advance marked the end of the Miocene, resulting in lowered sea-levels.

Marine Life

Although the species found in the Miocene are largely extinct, most of the residents of Miocene oceans would be familiar to us, as they belong to modern groups of organisms (e.g., corals, bivalves, sharks, whales, sea cows). One major change in the oceans during the Miocene was the evolution of the kelp forest ecosystem. Fossil kelps and associated animals are known from the mid-Miocene Monterey Formation in southern California, their first appearance in the fossil record. Another important ecological development was the evolution of algal ridge formation on coral reefs by coralline algae. Earlier, coralline algae had formed parts of coral reefs, but had not formed these ridges, which protect living reef systems from heavy surf conditions. The appearance of the algal ridge systems allowed the expansion of coral reef

systems into more coastal environments. During the Miocene, there was also a large radiation of species of whales and dolphins, including the first appearance of the sperm and baleen whales.

Terrestrial Life

Most of the animals present in the Miocene in North America and Eurasia, and to some extent, Africa, would be generally familiar to the modern eye, as they also belong to extant groups, even though the particular species are extinct. However, many groups were living in regions they no longer occupy today. For example, although North America lacked many groups of mammals currently found there (e.g., pigs), various species of camels and proboscideans were common components of North American Miocene faunas. These three continents had sufficient connections so that animals and plants could migrate between them at various times during the Miocene. By contrast, Australia and South America were island continents during this time interval, and their vertebrate faunas evolved in virtual isolation. Large groups of species that evolved on these continents are extinct, with no extant relatives.

Plants

In the earlier part of the Miocene, up to the time of the mid-Miocene Climactic Optimum, broad-leafed evergreen vegetation and coniferous forest were broadly distributed, and broad-leafed deciduous forest was reduced in area. Cooling and drying in global climates resulted in the establishment and spread of savannahs and grasslands at the expense of forested ecosystems.

By 20.0 Ma, all the families of plants present in the fossil record belong to families still living today. By 10.0 Ma all the modern genera were present. Thus, the Miocene vegetation was composed of familiar elements, although the vegetational structure and distribution were different from their modern states.

Early in the Miocene, forests were widespread. As climate warmed, up until the time of the mid-Miocene Climactic Optimum, broad-leafed evergreen forests (similar to the type found in modern tropical forests) spread to higher latitudes. During the subsequent cooling, broad-leafed evergreen forests contracted their range, giving way to the spread of broad-leafed deciduous forests, and in higher latitudes, evergreen coniferous forests.

Although grass pollen is present in the fossil record much earlier than the Miocene, fossil remains of grass plants are rare elements of the flora until the Middle Miocene. During the Middle and Late Miocene, species diversity in the grasses increased dramatically, and evidence of more open savannah ecosystems appeared in arid regions. The greatest increases in grass diversity were among the groups of species utilising a C4 photosynthetic pathway. This has been interpreted as response to increasing aridity during the later Miocene and possibly as a response to decreasing levels of atmospheric CO_2. The spread of grasslands was facilitated by climactic cooling and drying, particularly as seen in rain shadows created by uplift in the Cordilleran regions of the Americas.

Animals

The fossil record of terrestrial animals in the Miocene is variable. The limited fossil record of insects shows that most of the modern genera were present by the Miocene.

The reptile fauna worldwide was generally similar to that of today, although the Miocene is characterized by a major radiation in the snakes. This snake radiation seems to be a response to the diversification of small mammals, especially murid rodents (rats and mice) during this time.

The Miocene also saw diversification of many groups of birds, especially the dominant modern group of songbirds, the passerines. The modern genera of owls also appeared during the Miocene, along with the appearance of daytime predators such as falcons, hawks, and eagles. Several species of very large vulture-like predators (vultures and teratorns) appeared in the Miocene in the New World, probably evolving in response to the evolution of large herbivores living in open grasslands.

In the island continents of South America and Australia, a number of flightless forms evolved, and in South America one family, the phorusrhachids, was an important terrestrial predator. By the Middle Miocene, the modern ostrich *Struthio* had appeared in Africa.

North America The Miocene mammalian history of North America is documented by a rich and well-dated fossil record, including 31 families of mammals. In the Early Miocene, faunas are dominated by ungulates: the even-toed artiodactyls, including oreodonts, camels, and peccaries, and a new family, the cervids (deer and their allies); and the odd-toed perissodactyls, with numerous species of horses, rhinos, tapirs, and a now-extinct family, the large, clawed chalicotheres. Carnivores increased in diversity in the Early Miocene, with increases in the canid (dog), ursid (bear), and amphicyonid (extinct bear-dog) families. Rodent diversity increased in the geomyids (gophers), sciurids (squirrels), and castorids (beavers). At the time of the Middle Miocene Climatic Optimum, ungulate diversity was much higher than it is today, with a much higher proportion of browsing (leaf-eating) species

than known in any ecosystem today, where ungulate faunas are dominated by grazing (grass-eating) mammals. By the Late Miocene, many browsing ungulate species had become extinct.

The Miocene was also punctuated by interchanges with Eurasia. In the Early Miocene, the first of two pulses of immigration across the Bering Land Bridge brought antilocaprids (pronghorn) and mustelids (weasels and skunks) to North America. The first proboscideans (elephant relatives) appeared ~16.0 Ma, and 11.0 Ma the horse *Cormohipparion* arrived in Europe from North America.

Eurasia The Early Miocene mammalian faunas of Europe are not well differentiated from earlier Oligocene faunas. Proboscideans immigrated to Europe from Africa by 18.0 Ma, and by 17.5–15 Ma dispersal routes connected Europe with Asia, Africa, and North America, bringing the horse *Anchitherium* and the chalicotheres to Europe in the Early Miocene. A major immigration (~15.0 Ma) brought the bovids (cattle) and suids (pigs) to western Europe from western Asia and Africa. The later Miocene of Eurasia is characterized by a diverse open country woodland fauna, which included horses, rhinos, bovids, felids (cats), hyaenids (hyaenas), and proboscideans.

The fauna from southern Asia is known primarily from the Siwalik sequence of Pakistan, and differs from European and western Asian faunas. The Pakistani faunas contain more primates and omnivorous artiodactyls, and fewer browsing ungulates than in western Asia, and a number of archaic groups persisted there. About 9.5 Ma, large giraffids (giraffes), suids (pigs), and new horses emigrated from Eurasia. Around 7.4 Ma, the fauna experienced turnover, and at the same time, soil carbonate measurements indicate a shift in the ecosystem away from plants using the C3 metabolic pathway to grasses using C4 pathways, indicating a shift in environment to a drier climate.

Africa The Early Miocene of Africa was a time of faunal transition, as 29 new families appeared during this time interval. The fauna at this time consisted of endemic proboscideans, creodont carnivores, hyraxes, giraffids, bovids, and aardvarks evolved early in the Miocene. Perissodactyls arrived from Eurasia in the form of rhinos and chalicotheres; archaic suid artiodactyls (pigs) represented the artiodactyls, with viverrids (civets) and felids representing the carnivores.

During the Middle Miocene, the bovids radiated and came to dominate the African ungulate fauna, and the hippos evolved. The first horse, *Anchitherium*, emigrated from Eurasia, along with mustelid and hyaenid carnivores. The Late Miocene saw extensive interchanges with Eurasia.

South America The faunas from South America are comparatively alien, consisting of diverse marsupials, including large marsupial carnivores (borhyaenids), xenarthrans (armadillos, glyptodonts, sloths) and a large number of extinct endemic animals, mostly ungulates, including the large toxodonts, which resemble hippos, rabbit-like hegetotheres, and the camel and horse-like litopterns. In the Early Miocene, two groups entered South America, probably by waif dispersal from Africa. These were the New World monkeys and the caviomorph rodents (guinea pigs, porcupines). Rodents were the only placental mammals in South America until the Pliocene, and they radiated into 16 families. Six to eight million years ago the first true carnivore, a procyonid (raccoon) entered South America, and around the same time, a sabre-toothed marsupial carnivore, *Thylacosmilus*, evolved. This fauna was to change tremendously in the Pliocene, when full-scale interchange began with North American faunas.

Australia As in South America, the Australian fauna was entirely isolated from other continents, and a highly endemic fauna evolved from the original mammalian stock, consisting of marsupials and monotremes. During the Miocene, the climate in Australia was much wetter than it is today, as evidenced by the Riversleigh fauna. Riversleigh dates to ~15.0 Ma, and the fauna includes the marsupial wolf (thylacine) and marsupial lion *Wakaleo*, quolls, possum-like marsupials, early kangaroos and diprotodonts, a group of large herbivorous marsupials. Wombats and koalas are first known from the Miocene. Around 6.0 Ma, Australian environments became much more arid, and many animals like the koalas adapted to eating tougher vegetation.

Glossary

C4 photosynthetic pathway This photosynthetic pathway is used by many grass species. In most plants, called C3 plants, CO_2 is fixed in a chemical reaction using an enzyme called Rubisco. This enzyme binds CO_2 into a compound used in forming sugars during photosynthesis. Rubisco will also bind O_2, forming a compound that is toxic to the plant, a process known as photorespiration. When atmospheric oxygen levels were relatively low, the poor selectivity of Rubisco did not pose a problem for C3 plants, but as carbon dioxide levels declined relative to oxygen levels, photorespiration would have posed a challenge. C4 plants have evolved a mechanism where an additional reaction using a more selective enzyme binds CO_2 into another compound, which is

sequestered in the plant tissues. This compound can then be broken down and the CO_2 passed to Rubisco away from the presence of oxygen, so that little photorespiration can occur.

Chalicotheres An extinct group of perissodactyls, in the family Chalicotheriidae. These animals were very large, with clawed feet. Some had very long forelimbs, and were probably bipedal, feeding on leaves from tall trees. They are known from the latest Eocene up to the Pleistocene.

Creodont carnivore The creodonts are an extinct group of carnivorous mammals. It was long thought that they were ancestral to the modern order Carnivora, but more recent work indicates they may not be close relatives. They looked somewhat dog-like, with slicing carnassial teeth similar to those of Carnivora. However, in Carnivora the carnassial teeth are the last upper premolar and first lower molar, and in creodonts the carnassial teeth are the upper first and/or second molars and the lower second or third molar.

Rain shadow Dry region on the leeward side of a mountain or mountain range. The rain shadow effect is caused when moist air rises against the windward slope and is lost to precipitation on the windward side, leaving little moisture on the leeward side.

Ungulate Hoofed mammals, such as the ariodactyls (cows, pigs, sheep, deer, etc.) or perissodactyls (horses, rhinos). The last phalanx, or ungual phalanx, of each toe in ungulates is modified with a thick hoof instead of a claw.

Viverrids The members of the extant carnivoran family Viverridae, the civets and mongoose, known today in Africa and Asia. Viverrids are small, arboreal and generally fruit-eaters.

Waif dispersal An unusual form of inter-continental dispersal across large bodies of water by terrestrial animals. In an episode of waif dispersal, one or several animals inadvertently travels between two continents on vegetation rafts, and populates the new region on arrival. Waif dispersal may be responsible for the arrival of monkeys into South America.

Pliocene

C Soligo, The Natural History Museum, London, UK

Introduction

The Pliocene is the second and terminal epoch of the Neogene period. It marks the end of the Tertiary and precedes the Pleistocene, the first epoch of the Quaternary period. The term Pliocene (from the Greek *pleiõn* 'more' + *kainos* 'new') was first proposed in 1833 by Sir Charles Lyell (*see* **Famous Geologists:** Lyell) in his *Principles of Geology*. His *Newer Pliocene* was characterized by a molluscan fauna, of which 90% of species were then extant, contrasting with the *Older Pliocene,* from which only 33–50% of molluscan species had survived. Lyell subsequently renamed his *Newer Pliocene* the Pleistocene.

The Pliocene was a time of substantial climatic change and, most significantly, saw the onset of northern hemisphere glaciation, marking the start of the modern-day cycles of glacials and interglacials. In contrast, the Pliocene was also the last period that sustained global temperatures that were (over a prolonged period of time) higher on average than at present. Fauna, flora and geography were also similar to the modern day. As such the Pliocene epoch holds particular promise for the modelling of potential effects of global warming on the modern world.

The tectonic processes and climatic variability that characterized the Pliocene had a lasting impact on the distribution and evolution of plants and animals. The emergence of a land bridge between the North- and South-American continents resulted in extensive biotic movements and profoundly changed the floral and faunal characteristics of South America. In Africa, meanwhile, the Pliocene saw the diversification of our evolutionary lineage, the Homininae, and the emergence of our own genus, *Homo* (*see* **Fossil Vertebrates:** Hominids).

Definition

The Mediterranean region has traditionally been the focus of stratigraphic research aimed at defining the boundaries of the Pliocene Series and its stages. Sometime towards the end of the Miocene, the Mediterranean Sea became isolated form the Atlantic Ocean. As a result, most of the Mediterranean basin dried out, an event that has been termed the Messinian salinity crisis. The start of the Pliocene is defined to coincide with the time when oceanic waters burst through the area of today's straits of Gibraltar, refilling the Mediterranean basin in a sudden catastrophic flooding event. The abrupt transition from evaporites, precipitated from the hypersaline waters of the drying Mediterranean, back to marls, representative of deposition under normal open-marine conditions, marks the stratigraphic start of the Pliocene series. The series is thus unusual in that its base is not located within a continuous marine sedimentation record, but rather marks the sudden return of open-marine sedimentation following a period of non-marine sedimentation. Since the formal acceptance and ratification of the *Gelasian* in 1996, the Pliocene series now consists of three stages (Table 1).

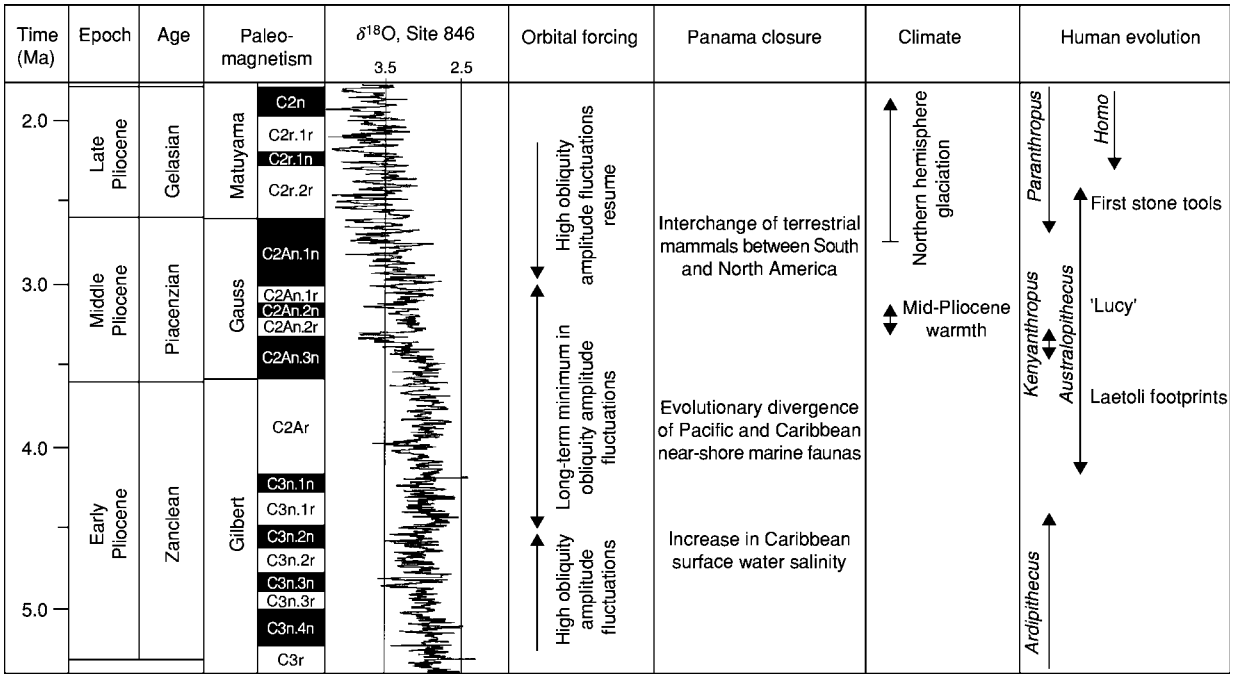
Zanclean (Lower Pliocene)

The Zanclean (from Zanclea, the classical name of Messina, Sicily) is the lowest stage of the Pliocene series. The Global Standard Stratotype section and Point (GSSP) for the Zanclean is located in the Eraclea Minoa section on the southern coast of Sicily (37°23′30″N; 13°16′50″E). The basal contact of this stage is where white Trubi Marl rests on dark brown Arenazzolo sands and marls. The base of the carbonate bed marking the small-scale Cycle 1 at the base of the stage corresponds to insolation Cycle 510 counted from the present, with an astrochronologic age of 5.33 Ma. Other tools for the global correlation of the base of the Zanclean stage include the base of the Thvera magnetic event (C3n.4n), dated to 5.236 Ma, coccoliths (the first occurrence of *Ceratolithus acutus* 5.37 Ma, the last occurrence of *Triquetrorhabdulus rugosus* 5.23 Ma and the last occurrence of *Discoaster quiqueramus* 5.537 Ma), and foraminifers (the first occurrences of *Globorotalia tumida* and *G. sphericomiozea* 5.6 Ma).

Piacenzian (Middle Pliocene)

The GSSP for the Piacenzian stage (after the town of Piacenza, Northern Italy) is located in the Punta Piccola section on the southern coast of Sicily (37°17′20″N; 13°29′36″E). The base of this stage is the base of the beige marl bed of the small-scale carbonate Cycle 77 and corresponds to the precessional excursion 347 counted from the present. Its astrochronologic age is estimated at 3.60 Ma. Further tools for the global correlation of the Piacenzian base include the Gilbert–Gauss magnetic reversal dated to 3.596 Ma and the location of the base within the obliquity-related $\delta^{18}O$ stage MG8 (O–176). Other correlation tools are geographically more restricted: within the Mediterranean region

Table 1 Composite table of Pliocene trends and events. $\delta^{18}O$, Site 846, from Shackleton *et al.*, 1995. *Proc ODP, Sci Results* 138: 337 355



the temporary disappearance of *Globorotalia puncticulata* (3.57 Ma), the first influx of *G. crassaformis*, the end of the paracme interval of *Discoaster pentaradiatus* (3.56 or 3.61 Ma) and the last occurrence of *Sphenolitus* spp. (3.73 or 3.70 Ma); in low- and mid-latitudes outside the Mediterranean, the last occurrences of *Globorotalia margaritae* (3.58 Ma) and of *Pulleniatina primalis* (3.65 Ma).

Gelasian (Upper Pliocene)

The Gelasian (after the town of Gela, Sicily) has only recently been ratified as the uppermost stage of the Pliocene series thereby establishing a threefold division of the Pliocene. The GSSP for the Gelasian stage is located in the Monte San Nicola section around 10 km N-NW of Gela in southern Sicily (Italy). The defined base of the Gelasian is the base of the marly layer overlying the Mediterranean Precession Related Sapropel (MPRS) 250 at 62 m in the Monte San Nicola section. The astrochronologic age of MPRS 250 (corresponding to precessional cycle 250 from the present) is 2.588 Ma. Other correlation tools include the Gauss–Matuyama boundary 20 Ky below the Gelasian base, nannofossils (last occurrences of *Discoaster pentaradiatus* and *D. surculus* 80 Ka above the base in most low- and mid-latitude areas) and foraminifers (last occurrence of *Globorotalia bononiensis* [*G. puncticulata* of some authors] 140 Ka above the boundary in the Mediterranean and North Atlantic). The last occurrence of *Stichocorys peregrina* (Radiolaria), the first occurrence of *Nitzschia joussaea* (Bacillariophycaceae/Diatomeae) in low-latitudes and the last occurrence of *Denticulopsis kamtschatica* (Bacillariophycaceae/Diatomeae) in the North-Pacific mid- and high-latitudes all approximate the Gauss–Matuyama boundary. The base of the Gelasian predates by 60 Ky the isotopic cold stage 100, which is marked by an increase in ice-rafted detritus in northern latitude oceanic sediments and the beginning of loess sedimentation in China. This base is also marked by changes in vegetation distribution patterns and continental vertebrate migrations (see below).

The end of the Pliocene series, of the Neogene and of the Tertiary period is determined by the Pliocene–Pleistocene boundary. The formal definition of that boundary has been the source of intense debate amongst stratigraphers. The currently validated Global Standard Stratotype Sections and Points (GSSP) for the base of the Pleistocene is located in the Vrica Section 4 km south of Crotone in southern Italy, just above the Olduvai subchron at an age of ~1.8 Ma.

Tectonics

The gradual formation of the isthmus of Panama(the land bridge connecting South and North America) cut off the Pacific Ocean from the Atlantic during the course of the Pliocene. The resulting rearrangement

of ocean currents profoundly influenced global climates. The isthmus formed as a result of a complex combination of lithospheric plate movements, which involved a north-western drift of the South American Plate and eastern drift of the Caribbean Plate. The gradual closure of the isthmus started during the Middle Miocene. By the Early Pliocene (4.6 Ma), it was advanced enough to affect deep-ocean circulation significantly. By 3.5 Ma the closure had progressed to the extent that evolutionary divergence had taken place between the Pacific and Caribbean shallow-water mollusc faunas. Evidence from nannofossils indicates that, between 3.65 and 2.76 Ma, the westward current between Caribbean and eastern Pacific ceased to exist while a northward intra-Caribbean current was established (Figure 1). However, the interchange of terrestrial mammals between the North and South American continents may have been delayed to 2.7 Ma, coinciding with the intensification of northern hemisphere glaciation and the associated sea-level drop. The substantial impact that the gradual shoaling of the Panama isthmus had on marine biota is exemplified by the observation that extinction rates of Pliocene molluscs in the western Atlantic and Gulf of Mexico were, on average, twice those in the eastern Pacific.

Other tectonic activities continued previous trends. In Africa-Arabia relative movements of the Nubian, Somalian and Arabian plates caused continued rifting along East Africa and initiated sea-floor spreading in the Red Sea. Many areas worldwide are thought to have undergone significant uplift throughout the Pliocene. Some of the most prominent areas being the South American Andes, the North American Sierra Nevada and Cascade Range, the African Atlas, the European Pyrenees and Alps, and the Himalayas and Tibetan Plateau in Asia.

The increased height of a large number of mountain ranges across the globe had a significant impact on local climates and may have influenced global climate. For example, the uplift of the Himalayas and Tibetan plateau, caused by the northward drift of the Indian plate and its crashing into the Asian plate, has been instrumental in shaping Asian climates at least since the Miocene. Continued uplift of northern and eastern parts of the Tibetan plateau have been linked to an intensification of both the summer and winter East Asian monsoons during the Middle Pliocene, 3.6–2.6 Ma. Increased volcanism is also likely to result from an increase in mountain building activity and a distinct increase in the frequency and thickness of tephra layers in ocean sediments from the Pliocene and the Quaternary support the notion of widespread orogenic activity during those periods. However, the absence of an obvious mechanism to underlie a global uplift of distinct

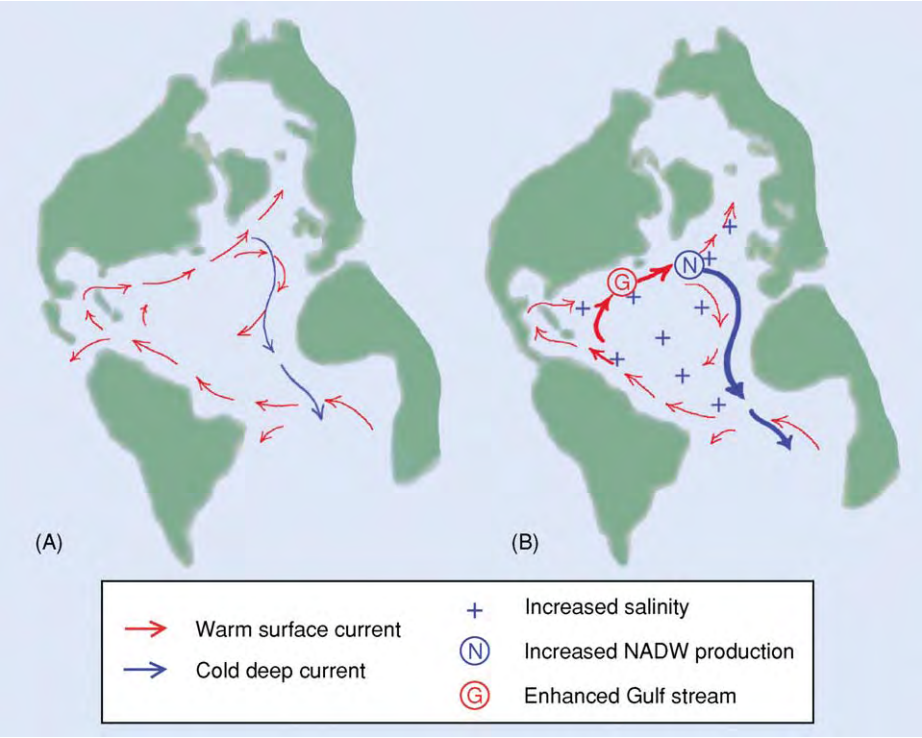


Figure 1 Atlantic marine currents before (A) and after (B) the emergence of the isthmus of Panama, showing intensified thermoha line circulation after the closure of the central American seaway. NADW: North Atlantic deep water.

mountain ranges of very varied ages has led some experts to question the existence of wide-ranging Plio-Quaternary uplift and to evoke the possibility that changes in climate have instead created the illusion of widespread uplift. Increased rates of erosion are widely cited as evidence for increased elevation gradients, but increased rates of erosion have also been associated with changes in global climate patterns, in particular with the enhancement of rainfall seasonality or the onset of rapid climatic oscillations in the later Pliocene.

Climate

The Pliocene was a time of profound climatic change. Starting with generally warm conditions up to the end of the Zanclean when global temperatures declined, resuming the trend of overall Cenozoic cooling. A subsequent phase of global warming, the 'mid-Pliocene warmth' (3.3–3.15 Ma) has been well documented and is a continued focus of intensive research due to its relevance to the prediction of future global warming events. The cooling that followed led to the northern hemisphere glacial-interglacial cycles, which continue to date. The onset of northern hemisphere glaciation was not synchronous. The first ice-sheets covered the Eurasian Arctic and north-east Asia by 2.75 Ma. Alaska became glaciated by 2.65 Ma, followed by the northeast American continent by 2.54 Ma. In terms of their potential to contribute to our understanding of the forces that drive and the consequences of global climatic change, the mid-Pliocene warm period and the onset of the modern ice age are of particular interest.

Mid-Pliocene Warming

With the exception of the last interglacial during which temperatures may have been briefly higher than today's, the period of mid-Pliocene warming (3.3–3.15 Ma) represents the most recent geological time span during which average global temperatures were higher than today's. Geography, flora and fauna of the mid-Pliocene were more similar to today's than during any other period of prolonged global warming. The mid-Pliocene, therefore, has the potential of providing the best indication of how the modern world may respond to future increases in global temperatures. Observational studies suggest that during the mid-Pliocene warmth sea levels were 20–40 m higher than today, the result of a reduced Antarctic ice-sheet area and the near complete absence of ice in the Arctic. Sea-surface temperatures were also substantially higher than today in the middle and higher latitudes. Warming was most pronounced in the north-eastern North Atlantic. Tropical sea-surface temperatures, however, were similar to those seen today.

Two basic factors have been suggested to explain the nature of Pliocene warmth: increased levels of atmospheric CO_2 (the greenhouse effect) and increased ocean heat transport. As increased atmospheric CO_2 is expected to increase temperatures globally and increased heat transport should result in a cooling of tropical waters, the reconstructed distribution of mid-Pliocene sea surface temperatures suggests that both mechanisms contributed to mid-Pliocene warming.

On land, there was a general shift of modern vegetation zones towards higher latitudes. Boreal forests occurred as far north as the Arctic coast, grading into temperate mixed-conifer and conifer-hardwood forest in the northern middle latitudes, and indicating the presence of temperatures that were much warmer than today in the Arctic regions of Iceland, Russia and North America as well as in western and central Europe. In contrast, some lower latitudinal areas may have seen temperatures drop below those of the modern day. The continental interiors of Africa, Asia and North America were more humid than they are today. Remains of pollen, leaves and wood of southern beech (*Nothofagus*) on Antarctica suggest a climate substantially warmer than at present. In the tropics, vegetation data point at temperatures lower than today in central America and East Africa, but warmer than at present in northern South America.

The Ice Age

The overwhelming climatic signature of the Pliocene is the increase in the levels of glaciation, and in particular the onset of large-scale glaciation of the northern hemisphere during the Middle Pliocene. At least three factors combined to initiate and sustain this glaciation. First, the overall trend of global cooling that prevailed through the Late Cenozoic ensured that precipitation over northern areas fell as snow rather than rain. Second, increased thermohaline circulation and Gulf Stream flow (a consequence of the closure of the isthmus of Panama) introduced the necessary moisture into far northern latitudes. Finally, a favourable Milankovitch orbital configuration between 3.1 and 2.5 Ma resulted in summers that were cool enough to prevent the snow from melting.

The onset of large-scale glaciation of the northern hemisphere is marked by an increase of $\delta^{18}O$ in benthic foraminifers between 3.0 Ma and 2.5 Ma and the appearance of substantial amounts of ice-rafted debris in the northern oceans from 2.7 Ma. The closure of the isthmus of Panama is likely to have

played a major role in the onset of northern hemisphere glaciation by redirecting surface currents within the Atlantic Ocean since 4.6 Ma and by influencing salinity levels. The resulting intensification of the Gulf Stream increased the transport of warm saline surface water to northern high latitudes and, consequently, the formation of North Atlantic deep water, which in turn, ensured increased import of warmer South Atlantic surface water into the northern hemisphere (**Figure 1**). Intensification of this marine 'conveyor belt' increased the potential for evaporation at high northern latitudes, thus supplying the additional moisture that would facilitate ice-sheet growth.

The gradual shoaling of the Panama isthmus and the associated changes in ocean currents and salinity gradients did not in themselves cause the onset of large-scale northern hemisphere glaciation. Initially, the enhanced Gulf Stream and increased transport of warm surface water into the high northern latitudes pushed global climates towards warmer conditions, culminating in the mid-Pliocene warm interval. The emergence of the Panama isthmus contributed significantly to creating the necessary preconditions for the initiation of large-scale northern hemisphere glaciation. However, other factors may have been involved (e.g. deepening of the Bering Straits, increased river discharge of fresh water into the Arctic Ocean from the Palaearctic). Continued Pliocene uplift or rejuvenation of various mountain ranges and plateaus across the world has also been suggested as a cause for the deterioration of Late Neogene climates. Invoked mechanisms include the influence of high elevation areas on atmospheric circulation as well as the reduction of atmospheric CO_2 concentrations through the weathering of newly exposed silicates and the resulting formation of carbonates, the increased burial of organic carbon due to increased rates of erosion, or increased ocean productivity through an increased delivery of phosphorus to the ocean, again as the result of increased erosion.

It is likely that several of these factors combined to create the preconditions necessary for the onset of northern hemisphere glaciation. The ultimate trigger, however, lay with the nature of fluctuations in the Earth's obliquity (*see* **Earth:** Orbital Variation (Including Milankovitch Cycles)). Low tilt angles of the Earth's rotational axis result in cold northern hemisphere summers. Just prior to the onset of northern hemisphere glaciation, 4.5–3.1 Ma, there was a prolonged period during which the amplitude of Earth's obliquity fluctuated only minimally. Records of $\delta^{18}O$ indicate that during this time, limited glaciations of the Arctic were initiated several times, but failed to substantiate. From around 3.0 Ma the gradual increase of the amplitude of obliquity fluctuations set the final stage for the current pattern of pronounced glacial and inter-glacial periods, which have prevailed since the end of the Middle Pliocene.

Biotic Events

The Great American Interchange

The emergence of the isthmus of Panama in the Middle Pliocene resulted in the first contact of South America with another continent since the opening of the Drake Passage finalized its separation from West Antarctica toward the end of the Eocene. Having been rifted from Gondwanaland ~100.0 Ma and spent most of the Cenozoic in total isolation, South America was inhabited by a distinct biota with a large proportion of endemic taxa. In contrast, the North American continent had previously had a long history of intermittent connections and resulting floral and faunal interchange with the Old World.

The emergence of a permanent land connection between these two sub-continents resulted in a substantial level of terrestrial biotic interchange. However, not all taxa proved equally successful at dispersing and the biotas of the two sub-continents were not equally affected. With respect to long-term effects, the influence that southern taxa have had on North American biotas is near negligible. In contrast, the long-term effect that the great American interchange has had on the South American mammal fauna is substantial. Today nearly half of the families and genera of South American mammals are members of groups that emigrated from North America since the emergence of the Panama land bridge. This does not appear to be due to a substantially larger number of species initially dispersing from north to south as opposed to from south to north. In fact, when differences in source area are taken into account, the extent of north to south dispersal was similar to that from south to north. The difference in the proportions of modern representatives arose through the fact that North American immigrants to the south underwent substantial diversification in their new environments, whereas South American immigrants in the north did not. The reasons for the substantial differences in success rates between North American and South American immigrants are not clear.

Movements across the Panamanian isthmus were not restricted to mammals, but data for other groups are scarcer. For birds the available data suggest a net movement of taxa from north to south, whereas the majority of dispersals of reptiles and amphibians appear to have been from south to

north with significant levels of dispersal already occurring prior to the final emergence of the isthmus. In addition, while more than 90% of the angiosperm species of lowland rainforests in central America are estimated to be of South American origins, most montane plant species in South America have North American roots.

The Trans-Arctic Interchange

The Bering Strait between Siberia and Alaska initially opened during or just before the Early Pliocene. This new connection between the Arctic-Atlantic and the North-Pacific basins resulted in biotic movements referred to as the 'marine trans-Arctic interchange'. Data from invertebrates and algae suggest that, overall, and in line with the present prevailing currents, the trans-Atlantic interchange heavily favoured invasion from the Pacific to the Atlantic. However, data from before 4.8 Ma reveal the presence of Atlantic bivalves in the Pacific, whereas after 3.6 Ma North-Pacific molluscs suddenly became widespread in the North Atlantic. This confirms that, in accordance with existing models, currents through the Bering Straits flowed from north to south during the Early Pliocene, but were reversed some time between 4.8 and 3.6 Ma, probably as a consequence of the gradual closure of the central American seaway.

Other Biotic Movements

The emergence of the Panama land bridge and the opening of the Bering Strait resulted in a general intensification of marine currents. From a biotic perspective these also resulted in interchange between northern and southern temperate biota in the eastern Pacific and between temperate biota of the eastern and western Atlantic.

Plants

The Pliocene's climatic trends were reflected in the nature and distribution of plants worldwide. During periods of cooling, many areas saw a transition from broadleaved to coniferous woods or from closed to more open, grassy vegetations. Climate change evidently influenced the patterns of distribution of plants, but changes in the nature of the vegetation may in turn have influenced Pliocene climates. Around the Miocene to Pliocene transition, the biomass of plants using C_4 as opposed to C_3 photosynthetic pathways increased in Africa, Asia, North and South America, probably as a result of decreasing concentrations of atmospheric CO_2. The increase took place during the Late Miocene in the lower latitudes and during the Early Pliocene in the higher latitudes. However, some local environments remained C_3-dominated and no increase in the biomass of C_4-plants appears to have taken place in western Europe. The continued spread of C_4-plants during the Pliocene may have had a direct effect on global climates. Due to their shallower roots and their increased efficiency at CO_2 fixation, C_4-plants return less water from the soil to the atmosphere than C_3-plants. They thereby affect the hydrologic cycle and generally promote drier conditions downwind.

Hominin Diversification

In Africa, the Pliocene epoch saw the evolutionary diversification of the human lineage, the Hominidae (*see* **Fossil Vertebrates:** Hominids). Only three species of hominin are known from the Late Miocene. In contrast, up to 12 additional species (almost all from the eastern rift of the African rift valley and from South African cave sites) have been

described from the Pliocene to date (Table 2). Around 4.0 to 3.5 Ma a shin bone, probably of *Australopithecus anamensis*, and a series of fossilized footprints (Figure 2) provide the first clear evidence of bipedal walking. The most famous hominin fossil ('Lucy', an *Australopithecus afarensis)* lived just over 3.0 Ma and the oldest stone artifacts are known from the Middle to Late Pliocene transition, ~2.5 Ma. The Pliocene diversification of early hominins coincided with climatic fluctuations and a general trend towards more arid and less wooded habitats in eastern and southern Africa. The traditional view, however, that typical hominin features such as bipedality evolved as a direct response to the increased aridity and opening up of the East-African landscape is no longer considered valid. Recent palaeoecological reconstructions of early hominin environments generally point at wooded and well-watered habitats. Only with the advent of the genus *Homo*, around 2.5 Ma, can hominins be considered to have been fully adapted for life in open and arid environments. This is confirmed by data from marine sediments. Marine records show that the African climate saw an increase in aridity after 2.8 Ma, coinciding with the onset of large-scale glaciation in the northern hemisphere.

Before 2.8 Ma, variations in the intensity of the African monsoon were mainly the result of variations in low-latitude insolation due to Earth orbital precession and caused 19 Ka–23 Ka cyclical alternations between dry and wet conditions. After 2.8 Ma the African climate became sensitive to the increased amplitude of high northern latitude climate variations and the cycles changed to 41 Ka, paralleling the periodicity of the Earth's orbital obliquity variation and the Late Pliocene cycles of northern hemisphere glacials and interglacials. From 2.8 Ma, periodically cooler and drier conditions and the transition towards overall lower and more seasonal precipitation strongly favoured open savannah vegetation in east Africa. It is clear that the appearance and spread of open savannah cannot be considered to have contributed to shape the earliest evolution and diversification of the hominin lineage. Instead, it is more likely, that the gradual reduction of areas of humid and wooded habitat towards the Middle to Late Pliocene transition contributed to the disappearance of many taxa. In contrast, the emergence of the genus *Homo* coincided with substantial aridification of much of the African continent.

Pleistocene and The Ice Age

A Currant, The Natural History Museum, London, UK

Introduction

Pleistocene is the name given to the geological epoch succeeding the Pliocene and preceding the Holocene. It is usually taken as beginning about 1.8 million years ago and ending with the termination of the last major cold stage and the beginning of the Holocene warm stage, about 10 000 years ago, but the start of the Pleistocene has proved difficult to define. Together, the Pleistocene and the Holocene form the Quaternary Period. The Pleistocene is characterized by great global climatic instability, particularly from the onset of major, cyclic, northern hemisphere, terrestrial ice accumulations about 700 000 years ago. This later period is popularly known as the Ice Age.

The term 'Pleistocene' was first used by Charles Lyell in 1839 to denote the age of sediments in and around the London and Paris basins, in which 70% of the molluscan fossils were considered to represent species that are still alive today. The deposits in question were clearly related to the ancient courses of the Thames and the Somme. Lyell's original definition was of limited value. It was very much at the mercy of changes in opinion on molluscan identification and taxonomy and had extremely restricted geographical utility, but the name remained and has been the subject of almost continual redefinition since Lyell's time. The current global stratigraphic section and point (GSSP) for the start of the Pleistocene at Virca in Italy still has unresolved dating problems. The start of the epoch is widely believed to be between 1.65 and 1.8 million years ago, although some authors push this back as far as 2.5 million years. The environmental distinction between the Late Pliocene and the Early Pleistocene is actually quite difficult to pin down, and there was considerable faunal and floral continuity between the two.

Historical Studies

In global terms, the Pleistocene was dominated by the changing extent of ice volume. Although sea-floor spreading and continental drift continued throughout the period, the effect of these longer term processes has been dwarfed by ice-related phenomena. The history of our changing and growing understanding of the Pleistocene is important to anyone examining the older literature related to the period, particularly that which deals with the 'Ice Age'. The pioneer geologist and geomorphologist Louis Agassiz published works on his studies of Alpine glaciers and glacial processes, *Étude sur les Glaciers* (1840) and *Système Glaciare* (1847), in which he put forward the idea of there having been a great Ice Age in which large parts of Europe had been covered by ice and the surface of the land was greatly modified under its influence. Agassiz then went on to make similar observations based on his travels in North America. The subsequent history of Ice Age studies has been one of very gradual recognition that there were probably multiple Ice Age events, widely referred to as 'glacials', punctuated by warmer phases, with temperatures as warm as or warmer than those now prevailing, known as 'interglacials'. Numerous models of Pleistocene climatic events have been put forward, but the one that held sway for longest and was most widely adopted was that proposed in 1909 by Penck and Bruckner in *Die Alpen im Eiszeitalter*, in which the authors suggested there had been four major Ice Age stages, the Gunz, Mindel, Riss, and Wurm. This system, based on the terrace deposits of Alpine rivers, became adopted all over the world, and although local names often replaced the Alpine originals, the fourfold division of Pleistocene ice ages was accepted almost everywhere. The intervening interglacial stages became named after the cold stages that delimited them, i.e., Gunz-Mindel, Mindel-Riss, and Riss-Wurm.

It is important to recognize that the early understanding of Pleistocene events was based on hybrid data. Evidence for the cold glacial stages was largely

derived from characteristic sediments and landforms whereas evidence for the warmer interglacial stages came mainly from organic sediments and the fossils they contained. The stratigraphic relationship between glacial and interglacial sequences was often obscure and the means of correlating between isolated terrestrial sequences was poorly defined. The Alpine model of Ice Age events became to a very large extent a self-perpetuating system. Although a number of lines of evidence began to emerge suggesting much greater overall complexity, the lack of clarity in the original stage definitions and the virtual impossibility to establish secure interregional correlations led to such evidence being subsumed into the model. Against the background of purely geological interpretations, there was also a growing body of archaeological evidence charting human prehistory through the Pleistocene in various parts of the world. It was not until the 1860s that it became widely accepted that the human race had any great antiquity, with stone tools that were clearly made by early people being found in undisturbed contexts along with the remains of extinct animals. Such a likelihood was first noted by the French antiquarian Jacques Boucher de Perthes, who from 1846 to 1857 published his findings of stone tools from the high-level (and therefore very ancient) terrace deposits of the River Somme near Abbeville. There was considerable opposition to the idea that there were human populations of great age represented in the fossil record, primarily from religious groups and individuals, and to some extent this opposition still survives today. For most people, the clinching discovery was that of prehistoric cave art in France and Spain, where people living in the last glaciation had painted pictures of contemporary woolly mammoths, woolly rhinos, reindeer, bison, and horses in the caves they also used for shelter – direct evidence with a ancient human signature. It quickly became clear that the record of human antiquity was longest in Africa, Europe, and southern Asia and relatively short in northern Asia, Australia, and the Americas.

There is probably no other period of Earth history that has been so intensively studied yet so badly misinterpreted than the Pleistocene, and all because the construction of theoretical models has tended to run ahead of the collection and interpretation of hard evidence. Far too little attention has been paid to testing models and far too much to reinforcing them. The Alpine Model of Pleistocene climatic events eventually fell victim to new evidence from the oceans. Cesare Emiliani and colleagues, working in the late 1950s and early 1960s on cores taken from deep-ocean sediments, found evidence from the shells of buried foraminifera that their oxygen isotope content varied through time. Emiliani had already worked on the palaeoclimate signals recovered from microfossils in older deposits, and he recognized his new data as being a direct record of changing global ice volume. The two significant isotopes of oxygen, ^{16}O and ^{18}O, behave differently during evaporation, leaving the oceans enriched with the heavier isotope. When water evaporates from the oceans and falls as rain or snow on the land, it is isotopically 'light', and if sufficient frozen water remains on land in large, stable ice-sheets, then the isotopic composition of the oceans will change to a measurable degree. When the ice melts, eventually the meltwater will ultimately return to the oceans, thus recentring the isotopic signal. Foraminifera living in the sea will deposit shells that reflect the chemistry of the seawater during their lifetime, and when they die, their shells fall to the seafloor and become incorporated in the sediments being deposited there, creating a retrievable record of changing global ice volume through time. Emiliani found evidence for many more episodes of global ice accumulation than were allowed for in the Alpine Model.

When plotted onto a graph, the marine isotope record bore a very strong resemblance to the theoretical curve of variations in the predicted amount of solar energy reaching a particular point on the planetary surface; this is determined by known variations in Earth's orbit. This curve had been calculated by the Serbian astrophysicist Milutin Milankovitch in the early twentieth century to explain long-term climatic variability, but, in the absence of any evidence to back his theory, Milankovitch's work remained largely ignored. Emiliani's recognition of the resemblance between the Milankovitch solar radiation curve and the oceanic oxygen isotope record has led to a completely new understanding of the driving forces behind global climatic change, now extending far back beyond the Pleistocene. Alongside plate tectonics, this must number as one of the greatest breakthroughs in geological science.

Milankovitch theory examines the combined effects of three known variables in Earth's orbit: the eccentricity of Earth's orbit around the Sun, the obliquity of Earth's axis relative to the Sun, and the precession of the equinoxes that changes the season at which Earth's axis is most tilted towards the Sun. Each of these has respective cycles of approximately 100 000, 41 000 and 23 000 years. In the past 700 000 years, the 100 000-year cycle has become dominant, giving major global cold stages at about this interval. Prior to this, there was considerable climatic instability during the earlier part of the Pleistocene, but not on anything like this dramatic scale. Amazingly detailed climatic signals for the last major climatic cycle

recovered by drilling through the Greenland ice-cap confirm and amplify the resolution of the marine isotope record for this later period.

It is now recognized that there have been about seven major global Ice Age events in the past 700 000 years, though these vary to some degree in intensity and progress. Armed with this information, it is now possible to re-examine the geological record and reinterpret the evidence for the relative order and extent of ice-sheet advance and for the intervening warmer interglacial stages. The modern terminology of Pleistocene subdivision is based on the marine isotopic signal. The isotope stages are numbered backwards from 1, with Marine Isotope Stage (MIS) 1 representing the Holocene. Warm stages have odd numbers and cold stages have even numbers. A historical anomaly in the last cold cycle has been divided up into three isotope stages (2, 3, and 4), so the last interglacial period is MIS 5, but otherwise the stages appear to represent single major climatic events (see **Figure 1**).

Life on Earth in the Pleistocene

The distribution of plants and animals on Earth's surface has been hugely influenced by large-scale high- to mid-latitude ice accumulation. Not only have ice-sheets periodically excluded life from large areas of land, but the effects of climate change have radically changed the normal distribution of many species, while significant areas of new land have become available for colonization at times of lowered sea-level. Interglacial sea-levels have generally been as high as those of today, or sometimes a few metres higher, but during cold stages, the amount of water locked up on land as ice has reduced global sea-levels by up to 120 m, exposing vast areas that are now continental shelf. Such drops in sea-level would unite the islands of south-east Asia into a single landmass, greatly extend the eastern seaboard of southern South America, make the British Isles a peninsula of north-west Europe, and connect Asia to North America by a broad northern land bridge (Beringia). In the southern hemisphere, the scope for significant increase in terrestrial ice cover is limited by the disposition of the continents. Antarctic ice masses grew and waned, but it was only in the Andean region of South America that very large, new, non-polar ice-sheets developed. The primary effect of Pleistocene ice accumulation is seen in the northern hemisphere, where the Hudson Bay area and Scandinavia became the central foci for the growth of major new ice-caps and large mountain glaciers developed in the Rockies and in the Alpine mountain belt.

The influence of Pleistocene cold-stage events is still very much with us today. Large regions of permanently frozen ground or permafrost in the arctic regions are attributable to the deep cold experienced by both glaciated and unglaciated higher latitudes, and the crustal distortion caused by the massive weight of former ice-sheets can be witnessed in a recovery phase around the Baltic Sea and Hudson Bay regions, where isostatic uplift is still very active. The Baltic Sea and Hudson Bay are no more than the slowly draining crustal depressions caused by former ice-sheets.

Rich sources of evidence for the faunal and floral history of the Pleistocene are to be found in the deposits laid down by major river systems. It is probably fortunate that the study of such deposits began in north-western Europe, where long-term regional uplift has created staircase-like terrace systems representing the former levels at which rivers ran as they progressively cut down to new base levels. The Pleistocene deposits of south-east England are an extremely good illustration of this kind of sequence, particularly those related to the Thames drainage. A fossil landscape is preserved beneath eastern England, buried beneath the debris of ice-sheets that invaded the area about 400 000 years ago. This glacial event (the Anglian glaciation, believed to represent Marine Isotope Stage 12) obliterated some of the major river systems of central England and diverted the Thames to something like its present course. Beneath the glacial tills, fossiliferous deposits representing these extinct river systems provide information on life in the area in the early Pleistocene and early middle Pleistocene.

From the Anglian glaciation onwards, the Lower Thames Valley preserves fragments of river deposits representing all the major climatic stages revealed by the oceanic isotope record. Because the terrace fragments can be related to the existing topography, it has been possible to build up a clear picture of the post-Anglian evolution of this particular landscape. The fact that the modern city of London is sited on the Thames plays no small part in unravelling the story. Almost every pocket of sand, gravel, and brickearth has at some stage in the recent past been excavated as an economic resource, and many of these sections have been carefully recorded and their fossils collected. It is a sad fact that the economic development that created the opportunity to understand the later Pleistocene history of the Thames has now destroyed much of the evidence on which that understanding was based, and it is one of the responsibilities of present-day geographers and Pleistocene specialists to make certain that what little remains is well documented and, where possible, conserved. This particular case history underlines the point that much of the evidence for terrestrial

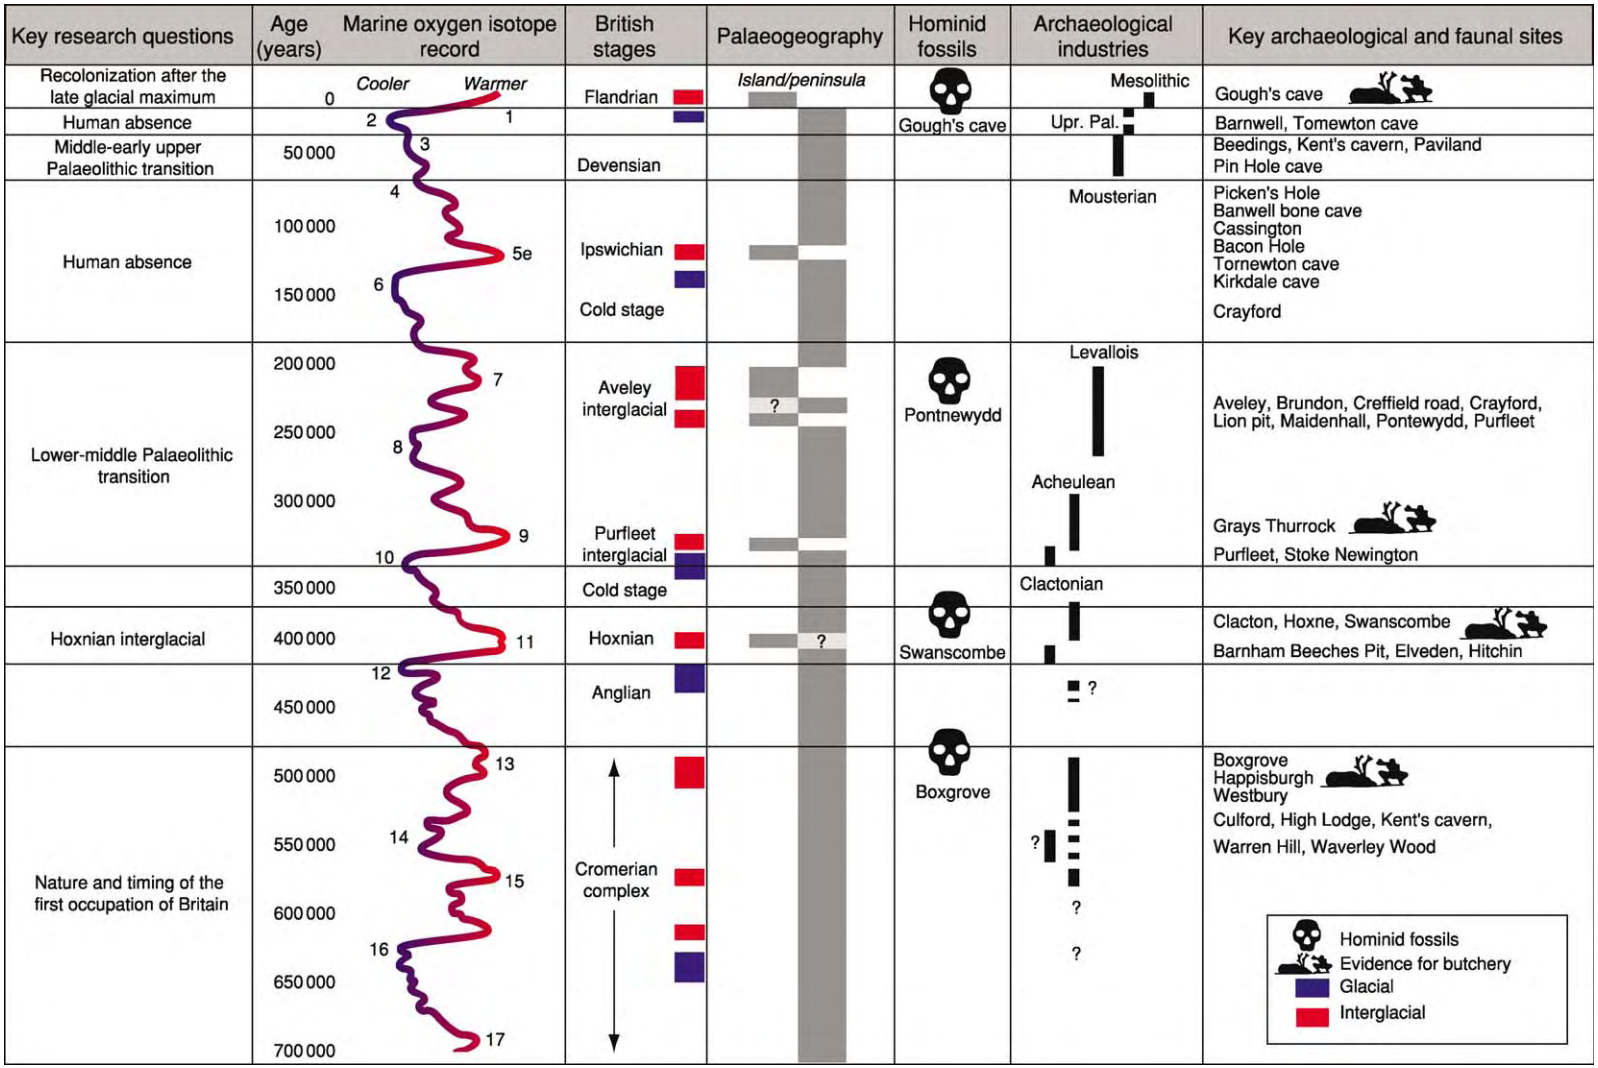

Figure 1 The relationship between apparent human occupation of the British Isles during the Pleistocene and climate change, based on the work of the Ancient Human Occupation of Britain research team directed by Professor C B Stringer FRS.

Pleistocene events lies buried within existing landscapes and can only usually be seen when it is artificially excavated.

In the Thames Valley, cold-stage deposits are usually poor in fossils, but the interglacial stages are represented by exceptionally rich organic levels containing bones, molluscs, beetles, and plants. Five distinct post-Anglian interglacials can be recognized, representing Marine Isotope Stages 11, 9, 7, 5, and 1 (stage 3 is not an interglacial, but is nonetheless well represented by cold-stage deposits laid down in the middle of the last glacial stage). Most of the known river terrace deposits have been found to have a cold–warm–cold sandwichlike structure, with an organic interglacial filling of varied lithology underlain and overlain by cold-stage gravels. The relationship and order of these terrace deposits can be worked out from their topographic position, but this interpretation has been greatly enhanced by study of their fossil content. Biostratigraphic data have been recovered from all of the major groups examined, but it has been found that the vertebrate faunas, particularly the mammals, give the most distinctive signature to each interglacial event. It has proved possible to use the distinctive mammalian faunas recovered from the Thames terrace sequence to correlate with other river and lake sequences around the country and even with fossiliferous cave deposits. The importance of cave sequences cannot be overstated, because they currently offer the only reliable means of direct dating (uranium series age determinations on clean stalagmite) that is available for Pleistocene sequences beyond the range of radiocarbon.

Many other river systems around the world are now being studied systematically to understand their distinctive depositional cycles and the ways in which these reflect Pleistocene climatic variation. Just as ice-sheets were restricted to particular areas of Earth's surface, so drainage systems have their own dynamics, according to the regions they drain. It is essential to understand those dynamics before trying to interpret the palaeoclimatic evidence that they may contain, in particular their fossil content. Returning briefly to the Thames, the great paucity of fossils relating to cold periods before the last one is a rather odd feature, particularly given the richness of interglacial sequences within the same region, but this is the signature of this particular river system. In other parts of the world, different parts of the climatic cycle may be better represented, and it is certainly the case that other European drainage systems have quite different depositional histories.

Historically, caves have been a great focus of interest. Caves are natural dustbins, anomalous sites for the temporary deposition of detritus that would otherwise be destroyed by natural processes (Figure 2). They are a natural focus for biological activity and wide range of animals use them for shelter and to raise their young. This includes amphibians, bats, a variety of mammalian and avian carnivores, and humans. Bone tends to be preserved preferentially in limestone environments, and most caves are to be found in limestones. Many caves have been found in which animal bone is one of the primary constituents of the cavern infilling. One of the most significant features of caves is that they are one of the few places in the terrestrial environment where there is at least the possibility of preserving quite long sequences of deposits representing multiple climatic cycles. Long stratigraphic sequences are comparatively rare on land in the Pleistocene.

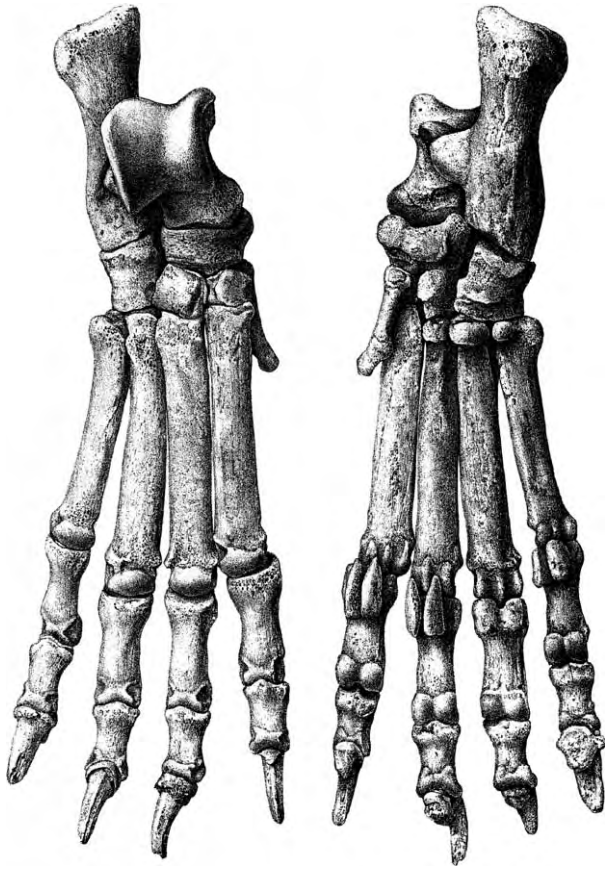

Figure 2 Engraving of the hind foot bones of a Pleistocene spotted hyena, *Crocuta crocuta*, from Tornewton Cave, Devon. Caves often contain exceptionally well preserved fossilized mammalian bones, particularly those of the carnivores that have used them as lairs or dens.

One of the great biological phenomena of the Pleistocene is the terminal Pleistocene extinction event, and a huge body of literature has been devoted

to its likely causes. Somewhere around the very end of the Pleistocene and extending in numerous cases into the early Holocene, a large number of large to medium-sized mammals died out in a relatively short time. It is informative to look at the anatomy of this extinction event. The areas in which the extinctions took place were Europe, northern Asia, Australia, and the Americas. Generally speaking, the faunas of southern Asia and Africa survived intact. There had previously been numerous rapid transitions from late glacial to early temperate environments, but no other event during the Pleistocene had seen global-scale extinctions. Some have suggested that environmental change alone caused mass extinction, but the evidence on the ground does not support this case very well.

Southern Asia and Africa both seem to have a long and continuous record of human activity, extending well back into the Pleistocene, and in Africa earlier still. The mammals of these areas are likely to have had long-standing adaptive responses to the presence of dangerous and effective bipedal predators. In Europe, the co-existence of people and native mammals was markedly sporadic, particularly during the later Pleistocene, whereas in much of northern Asia and in Australia and the Americas co-existence was either very limited or perhaps even completely absent. When anatomically modern humans began to spread across Europe, Asia, and beyond, the animals living in these regions would probably never have encountered people before and had little or no time to adapt to their presence. If this natural naivety of the animal populations was coupled with the great environmental stress of rapid environmental change, undoubtedly causing a natural crash in population numbers, then this is more likely to account for the widespread but highly regionalized pattern of extinction.

One particular case history is illuminating. By the time modern human populations had spread along the newly formed Arctic Ocean shoreline at the end of the Pleistocene, sea-levels were already beginning to rise, and a population of mammoths had become isolated beyond human reach on what is now Wrangel Island. Though mammoth populations on the European and Asian mainland and throughout North America dwindled to extinction by the end of the Pleistocene, the isolated animals on Wrangel Island survived to as recently as 4500 years ago, in one of the most inhospitable environments on Earth. It was only when humans eventually reached the island that the mammoths finally vanished. So when the great megalithic monument at Stonehenge was under construction on the grasslands of southern England, there were still woolly mammoths alive on an island in the Arctic Ocean.

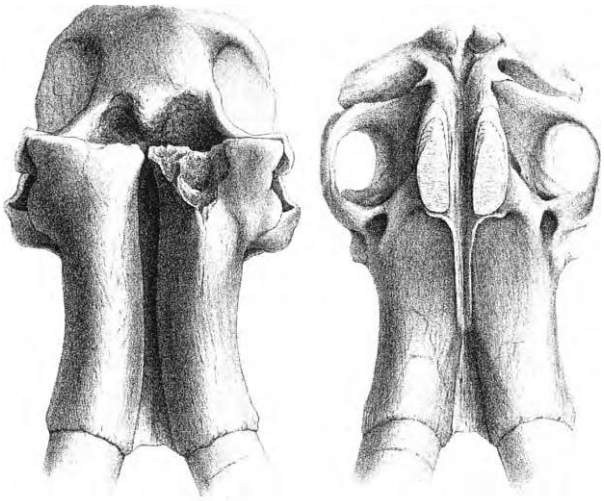

Figure 3 Engraving of the skull of a Pleistocene mammoth, *Mammuthus* cf. *primigenius*, from Ilford, Essex. Megaherbivores such as the mammoth were significant creators and modifiers throughout the Pleistocene and their activities helped maintain the preferred habitats of many other plants and animals.

The effects of mammalian extinctions in the Americas and in Australia were particularly severe, with the loss of all of the megaherbivores (animals weighting a tonne or more; Figure 3) as well as a large number of medium-sized species. Mammoths, mastodonts, giant sloths, glyptodons, native horses, notoungulates, litopterns, and many other forms were completely wiped out in the Americas, and Australia lost all of its larger marsupials. Large animals with long regeneration times and slow-growing, vulnerable young seem to have been pushed to extinction by the rapid spread of modern humans to new parts of the globe. The timing of both events coincides perfectly and it seems strange not to accept a direct link between the two phenomena. The significance of the loss of the Pleistocene megaherbivores cannot be overstated, for these animals were the environment creators of the higher latitudes. The vast cold, dry grasslands of Eurasia and North America were created and maintained by creatures such as mammoths throughout the Pleistocene. Once these animals became extinct, the environment that they had helped to create disappeared with them, destroying the habitat that had supported many smaller species, and the northern coniferous woodlands took over. In the longer term, human populations have effectively replaced the larger Pleistocene herbivorous mammals in living primarily on cultivated grasses such as wheat, maize, rice, and millet. In

summary, the Pleistocene was a period of large-scale, cyclic environmental change. Plants and animals showed considerable adaptive responses to these changes, but in the case of the environmentally important megaherbivores, their progress was cut short, probably by the rapid spread of modern humans.

THERMAL METAMORPHISM

R Abart and R Milke, University of Basel, Basel, Switzerland

Introduction

In the course of geological processes, rocks may be subject to changing pressure-temperature and chemical conditions. This may induce mineral transformations and re-crystallization. If the mineralogical and (micro)structural changes take place, when the rock is in the solid state, this is referred to as metamorphism. Metamorphic transformations, which are primarily driven by elevated temperature at constant (low) pressure, may be referred to as thermal metamorphism. In this chapter, we summarize the settings in which thermal metamorphism may occur. We then describe characteristic mineralogical patterns of thermal metamorphism. We address the timing of thermal metamorphism and its implications on the extent of equilibration and the development of microstructures and reaction textures. Finally, we address fluid flow and associated chemical transport during thermal metamorphism.

Geological Settings of Thermal Metamorphism

Both pressure and temperature increase with depth. Whereas isobars, i.e., loci of equal pressure, constitute approximately horizontal surfaces, the thermal structure of the Earth's crust may be rather complex (Figure 1). Heat is constantly liberated by radioactive decay and by slow cooling and solidification of the Earth's interior. Heat is transported to the relatively cool surface primarily through thermal conduction. In the absence of mass flow associated with tectonic and magmatic activity and with fluid circulation, a time invariant relation between depth and temperature would be established in the subsurface, which may be referred to as a stable geothermal gradient. Conduction of heat is a relatively slow process, and the geothermal gradient may be modified, if heat is transported passively with moving matter. There are several processes which may cause deviations from a stable geothermal gradient towards high temperatures.

Processes, which may cause thermal perturbations on a regional scale

Large fragments of the lithosphere may be displaced by tectonic or gravity mechanisms. If the movement includes a vertical component, the uplifted lithosphere transports heat to shallower depths, thereby raising and condensing the isotherms in the crust. An efficient mechanism to transport thermal energy is magmatic underplating. This is the formation of extended mafic intrusions at deep-crustal or subcrustal level. Seismic signals indicate that underplating melt bodies may have thicknesses of several kilometres. Such large magma bodies increase the heat flow to the Earth's surface on a regional scale. Due to the lower density of the underplating magma compared to the lithospheric mantle, it may also give rise to surface uplift. The elevation of the highest cenozoic mountain ranges cannot be explained by isostatic movement of the post-collisional thickened lithosphere alone. They require a combination of isostatic uplift, magmatic underplating, and thinning of the lithospheric mantle from its root. Areas of increased heat flow are also found in zones of extensional geotectonic regime. Thinning of the lithosphere may occur by horizontal stretching or movement on normal faults. At the base of the lithosphere, mantle material rises to compensate for the lost volume. Since the rate of tectonic transport is generally faster than the rate of heat transfer, each point of the pre-extensional geotherm moves vertically to establish the new geotherm.

All regional scale processes that lead to thermal perturbations, increased heat flow, and raised geotherms involve vertical displacement of the crust

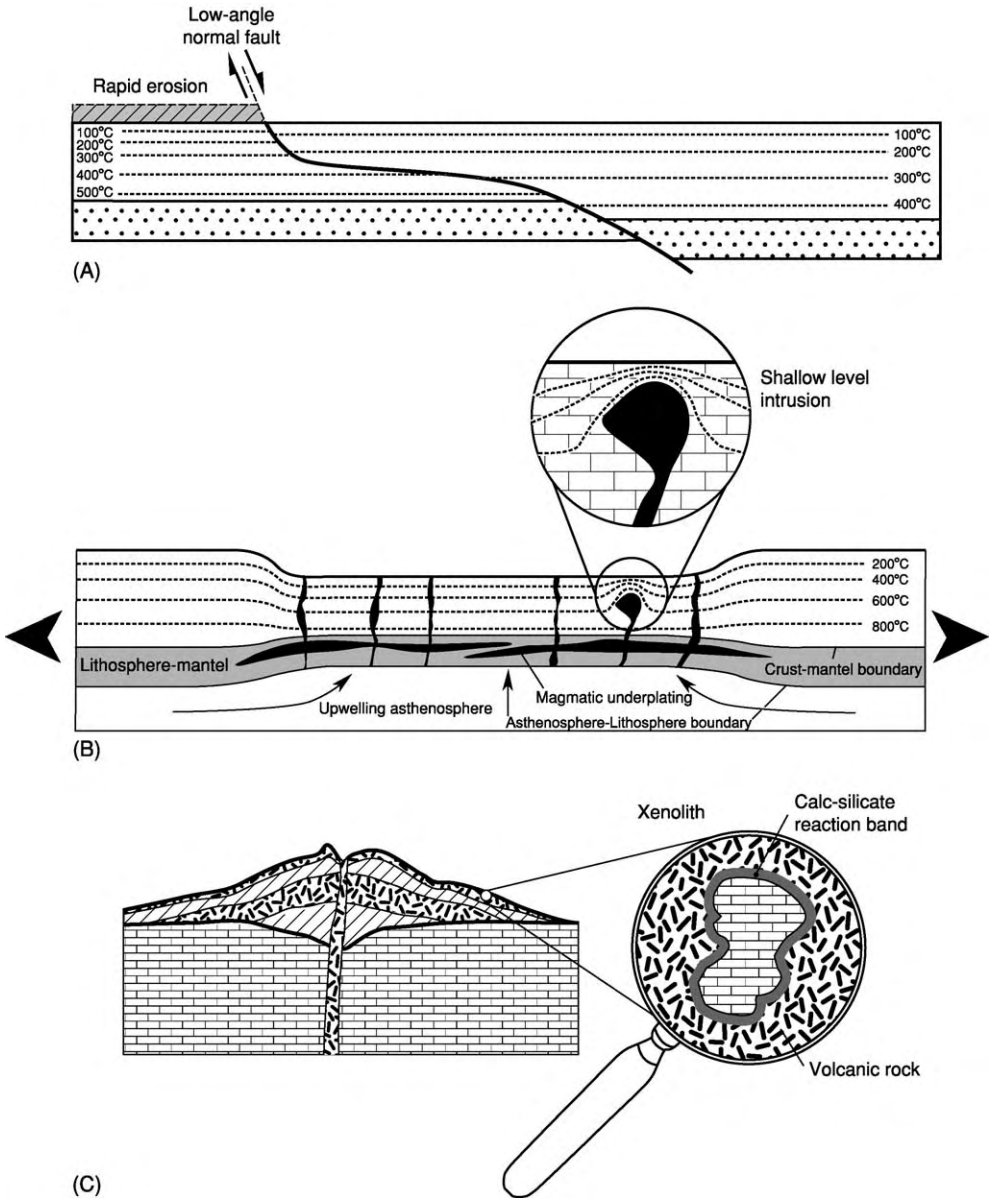

Figure 1 Settings of thermal metamorphism: (A) condensation of isotherms during tectonic exhumation of crustal fragments along low angle normal fault; (B) condensation of isotherms in the course of lithospheric thinning in an extensional regime; also shown is the effect of magmatic underplating, which is often associated with lithospheric thinning; insert shows the effect on the thermal structure of a shallow level intrusion; (C) thermal overprint of xenoliths in a volcanic setting.

and thus induce both changes in temperature and pressure conditions. Thermal metamorphism in a narrow sense, that is at constant pressure, is restricted to processes that operate on a local scale.

Processes, which may cause thermal perturbations on a local scale

Magmatic intrusions Large amounts of heat may be transported into shallow levels of the crust via the intrusion of magmas. Heat is liberated during solidification (latent heat of crystallization) and during cooling of the magma intrusion and it is transferred into the country rocks via thermal conduction and possibly via fluid circulation. The domain of thermal perturbation surrounding a shallow intrusion is referred to as the thermal aureole or the contact aureole and the associated metamorphic transformations are referred to as contact metamorphism. Within a thermal aureole peak metamorphic temperatures increase exponentially with decreasing distance from the intrusive contact, from background temperatures at the outer limit to maximum temperatures at the intrusive

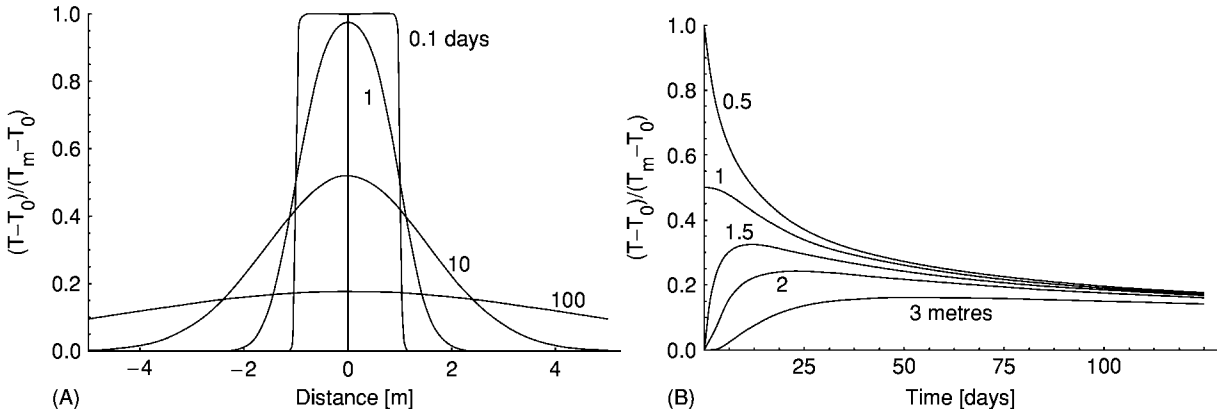

Figure 2 Temperature distribution around a dyke intrusion; for construction of this figure it was assumed that the magma intruded at a temperature T_m and the country rock was at a uniform temperature T_0 prior to magma intrusion; the magma and the country rock were assigned similar thermal diffusivities of 10^{-6} m^2/s; (A) shows the temperature distribution across the dike for different times after intrusion; (B) shows the evolution of temperature with time at different distances from the dyke centre.

contact. This gives rise to characteristic sequences of metamorphic parageneses (see below). Peak metamorphic temperatures at the intrusive contact, among others, depend on the temperature of the intruding magma, the temperature of the country rocks prior to magma intrusion, and on the rate and extent of heat production during crystallisation. The temperature pattern produced by the intrusion of a magmatic dike and its evolution with time are illustrated in Figure 2. It is important to note that the thermal evolution of a rock depends on its distance from the dike. Whereas the dyke material is subject to strictly monotonic cooling after intrusion the country rocks go through an initial heating stage before they start cooling. Peak metamorphic temperatures and heating rates are high close to the intrusive contact and relatively low further out in the country rock. Penetrative deformation associated with magma intrusion is usually confined to the immediate contact region and metamorphic crystallization is usually static in large portions of the contact aureole.

Volcanic activity Effusion of lavas in the course of volcanic activity is an obvious setting of thermal metamorphism. On the one hand, lavas may substantially heat the material over which they flow and cause sharp thermal aureoles of limited extent. On the other hand, on their way to the surface, magmas may incorporate fragments of country rocks, which then are quickly heated to magmatic temperatures. Many of the calc-silicate minerals have first been described from limestone derived xenoliths, which were metamorphosed in lavas of the Monte Somma volcano in southern Italy.

Thermal metamorphism on a regional scale is associated with the production of basaltic lavas at mid-ocean ridges. Thermal metamorphism in the mid-ocean-ridge environment is usually accompanied by intense hydrothermal activity, which may lead to pronounced chemical alteration of the original mid-ocean-ridge basalts.

Natural coal seam and hydrocarbon seepage burns, the production of fulgurites from lightning strikes, the formation of pseudotachylites from frictional heating, and the transformation of kinetic into thermal energy associated with meteoritic impacts may be considered as short-term and very localised special cases of thermal metamorphism.

Mineral Zones in Thermal Metamorphism

Mineral zones are defined by the systematic appearence of new minerals in a series of rocks with identical whole rock composition. These minerals are referred to as index minerals. Mineral zones can be mapped in the field.

Isograds are lines on a map connecting points of equal metamorphic grade. The practical application of this definition to rocks is problematic since there are sets of P-T-X conditions that satisfy reaction equilibrium for a given mineral assemblage. In practice, it is therefore difficult to exactly pin down the metamorphic grade and it is more practical to use the concept of reaction isograds to describe metamorphic rock series. Reaction isograds are lines joining points that are characterized by the equilibrium assemblage of a given reaction.

In thermal metamorphism, temperature is the leading variable controlling metamorphic grade. Contact aureoles are characterised by spatial patterns of reaction isograds that parallel the intrusive contact

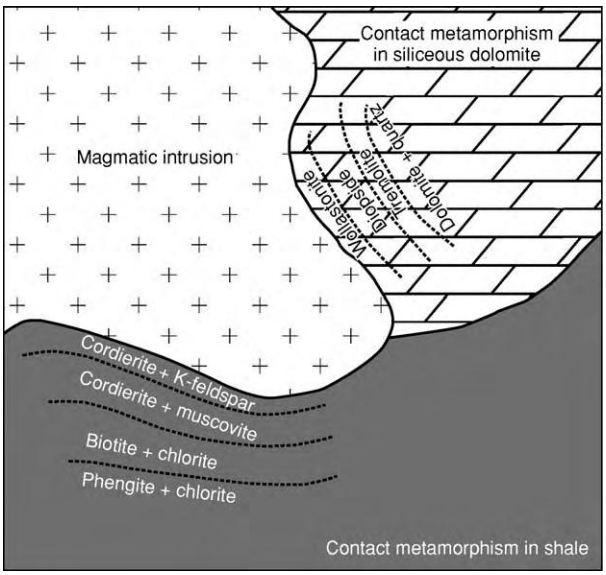

Figure 3 Schematic map of a shallow magmatic intrusion into country rocks of sedimentary origin. For a given lithology, different mineral zones characterized by index minerals evolve depending on the distance to the heat source.

and result in mineral zones (Figure 3). Contact metamorphism is most pronounced if the intruded rocks were previously unmetamorphosed or had only been subjected to low-grade regional metamorphism. The respective succession of mineral zones depends on the lithology of the metamorphosed rocks and comprises different index minerals for contact metamorphism of shales, impure carbonates, ultramafic rocks, or other country rocks. For the reconstruction of the thermal evolution in a contact aureole, simple rock compositions with clearly defined reactions are most convenient, e.g., siliceous dolomites (Figure 3).

H_2O and CO_2 are the prime constituents of metamorphic fluids. These species may be liberated or sequestred in the course of mixed-volatile mineral reactions. As a consequence, the composition of the pore fluid is influenced by mineral reactions and has an important influence on the stability of mineral parageneses.

The kinetics of mineral reactions may be slow compared to the time-scales of thermal perturbations. High heating rates in contact aureoles may lead to significant overstepping of mineral equilibria, such that the formation of mineral zones lags behind the thermal evolution.

Fluid-Rock Interaction

Thermal metamorphism, in particular contact metamorphism, is often accompanied by fluid migration. On the one hand, magmas may dissolve significant amounts of volatiles and fluid may be liberated during crystallization. On the other hand, thermal perturbations may cause bouyancy driven fluid circulation. Fluid flow tends to be pervasive during early stages of contact metamorphism, and it may become focused along joints and fractures at later stages. The fluid in the pore space of rocks is the most efficient transport medium in the solid crust. Fluid may transport dissolved species and isotopes. The chemical and isotopic signature of fluids is imprinted on the solid phases of the rocks via fluid rock interaction. If metamorphic transformations are accompanied by changes of the bulk rock chemical composition, this process may be referred to as allochemical metamorphism or metasomatism. Mineralogical and (stable)isotope alteration patterns are robust and enduring manifestations of palaeo fluid flow.

Introduction

Boundary stratotypes of stages, high-resolution radioisotopic dating, earth-orbit tuning of cyclic sequences, advances in biostratigraphic scaling of stages, and detailed error analysis are keys to the standard geological time-scale. Construction and assembly of the geological time-scale follow several well-defined steps, including (1) construction of an updated global chronostratigraphic scale for Earth's rock record, (2) identification of key linear-age calibration levels for the chronostratigraphic scale using high-resolution radioisotopic (or other source of) absolute age dates, (3) application of earth-orbit tuning to intervals with cyclic sediments or stable isotope sequences that have sufficient biostratigraphic or magnetostratigraphic ties, (4) interpolation of the combined chronostratigraphic and chronometric scale when direct information is insufficient, and (5) calculation or estimation of error statistics on the combined chronostratigraphic and chronometric information to obtain a geological time-scale with estimates of uncertainty on boundaries and unit durations. The International Commission on Stratigraphy (ICS) cosponsors the standard globally applicable geological time-scale.

Human Time

Time is an indispensable tool for all of us. The time kept by innumerable watches and clocks regulates our everyday life, and the familiar calendar governs our weekly, monthly, and yearly doings. These sequences eventually condense into the historical record of events over centuries. The standard unit of modern timekeeping is the second, defined as the duration of 9 192 631 770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the caesium-133 atom. This value was established to agree as closely as possible with the ephemeris second based on Earth's motion. The advantage of having the atomic second as the unit of time in the International System of Units is the relative ease, in theory, for anyone to build and calibrate an atomic clock with a precision of 1 part per 10^{11} (or better). In practise, clocks are calibrated against broadcast time signals, with frequency oscillations in hertz being the 'pendulum' of the atomic timekeeping device.

The tick of the second paces the quick heartbeat, and traditionally was the 60th part of the 60th part of the 24th part of the 24-h day, with the minute and the hour being convenient multiples to organize daily life. The day carries the record of light and dark, the month is marked by the regularly returning shapes of the moon, and the year is represented by the cycle of the seasons and the apparent path of the sun. All of these time passages are clearly understood, and humans have long recognized the notion that time is a vector, pointing from the present to the future. Events along its path mark the 'arrow of time', and the arrow is graded either in relative 'natural' units, or in units of duration – the standard second and its multiples, such as hours and years.

Geological Time and the Rock Record

What is often less clear is the concept of geological time, the bases of its units, and how to use these units properly. A good understanding of geological time is vital for every earth scientist, especially those who strive to understand geological processes and determine rates of change. This understanding takes place in a framework called 'Earth geological history', a kind of supercalendar of local and global events. The challenge to this understanding is reading, organizing, and sorting Earth's stone calendar pages, and, as best as we can, reconstructing the content of any missing pages. Stratigraphic correlation is a vital part of this event-reconstruction process.

One of the earliest reconstructions was made by Nicolas Steno (*see* **Famous Geologists:** Steno) (1631–1687), who made careful and original stratigraphic observations. Based on these observations, Steno concluded that Earth's strata contain the superimposed records of a chronological sequence of events that can be correlated worldwide. Geological correlation formally is expressed in terms of five consecutive operations and units:

- Rock units, such as formations or well log intervals (lithostratigraphic correlation; e.g., the Kimmeridge Clay Formation of England).
- Fossil units, such as zones (biostratigraphic correlation; e.g., the *Turrilina alsatica* benthic foraminifer range zone).
- Relative time units (geochronological ('Earth time') correlations; e.g., Jurassic Period, Eocene Epoch, Oxfordian Age, Magnetic Polarity Chron C29R).

- Rocks deposited during these time units (chronostratigraphic (time–rock) correlation; e.g., Jurassic System, Eocene Series, Oxfordian Stage, Magnetic Polarity Zone C29R).
- Linear time units or ages (geochronological correlation; e.g., 150 Ma, 10 ka).

Without correlation to a global reference scale, successions of strata (i.e., events in time derived in one area) are unique and contribute nothing to an understanding of Earth history elsewhere. The rules of hierarchy in geological correlation—from rocks and fossils to relative and linear time—are carefully laid down in the *International Stratigraphic Guide*. An abbreviated copy of this 'rule book' with further references may be found on the website of the International Commission on Stratigraphy (http://www.stratigraphy.org).

Before dealing further with linear geological time, consider the common geological calendar built from relative age units. This chronostratigraphic scheme is not unlike a historical calendar in which societal periods (e.g., the Minoan Period, the reign of Louis XIV, or the American Civil War) are used as building blocks, devoid of a linear scale. Archaeological relicts deposited during these intervals (the Palace of Minos on Crete, Versailles, or spent cannon balls at Gettysburg, respectively) comprise the associated physical chronostratigraphic record. A chronostratigraphic scale is assembled from rock sequences stacked and segmented in relative units based on their unique fossil and physical content. When unique local fossil and physical records are matched with those of other rock sequences across the globe – in a process known as stratigraphic correlation – a relative scale can be assembled; when calibrated to stage-type sections, this scale becomes a chronostratigraphic scale.

The standard chronostratigraphic scale, in downloadable graphics format, is available from the ICS website. This time-scale is made up of up of successive stages in the rock record (e.g., Cenomanian, Turonian, and Coniacian within the Cretaceous System). Originally, each stage unit was a well-defined body of rocks at a specific location of an assigned and agreed upon relative age span, younger than typical rocks of the underlying stage (Jurassic) and older than the typical rocks of the next higher stage (Paleogene). This is the concept of defining stage units with stage-type sections, commonly referred to as stratotype sections. The principles and building blocks of this chronostratigraphy were slowly established during centuries of study in many discontinuous and incomplete outcrop sections. Inevitably, lateral changes in lithology between regions and lack of agreement on criteria (particularly, which fossils were characteristic of which relative unit of rock), have always resulted in considerable confusion and disagreement with respect to stage nomenclature and use. Almost invariably, classical stage stratotypes turned out to represent only parts of stages. Hence, a suite of global subdivisions with precise correlation horizons was required.

Global Stratotype Section and Point

Now, relatively rapid progress is being made with definition of Global Stratotype Sections and Points (GSSPs) to fix the lower boundary of all geological stages, using discrete fossil and physical events that correlate well in the rock record. For the ladder of chronostratigraphy, this GSSP concept switches the emphasis from marking the spaces between steps (stage stratotypes) to fixing the rungs (stage boundaries).

Each progressive pair of GSSPs in the rock record also precisely defines the associated subdivision of geological time. Hence, philosophical arguments are being heard to cut out time–rock units, and deal only with rock, fossil, and time units *sensu strictu*. Essentially, the argument is that dual systems of precisely defined subdivisions of geological time and of parallel similarly defined subdivisions of the time–rock record are redundant. Or, even more radical, why not replace the hundreds of melodious, but confusing, 'ian' subdivisions of stages (Gelasian, Sinemurian, Spathian, Emsian, etc.) with simple 'real' ages – who needs the 'Victorian Age' when there is a 'nineteenth century'?

It is now 25 years ago that a 'golden spike' struck the first GSSP. This event (of historic proportions for development of the geological time-scale) involved the boundary between the Silurian and Devonian periods, or rather the lower limit of the Devonian, at a locality called Plonk in Czechoslovakia. The problem of the Silurian–Devonian boundary and its consensus settlement in the Klonk section hinged on a century-old debate, known as the 'Hercynian Question', that touched many outstanding geoscientists of the previous century. The issue came to the foreground after 1877, when Kaiser stated that the youngest stages (étages) of Barrande's 'Silurian System' in Bohemia correspond to the Devonian System in the Harz Mountains of Germany and other regions. Kaiser's findings contrasted with the conventional nineteenth-century wisdom that graptolites became extinct at the end of the Silurian. Eventually, it became clear that so-called Silurian graptolites in some sections occur together with so-called Devonian fossils in other sections, leading to the modern consensus that graptolites are not limited to Silurian strata.

A bronze plaque in the Plonk outcrop shows the exact position of the modern Silurian–Devonian Boundary, which is taken at the base of the Lochkovian Stage, the lowest stage of the Devonian. The base of the Lochkovian Stage is defined by the first occurrence of the Devonian graptolite *Monograptus uniformis* in Bed #20 of the Klonk Section, northeast of the village of Suchomasty. The Lower Lochkovian index trilobites with representatives of the *Warburgella rugulosa* group occur in the next younger limestone Bed #21 of that section.

The concept of the GSSP has gained acceptance among those stratigraphers who consider it a pragmatic and practical solution to the common problem that conventional stage-type sections inevitably leave gaps, or lead to overlap between successive stages. The boundary stratotype very much relies on the notion that it is possible to arrive at accuracy in correlation through the use of events (e.g., a geomagnetic reversal, a global change in a stable isotope value, or the evolutionary appearance of one or more prominent and widespread fossil taxa). Thus, the limits of a stage can now be defined with multiple event criteria that, using the best of current knowledge, are synchronous over the world. Delimiting successive stages in a clear and practical manner enhances their value as standard units in chronostratigraphy and ultimately in geochronology. Without standardised units, neither the (relative) stratigraphic scale nor the (absolute) time-scale can exist.

This is not to say that the classical concept of the stage stratotype has suddenly become obsolete, and should be abolished. Although the GSSP concept is not ruled by priority regulation, going back through the historical notions of how and where a stage was originally conceived, defined, and correlated sheds valuable light on the geological meaning and correlative content of stages and the historical notion of their boundaries. Nevertheless, it is clear that, at a time when scientific viewpoints are becoming increasingly more global, stage stratotypes have more regional rather than global significance. At present, nearly 50 GSSPs have been defined (**Figures 1** and **2**). Over 50 more Phanerozoic stages are in need of base definition, and ICS has set the year 2008 as the completion date for all remaining GSSPs.

Due to the fact that most of the Proterozoic lacks adequate fossils for correlation, a different type of boundary stratotype, the Global Standard Stratigraphic Age (GSSA), is in use for this interval of Earth history. The definition of a boundary by its linear age is the consequence of the fact that the Proterozoic now recognizes units of global stratigraphic subdivision, with the boundaries being defined in terms of the abstract age in millions of years. Summaries of ratified GSSAs may be found in **Figure 2**. Although there appears to be consensus that the subdivision of the Proterozoic in three eras (Palaeoproterozoic, Mesoproterozoic, and Neoproterozoic) is excellent, the finer subdivisions often contain no dated rocks, which makes their use haphazard. An intensive search is going on for physical events in the Proterozoic rock record suitable to qualify as 'golden spikes'.

It is desirable to add some documentation to a GSSP proposal about the historical significance of a new-stage GSSP in the hierarchy of stratigraphic units of higher rank. Careful consideration needs to be given to the fact that, for example, the GSSP for the base of the Triassic Period in Meishan, China, automatically defines the boundary of the Permian–Triassic, and the base of the Induan Stage. Because the Triassic is considered the lowest period in the Mesozoic, the golden spike in the Meishan section also separates the Palaeozoic from Mesozoic. In the same vein, the base of the Cambrian Period as defined in a GSSP in the Fortune Head section in south-west Newfoundland also defines the base of the Nemakitian-Daldynian Stage, often considered to be the lowest stage in the Cambrian. Because the Cambrian, by consensus, is considered to be the lowest period in the Palaeozoic Era and the lowest major unit in the Phanerozoic Aeon, the Fortune Head GSSP also defines the lower boundary of these major chronostratigraphic units. This leads to correlation in linear time units, called geochronological correlation, with reference to the geochronological calendar of Earth events. Whereas the chronostratigraphic scale is a convention to be agreed upon rather than discovered, calibration of the scale in seconds and (mega-) years is a matter for discovery and estimation rather than agreement. Like human time, linear geological time is expressed in units of standard duration – the second, and hence (thousands or millions of) years.

Building a Geological Time-Scale

The ideal time-scale is built from accurate radioisotopic ages, taken precisely at stage boundaries throughout the stratigraphic column in the Phanerozoic. There are two basic measuring (dating) tools to build the linear geological time-scale: (1) stratigraphically meaningfull readiometric dates in millions of years and (2) Earth-orbit-tuned sedimentary cycles in thousands of years. Both types of measurements are achieved in rocks that are stratigraphically discontinuous. Also required is a certain amount of luck in finding core or outcrop sections suitable for dating with index fossils, geomagnetic reversals, stable isotope anomalies, etc.

Global Boundary Stratotype Sections and Points (GSSPs)

Status in Oct 2003; see ICS website (http://www.stratigraphy.org) for updates.

EON, Era, System, *Series*, Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
PHANEROZOIC							
Cenozoic Era							
Neogene System				*"Quaternary"* is traditionally considered to be the interval of oscillating climatic extremes (glacia and interglacial episodes) that was initiated at about 2.5 Ma, therefore encompasses the Holocene, Pleistocene and uppermost Pliocene. It is not a formal chronostratigraphic unit.			
Holocene Series							
Base Holocene	11.5 ka	0.00	Carbon-14 dating calibration	exactly 10,000 Carbon-14 years (= 11.5 ka calendar years BP) at the end of the Younger Dryas cold spell		Informal working definition	
Pleistocene Series							
Base Upper Pleistocene subseries	0.126	0.00	Astronomical cycles in sediments	base of the Eemian interglacial stage (= base of marine isotope stage 5e) before final glacial episode of Pleistocene	Potentially, within sediment core under the Netherlands (Eemian type area)	Informal working definition	
Base Middle Pleistocene subseries	0.781	0.00	Astronomical cycles in sediments	Brunhes-Matuyama magnetic reversal		Informal working definition	
Base Pleistocene Series	1.806	0.00	Astronomical cycles in sediments	Just above top of magnetic polarity chronozone C2n (Olduvai) and the extinction level of calcareous nannofossil *Discoaster brouweri* (base Zone CN13). Above are lowest occurrence of calcareous nannofossil medium *Gephyrocapsa* spp. and extinction level of planktonic foraminifer *Globigerinoides extremus.*	Top of sapropel layer 'e', Vrica section, Calabria, Italy	Ratified 1985	Episodes 8 (2), p. 116–120, 1985
Pliocene Series							
Base Gelasian Stage	2.588	0.00	Astronomical cycles in sediments	Isotopic stage 103, base of magnetic polarity chronozone C2r (Matuyama). Above are extinction levels of calcareous nannofossil *Discoaster pentaradiatus* and *D. surculus* (base Zone CN12c).	Midpoint of sapropelic Nicola Bed ("A5"), Monte San Nicola, Gela, Sicily, Italy	Ratified 1996	Episodes 21 (2), p. 82–87, 1998
Base Piacenzian Stage	3.60	0.00	Astronomical cycles in sediments	Base of magnetic polarity chronozone C2An (Gauss); extinction levels of planktonic foraminifers *Globorotalia margaritae* (base Zone PL3) and *Pulleniatina primalis.*	Base of beige layer of carbonate cycle 77, Punta Piccola, Sicily, Italy	Ratified 1997	Episodes 21 (2), p. 88–93, 1998
Base Zanclean Stage, base Pliocene Series	5.333	0.00	Astronomical cycles in sediments	Top of magnetic polarity chronozone C3r, ~100 kyr before Thvera normal-polarity subchronozone (C3n.4n). Calcareous nannofossils – near extinction level of *Triquetrorhabdulus rugosus* (base Zone CN10b) and the lowest occurrence of *Ceratolithus acutus.*	Base of Trubi Fm (base of carbonate cycle 1), Eraclea Minoa, Sicily, Italy	Ratified 2000	Episodes 23 (3), p. 179–187, 2000
Miocene Series							
Base Messinian Stage	7.248	0.00	Astronomical cycles in sediments	Astrochronology age of 7.251 Ma; middle of magnetic polarity chronozone C3Br.1r; lowest regular occurrence of the *Globorotalia conomiozea* planktonic foraminifer group.	Base of red layer of carbonate cycle 15, Oued Akrech, Rabat, Morocco	Ratified 2000	Episodes 23 (3), p. 172–178, 2000
Base Tortonian Stage	11.608	0.00	Astronomical cycles in sediments	Last Common Occurrences of the calcareous nannofossil *Discoaster kugleri* and the planktonic foraminifer *Globigerinoides subquadratus.* Associated with the short normal-polarity subchron C5r.2n.	Midpoint of sapropel 76, Monte dei Corvi beach section, Ancona, Italy	Ratified 2003	Episodes article in preparation

Figure 1 Overview of Global Stratotype Sections and Points in the Mesozoic and Cenozoic. The Internet version (see http://www.stratigraphy.org) is being updated regularly to reflect the growing number of ratified stratigraphic boundaries. Reprinted from the International Commission on Stratigraphy (2003), with permission.

EON, Era, System, *Series,* Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
Base Serravallian Stage	13.64	0.00	Astronomical cycles in sediments	Near lowest occurrence of nannofossil *Sphenolithus heteromorphus,* and within magnetic polarity chronozone C5ABr		GSSP anticipated in 2004	
Base Langhian Stage	15.97	0.0	Calibrated magnetic anomaly scale	Near first occurrence of planktonic foraminifer *Praeorbulina glomerosa* and top of magnetic polarity chronozone C5Cn.1		GSSP anticipated in 2004	
Base Burdigalian Stage	20.43	0.0	Calibrated magnetic anomaly scale	Near lowest occurrence of planktonic foraminifer *Globigerinoides altiaperturus* or near top of magnetic polarity chronozone C6An		Guide event is undecided	
Base Aquitanian Stage, base Miocene Series, base Neogene System	23.03	0.0	Astronomical cycles in sediments	Base of magnetic polarity chronozone C6Cn.2n; lowest occurrence of planktonic foraminifer *Paragloborotalia kugleri*; near extinction of calcareous nannofossil *Reticulofenestra bisecta* (base Zone NN1).	35 m from top of Lemme-Carrosio section, Carrosio village, north of Genoa, Italy	Ratified 1996	Episodes 20 (1), p. 23–28, 1997
Paleogene System							
Oligocene Series							
Base Chattian Stage	28.4	0.1	Calibrated magnetic anomaly scale relative to base-Miocene and C24n. Arbitrary 100 kyr uncertainty assigned.	Planktonic foraminifer, extinction of *Chiloguembelina* (base Zone P21b)	Probably in Umbria-Marche region of Italy	GSSP anticipated in 2004	
Base Rupelian Stage, base Oligocene Series	33.9	0.1	Calibrated magnetic anomaly scale relative to base-Miocene and C24n.	Planktonic foraminifer, extinction of *Hantkenina*	Base of marl bed at 19m above base of Massignano quarry, Ancona, Italy	Ratified 1992	Episodes 16 (3), p. 379–382, 1993
Eocene Series							
Base Priabonian Stage	37.2	0.1	Calibrated magnetic anomaly scale relative to base-Miocene and C24n.	Near lowest occurrence of calcareous nannofossil *Chiasmolithus oamaruensis* (base Zone NP18)	Probably in Umbria-Marche region of Italy		
Base Bartonian Stage	40.4	0.2	Calibrated magnetic anomaly scale relative to base-Miocene and C24n.	Near extinction of calcareous nannofossil *Reticulofenestra reticulata*			
Base Lutetian Stage	48.6	0.2	Calibrated magnetic anomaly scale relative to base-Miocene and C24n.	Planktonic foraminifer, lowest occurrence of *Hantkenina*	Leading candidate is Fortuna section, Murcia province, Betic Cordilleras, Spain	GSSP anticipated in 2004	
Base Ypresian Stage, base Eocene Series	55.8	0.2	Astronomical cycles in sediments scaled from base-Paleocene	Base of negative carbon-isotope excursion	Dababiya section near Luxor, Egypt	Ratified 2003	Episodes article in preparation
Paleocene Series							
Base Thanetian Stage	58.7	0.2	Astronomical cycles in sediments scaled from base Paleocene, using base of magnetic polarity chronozone C26n. Arbitrary 0.1 (2 precession cycles, plus the base-Paleogene radiometric) uncertainty assigned to all estimates.	Magnetic polarity chronozone, base of C26n, is a temporary assignment	Leading candidate is Zumaya section, northern Spain	Guide event is undecided	
Base Selandian Stage	61.7	0.2	Astronomical cycles in sediments scaled from base Paleocene, using magnetic polarity chronozone placement of C27n.9	Boundary task group is considering a higher level - base of calcareous nannofossil zone NP5 – which would be ~1 myr younger.	Leading candidate is Zumaya section, northern Spain	Guide event is undecided

EON, Era, System, *Series,* Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
Base Danian Stage, base Paleogene System, base Cenozoic	65.5	0.3	Ar-Ar and U-Pb age agreement	Iridium geochemical anomaly. Associated with a major extinction horizon (foraminifers, calcareous nannofossils, dinosaurs, etc.);	Base of boundary clay, El Kef, Tunisia *(but deterioration may require assigning a replacement section)*	Ratified 1991	
Mesozoic Era							
Cretaceous System				*Most substages of Cretaceous also have recommended GSSP criteria*			
Upper							
Base Maastrichtian Stage	70.6	0.6	Estimated placement relative to Ar-Ar calibrated Sr-curve	Mean of 12 biostratigraphic criteria of equal importance. Closely above is lowest occurrence of ammonite *Pachydiscus neubergicus.* Boreal proxy is lowest occurrence of belemnite *Belemnella lanceolata.*	115.2 m level in Grande Carrière quarry, Tercis-les-Bains, Landes province, SW France	Ratified 2001	Episodes 24 (4), p. 229–238, 2001; Odin (ed.) IUGS Spec. Publ. Series, v.36, Elsevier, 910pp.
Base Campanian Stage	83.5	0.7	Spline fit of Ar-Ar ages and ammonite zones.	Crinoid, extinction of *Marsupites testudinarius*	Leading candidates are in southern England and in Texas		
Base Santonian Stage	85.9	0.7	Spline fit of Ar-Ar ages and ammonite zones.	Inoceramid bivalve, lowest occurrence of *Cladoceramus undulatoplicatus*	Leading candidates are in Spain, England and Texas		
Base Coniacian Stage	89.3	1.0	Spline fit of Ar-Ar ages and ammonite zones.	Inoceramid bivalve, lowest occurrence of *Cremnoceramus rotundatus* (*sensu* Tröger *non* Fiege)	Base of Bed MK47, Salzgitter Salder Quarry, SW of Hannover, Lower Saxony, northern Germany	GSSP anticipated in 2004	
Base Turonian Stage	93.6	0.8	Spline fit of Ar-Ar ages and ammonite zones.	Ammonite, lowest occurrence of *Watinoceras devonense*	Base of Bed 120, Rock Canyon Anticline, east of Pueblo, Colorado, west-central USA	Ratified 2003	Episodes article in preparation
Base Cenomanian Stage	99.6	0.9	Spline fit of Ar-Ar ages and ammonite zones, plus monitor standard correction. Then cycle stratigraphy to place foraminifer datum relative to ammonite zonation.	Planktonic foraminifer, lowest occurrence of *Rotalipora globotruncanoides*	36 m below top of Marnes Bleues Formation, Mont Risou, Rosans, Haute-Alpes, SE France	Ratified 2002	Episodes article in preparation
Lower							
Base Albian Stage	112.0	1.0	Estimated placement relative to bases of Cenomanian and Aptian, with large uncertainty due to lack of GSSP criteria. Ar-Ar age of 114.6 +/– 0.7 Ma from *Parahoplites nutfieldensis* below.	Calcareous nannofossil, lowest occurrence of *Praediscosphaera columnata* (= *P. cretacea* of some earlier studies), is one potential marker.		Guide event is undecided	
Base Aptian Stage	125.0	1.0	Base of M0r, as recomputed from Ar-Ar age from MIT guyot	Magnetic polarity chronozone, base of M0r	Leading candidate is Gorgo a Cerbara, Piobbico, Umbria-Marche, central Italy		
Base Barremian Stage	130.0	1.5	Pacific spreading model for magnetic anomaly ages (variable rate), using placement at M5n.8.	Ammonite, lowest occurrence of *Spitidiscus hugii – Spitidiscus vandeckii* group	Leading candidate is Río Argos near Caravaca, Murcia province, Spain		
Base Hauterivian Stage	136.4	2.0	Pacific spreading model for magnetic anomaly ages (variable rate), using placement at base M11n.	Ammonite, lowest occurrence of genus *Acanthodiscus* (especially *A. radiatus*)	Leading candidate is La Charce village, Drôme province, southeast France		
Base Valanginian Stage	140.2	3.0	Pacific spreading model for magnetic anomaly ages (variable rate), using placement at M14r.3 (base *T. pertransiens*).	Calpionellid, lowest occurrence of *Calpionellites darderi* (base of – Calpionellid Zone E); followed by the lowest occurrence of ammonite *"Thurmanniceras" pertransiens*	Leading candidate is near Montbrun-les-Bains, Drôme province, southeast France		

EON, Era, System, *Series*, Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
Base Berriasian Stage, base Cretaceous System	145.5	4.0	Pacific spreading model for magnetic anomaly ages (variable rate), assigning to base of *Berriasella jacobi* zone (M19n.2n.55)	Maybe near lowest occurrence of ammonite *Berriasella jacobi*		Guide event is undecided	
Jurassic System							
Upper							
Base Tithonian Stage	150.8	4.0	Pacific spreading model for magnetic anomaly ages (variable rate), assigning to base M22An	Near base of *Hybonoticeras hybonotum* ammonite zone and lowest occurrence of *Gravesia* genus, and the base of magnetic polarity chronozone M22Ar		Guide event is undecided	
Base Kimmeridgian Stage	155.7	4.0	Pacific spreading model for magnetic anomaly ages (variable rate), assigning to base M26r.2 (Boreal ammonite definition)	Ammonite, near base of *Pictonia baylei* ammonite zone of Boreal realm	Leading candidates are in Scotland, SE France and Poland	GSSP anticipated in 2004	
Base Oxfordian Stage	161.2	4.0	Pacific spreading model for magnetic anomaly ages (variable rate), assigning to base M36An	Ammonite, *Brightia thuouxensis* Horizon at base of the *Cardioceras scarburgense* Subzone (*Quenstedtoceras mariae* Zone)	Leading candidates are in SE France and southernEngland	GSSP anticipated in 2004	
Middle							
Base Callovian Stage	164.7	4.0	Equal subzones scale Bajo-Bath-Callov	Ammonite, lowest occurrence of the genus *Kepplerites (Kosmoceratidae)* (defines base of *Macrocephalites herveyi* Zone in sub-Boreal province of Great Britain to southwest Germany)	Leading candidate is Pfeffingen, Swabian Alb, SW Germany	GSSP anticipated in 2004	
Base Bathonian Stage	167.7	3.5	Equal subzones scale Bajo-Bath-Callov	Ammonite, lowest occurrence of *Parkinsonia (G.) convergens* (defines base of *Zigzagiceras zigzag* Zone)			
Base Bajocian Stage	171.6	3.0	Equal subzones scale Bajo-Bath-Callov	Ammonite, lowest occurrence of the genus *Hyperlioceras* (defines base of the *Hyperlioceras discites* Zone)	Base of Bed AB11, 77.8 m above base of Murtinheira section, Cabo Mondego, western Portugal	Ratified 1996	Episodes 20 (1), p. 16–22, 1997
Base Aalenian Stage	175.6	2.0	Duration of Aalenian-Toarcian from cycle stratigraphy	Ammonite, lowest occurrence of *Leioceras* genus	base of Bed FZ107, Fuentelsalz, central Spain	Ratified 2000	Episodes 24 (3), p. 166–175, 2001
Lower							
Base Toarcian Stage	183.0	1.5	Duration of Aalenian-Toarcian from cycle stratigraphy	Ammonite, near lowest occurrence of a diversified *Eodactylites* ammonite fauna; correlates with the NW European *Paltus* horizon.		Guide event is undecided	
Base Pliensbachian Stage	189.6	1.5	Cycle-scaled linear Sr trend	Ammonite, lowest occurrences of *Bifericeras donovani* and of genera *Apoderoceras* and *Gleviceras.*	Wine Haven section, Robin Hood's Bay, Yorkshire, England, UK	GSSP anticipated in 2003	
Base Sinemurian Stage	196.5	1.0	Cycle-scaled linear Sr trend	Ammonite, lowest occurrence of arietitid genera *Vermiceras* and *Metophioceras*	0.9 m above base of Bed 145, East Quantoxhead, Watchet, West Somerset, SW England, UK	Ratified 2000	Episodes 25 (1), p. 22–26, 2002
Base Hettangian Stage, base Jurassic System	199.6	0.6	U-Pb age just below proposed GSSP for base-Jurassic	Near lowest occurrence of smooth *Psiloceras planorbis* ammonite group		Guide event is undecided	
Triassic System							
Upper							
Base Rhaetian Stage	203.3	1.5	Magnetostratigraphic correlation to cycle-scaled Newark magnetic polarity pattern	Near lowest occurrence of ammonite *Cochlocera*,conodonts *Misikella* spp. and *Epigondolella mosheri*, and radiolarian *Proparvicingula moniliformis.*	Key sections in Austria, British Columbia (Canada), and Turkey	Guide event is undecided

EON, Era, System, *Series*, Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
Base Norian Stage	216.5	2.0	Magnetostratigraphic correlation to cycle-scaled Newark magnetic polarity pattern	Base of *Klamathites macrolobatus* or *Stikinoceras kerri* ammonoid zones and the *Metapolygnathus communisti* or *M. primitius* conodont zones.	Leading candidates are in British Columbia (Canada), Sicily (Italy), and possibly Slovakia, Turkey (Antalya Taurus) and Oman.	Guide event is undecided	
Base Carnian Stage	228.0	2.0	Magnetostratigraphic correlation to cycle-scaled Newark magnetic polarity pattern	Near first occurrence of the ammonoids *Daxatina* or *Trachyceras*, and of the conodont *Metapolygnathus polygnathiformis*	Candidate section at Prati di Stuores, Dolomites, northern Italy. Important reference sections in Spiti (India) and New Pass, Nevada (USA).	Guide event is undecided	
Middle							
Base Ladinian Stage	237.0	2.0	U-Pb array by Mundil *et al.* on levels near *Nevadites* (= *Secedensis*) ammonite zone in Dolomites, plus placement relative to magnetostratigraphy corrlations to cycle-scaled Newark magnetic polarity pattern	Alternate levels are near base of *Reitzi, Secedensis,* or *Curionii* ammonite zone; near first occurrence of the conodont genus *Budurovignathus.*	Leading candidates are Bagolino (Italy) and Felsoons (Hungary). Important reference sections in the Humboldt Range, Nevada (USA).	Guide event is undecided	
Base Anisian Stage	245.0	1.5	Proportional subzonal scaling	Ammonite, near lowest occurrences of genera *Japonites, Paradanubites, and Paracrochordiceras;* and of the conodont *Chiosella timorensis*	Candidate section probable at Desli Caira, Dobrogea, Romania; significant sections in Guizhou Province (China).	GSSP anticipated in 2004	
Lower							
Base Olenekian Stage	249.7	0.7	Composite standard from conodonts scaled to base-Anisian and base-Triassic	Near lowest occurrence of *Hedenstroemia* or *Meekoceras gracilitatis* ammonites, and of the conodont *Neospathodus waageni.*	Candidate sections in Siberia (Russia) and probably Chaohu, Anhui Province, China. Important sections also in Spiti.	Guide event is undecided	
Base Induan Stage, base Triassic System, base Mesozoic	251.0	0.4	U-Pb ages bracket GSSP (Bowring *et al.*, 1998)	Conodont, lowest occurrence of *Hindeodus parvus*; termination of major negative carbon-isotope excursion. About 1 myr after peak of Late Permian extinctions.	Base of Bed 27c, Meishan, Zhejiang, China	Ratified 2001	Episodes 24 (2), p. 102–114, 2001

The steps involved in modern time-scale construction can be summarized as follows:

Step 1. Construct an updated global chronostratigraphic scale for Earth's rock record.

Step 2. Identify key linear-age calibration levels for the chronostratigraphic scale using radioisotopic age dates.

Step 3. Apply Earth-orbit tuning to intervals with cyclic sediments or stable isotope sequences that have sufficient biostratigraphic or magnetostratigraphic ties.

Step 4. Interpolate the combined chronostratigraphic and chronometric scale when direct information is insufficient.

Step 5. Calculate or estimate error bars on the combined chronostratigraphic and chronometric information to obtain a geological time-scale with estimates of uncertainty on boundaries and on unit durations.

Step 6. Peer-review the resultant geological time-scale.

The first step, integrating multiple types of stratigraphic information in order to construct the chronostratigraphic scale, is the most time-consuming; it summarizes and synthesizes centuries of detailed geological research and tries to understand all relative correlations and calibration to the standard chronostratigraphic scale.

The second step, identifying which radiometric and cycle-stratigraphic studies to use as the primary constraints for assigning linear ages, is the one that has much evolved. Historically, Phanerozoic time-scale building went from an exercise with very few and relatively inaccurate radioisotopic dates, as available to the pioneer of the geological time-scale Arthur Holmes, to one with many dates with greatly varying analytical precision, as in the mid-1980s of the past century. Next, time-scale studies started

Global Boundary Stratotype Sections and Points (GSSPs)

Status in Oct 2003; see ICS website (www.stratigraphy.org) for updates.

Base Kasimovian Stage	306.5	1.0	"	Near base of *Obsoletes obsoletes* and *Protriticites pseudomontiparus* fusulinid zone, or lowest occurrence of *Parashumardites* ammonoid.		Guide event is undecided	
Base Moscovian Stage	311.7	1.1	"	Near lowest occurrences of *Declinognathodus donetzianus* and/or *Idiognathoides postsulcatus* conodont species, and fusulinid species *Aljutovella aljutovica*.		Guide event is undecided	
Base Bashkirian Stage, base Pennsylvanian Subsystem	318.1	1.3	"	Conodont, lowest occurrence of *Declinognathodus nodiliferus* s.l.	82.9 m above top of Battleship Wash Fm., Arrow Canyon, southern Nevada, USA	GSSP ratified 1996. Subsystem rank of Mississippian and Pennsylvanian names ratified 2000.	Episodes 22 (4), p. 272–283, 1999
Mississippian Subsystem				*Series classification and nomenclature are currently under discussion*			
Base Serpukhovian	326.4	1.6	"	Near lowest occurrence of conodont, *Lochriea crusiformis*.		Guide event is undecided	
Base Visean	345.3	2.1	"	Foraminifer, lineage *Eoparastaffella simplex* morphotype 1/morphotype 2	Leading candidate is Pengchong, south China		
Base Tournaisian, base Mississippian Subsystem, base Carboniferous System	359.2	2.5	"	Conodont, above lowest occurrence of *Siphonodella sulcata*	Base of Bed 89, La Serre, Montagne Noir, Cabrières, southern France	Ratified 1990	Episodes 14 (4), p. 331–336, 1991
Devonian System			Devonian time scale is a statistical fit of a composite biostratigraphic zonation (based on Figure 8 of Williams *et al.*, 2000) to selected radiometric ages				
Upper							
Base Famennian Stage	374.5	2.6	"	Just above major extinction horizon (Upper Kellwasser Event), including conodonts *Ancyrodella* and *Ozarkodina and goniatites of Gephuroceratidae and Beloceratidae*	base of Bed 32a, upper Coumiac quarry, Cessenon, Montagne Noir, southern France	Ratified 1993	Episodes 16 (4), p. 433–441, 1993
Base Frasnian Stage	385.3	2.6	"	Conodont, lowest occurrence of *Ancyrodella rotundiloba* (defines base of Lower *Polygnathus asymmetricus* conodont Zone)	Base of Bed 42a', Col du Puech de la Suque section, St. Nazaire-de Ladarez, SE Montagne Noir, southern France	Ratified 1986	Episodes 10 (2), p. 97–101, 1987
Middle							
Base Givetian Stage	391.8	2.7	"	Conodont, lowest occurrence of Polygnathus hemiansatus, near base of goniatite Maenioceras Stufe	Base of Bed 123, Jebel Mech Irdane ridge, Tafilalt, Morocco	Ratified 1994	Episodes 18 (3), p. 107–115, 1995
Base Eifelian Stage	397.5	2.7	"	Conodont, lowest occurrence of *Polygnathus costatus partitus*; major faunal turnover	Base unit WP30, trench at Wetteldorf Richtschnitt, Schönecken-Wetteldorf, Eifel Hills, western Germany	Ratified 1985	Episodes 8 (2), p. 104–109, 1985
Lower							
Base Emsian Stage	407.0	2.8	"	Conodont, lowest occurrence of *Polygnathus kitabicus* (= *Po. dehiscens*)	Base of Bed 9/5, Zinzil' ban Gorge, SE of Samarkand, Uzbekistan	Ratified 1995	Episodes 20 (4), p. 235–240, 1997
Base Pragian Stage	411.2	2.8	"	Conodont, lowest occurrence of *Eognathodus sulcatus*	Base of Bed 12, Velká Chuchle quarry, southwest part of Prague city, Czech Republic	Ratified 1989	Episodes 12 (2), p. 109–113, 1989

EON, Era, System, *Series*, Stage	Age (Ma) GTS2004	Est. ± myr	Derivation of Age	Principal correlative events	GSSP and location	Status	Publication
Base Lochkovian Stage, base Devonian System	416.0	2.8	base-Devonian from scale in Cooper (this volume), which is 1 myr younger than Tucker et al (1998) estimate.	Graptolite, lowest occurrence of *Monograptus uniformis*	Within Bed 20, Klonk, Barrandian area, southwest of Prague, Czech Republic	Ratified 1972	Martinsson (ed.), The Silurian-Devonian Boundary, IUGS Series A, no.5, 349 pp., 1977
Silurian System			Silurian and Ordovician time scales are from calibrating a CONOP composite graptolite zonation to selecte radiometric ages				Holland and Bassett (eds), *A Global Standard for the Silurian System*, Nat. Mus. Wales, Geol. Series No.10, Cardiff, 325 pp., 1989
Pridoli Series							
Base Prídolí Series *(not subdivided in stages)*	418.7	2.7	"	Graptolite, lowest occurrence of *Monograptus parultimus*	Within Bed 96, Pozáry section near Reporje, Barrandian area, Prague, Czech Republic	Ratified 1984	Episodes 8 (2), p. 101–103, 1985
Ludlow Series		2.6					
Base Ludfordian Stage	421.3	2.6	"	*Imprecise.* May be near base of *Saetograptus leintwardinensis* graptolite zone.	Base of lithological unit C, Sunnyhill Quarry, Ludlow, Shropshire, southwest England, UK.	Ratified 1980	Lethaia 14, p.168, 1981; Episodes 5 (3), p. 21–23, 1982
Base Gorstian Stage	422.9	2.5	"	*Imprecise.*Just below base of local acritarch *Leptobrachion longhopense* range zone. May be near base of *Neodiversograptus nilssoni* graptolite zone.	Base of lithological unit F, Pitch Coppice quarry, Ludlow, Shropshire, southwest England, UK	Ratified 1980	Lethaia 14, p.168, 1981; Episodes 5 (3), p. 21–23, 1982
Wenlock Series							
Base Homerian Stage	426.2	2.4	"	Graptolite, lowest occurrence of *Cyrtograptus lundgreni* (defines base of *C. lundgreni* graptolite zone)	Graptolite biozone intersection in stream section in Whitwell Coppice, Homer, Shropshire, southwest England, UK	Ratified 1980	Lethaia 14, p.168, 1981; Episodes 5 (3), p. 21–23, 1982
Base Sheinwoodian Stage	428.2	2.3	"	*Imprecise.* Between the base of acritarch biozone 5 and extinction of conodont *Pterospathodus amorphognathoides.* May be near base of *Cyrtograptus centrifugus* graptolite zone.	Base of lithological unit G, Hughley Brook, Apedale, Shropshire, southwest England, UK	Ratified 1980	Lethaia 14, p.168, 1981; Episodes 5 (3), p. 21–23, 1982
Llandovery Series							
Base Telychian Stage	436.1	1.9	"	Brachiopods, just above extinction of *Eocoelia intermedia* and below lowest succeeding species *Eocoelia curtisi.* Near base of *Monograptus turriculatus* graptolite zone.	Locality 162 in transect d, Cefn Cerig road, Llandovery area, south-central Wales, UK	Ratified 1984	Episodes 8 (2), p. 101–103, 1985
Base Aeronian Stage	439.0	1.8	"	Graptolite, lowest occurrence of *Monograptus austerus sequens* (defines base of *Monograptus triangulatus* graptolite zone)	Base of locality 72 in transect h, Trefawr forestry road, north of Cwm-coed-Aeron Farm, Llandovery area, south-central Wales, UK	Ratified 1984	Episodes 8 (2), p. 101–103, 1985
Base Rhuddanian Stage, base Silurian System	443.7	1.5	"	Graptolites, lowest occurrences of *Parakidograptus acuminatus* and *Akidograptus ascensus*	1.6 m above base of Birkhill Shale Fm., Dob's Linn, Moffat, Scotland, UK	Ratified 1984	Episodes 8 (2), p. 98–100, 1985
Ordovician System							
Upper							
Base of sixth stage *(not yet named)*	450.2	1.6	"	Potentially near first appearance of the graptolite *Dicellograptus complanatus* and of the conodont *Amorphognathus ordovicicus.*		*Guide event is undecided*

to appear for selected intervals, such as Paleogene, Late Cretaceous, or Ordovician; these studies selected a small suite of radioisotopic dates with high internal analytical precision and relatively precise stratigraphic position. At the same time, a high-resolution Neogene time-scale started to take shape, using orbital tuning of long sequences of sedimentary and/or oxygen isotope cycles in the Mediterranean region and in Atlantic and Pacific pelagic sediments. The present trend for the pre-Neogene is to incorporate radioisotopic dates that have very small analytical and stratigraphic uncertainties, and pass the most stringent tests.

The third step, interpolating the stratigraphic and radiometric information, has also evolved. An early method had already constructed the basic two-way graph and was being used. This graph plotted the cumulative sum of maximum thicknesses of strata in thousands of feet per stratigraphic unit along the vertical axis and selected dates from volcanic tuffs, glauconites, and magmatic intrusives along the horizontal linear axis. This 'best-fit' line method, shown in Figure 3 as it was used in 1960, incorporated an uncertainty envelope from the errors on the radioisotopic age constraints. Despite its crudeness, the method was remarkably effective, but is a far cry from methods used today.

In the mid-1990s, Frits Agterberg and Felix Gradstein started to apply mathematical-statistical error analysis to the time-scale ages, which, for the first time, allowed them to assign fairly realistic error bars to ages of Mesozoic stage boundaries, a trend that persists today. A simplified introduction to the modern building tools is presented the following discussions, but first consider a frequently asked question: 'Which time-scale should be used?'.

Which Time Scale Should Be Used?

Of the several geological time-scales published in the past decade, a simple answer is to use the most recent one. A better answer is to investigate the pros and cons of these time-scales, the improvements that a new one might bring to a study, and to remember that it is not desirable to change units of measurement during execution of an experiment or survey or basin modelling exercise.

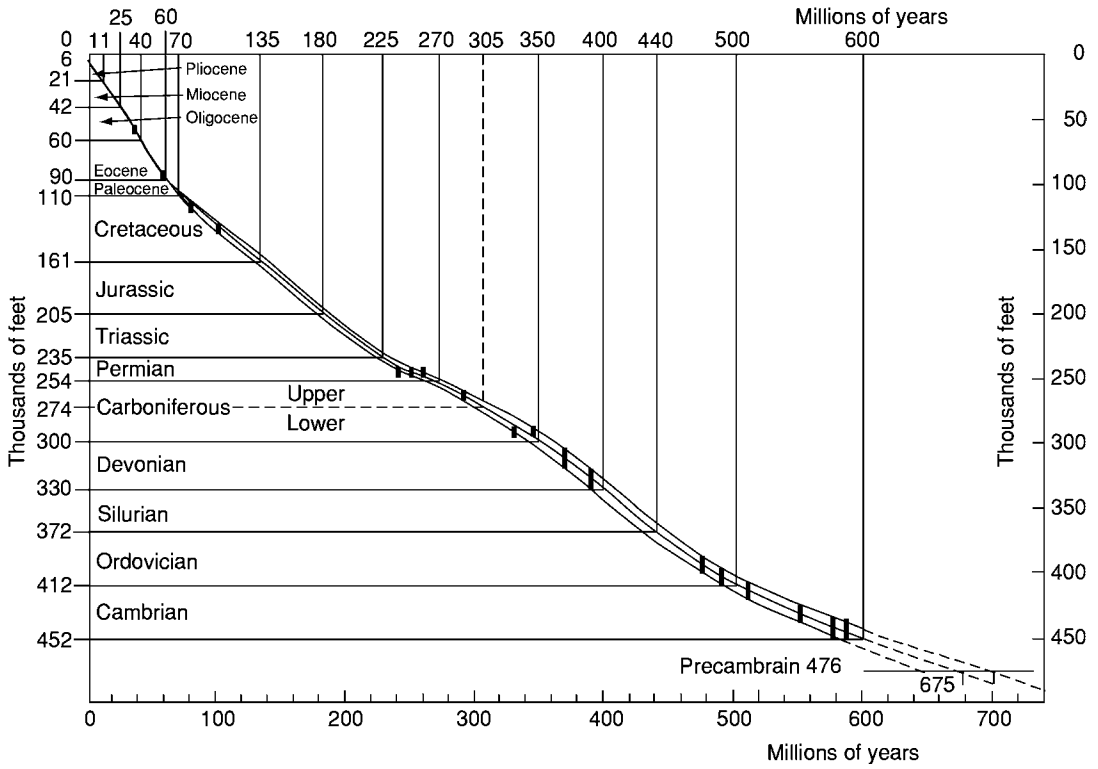

Figure 3 Scaling concept employed by Arthur Holmes in the first half of the twentieth century to construct the geological time scale. The cumulative sum of maximum thicknesses of strata, in thousands of feet per stratigraphic unit, is plotted along the vertical axis; selected radiometric dates from volcanic tuffs, glauconites, and magmatic intrusives are plotted along the horizontal linear axis. This version incorporated an uncertainty envelope from the errors on the radiometric age constraints. Modified from Holmes A (1960) A revised geological time scale. *Transactions of the Edinburgh Geological Society* 17: 183 216, with permission.

Certain qualities of a geological time-scale should be considered:

1. Does it use updated chronostratigraphic nomenclature of international standard?
2. Does it use all stratigraphic tools relevant to the interval for which the time-scale is intended, including magnetostratigraphy and its chronology, standard biozonations, stable isotope stratigraphy, cyclic stratigraphy interpolations, and/or orbital time-scale calibrations?
3. Are the stratigraphically meaningful radiometric age dates based on rigorous methodology, with the most up-to-date and accepted interlaboratory standards?
4. Does the scale bring out uncertainty in the age of individual stratigraphic boundaries?
5. Is the scale used in major geological projects and studies?

The ICS is actively engaged in time-scale construction and publication, which assists in bringing consensus and stability to the use of this international geological standard. Figure 4 shows the most up-to-date edition of the ICS scale.

Music of the Spheres

The sedimentary cycles approach to time-scale building, as is now standard for the time-scale of the past 23 My (Neogene), provides superior resolution and precision. Gravitational interactions of Earth with the sun, moon, and other planets cause systematic changes in Earth's orbital and rotational systems. These interactions give rise to cyclic oscillations in the eccentricity of Earth's orbit, and in the tilt and precession of Earth's rotational axis, with mean dominant periods of 100 000, 41 000, and 21 000 years, respectively (*see* **Earth:** Orbital Variation (Including Milankovitch Cycles)). The associated cyclic variations in annual and seasonal solar radiation falling onto different latitudes alter long-term climate in colder versus warmer, and wetter versus dryer, periods. These, in turn, create easily recognizable sedimentary cycles, such as regular interbeds of limy and shaly facies. Massive outcrops of hundreds or thousands of such cycles are observed in numerous geological basins (e.g., around the Mediterranean) and in sediment cores from ocean-based drilling sites.

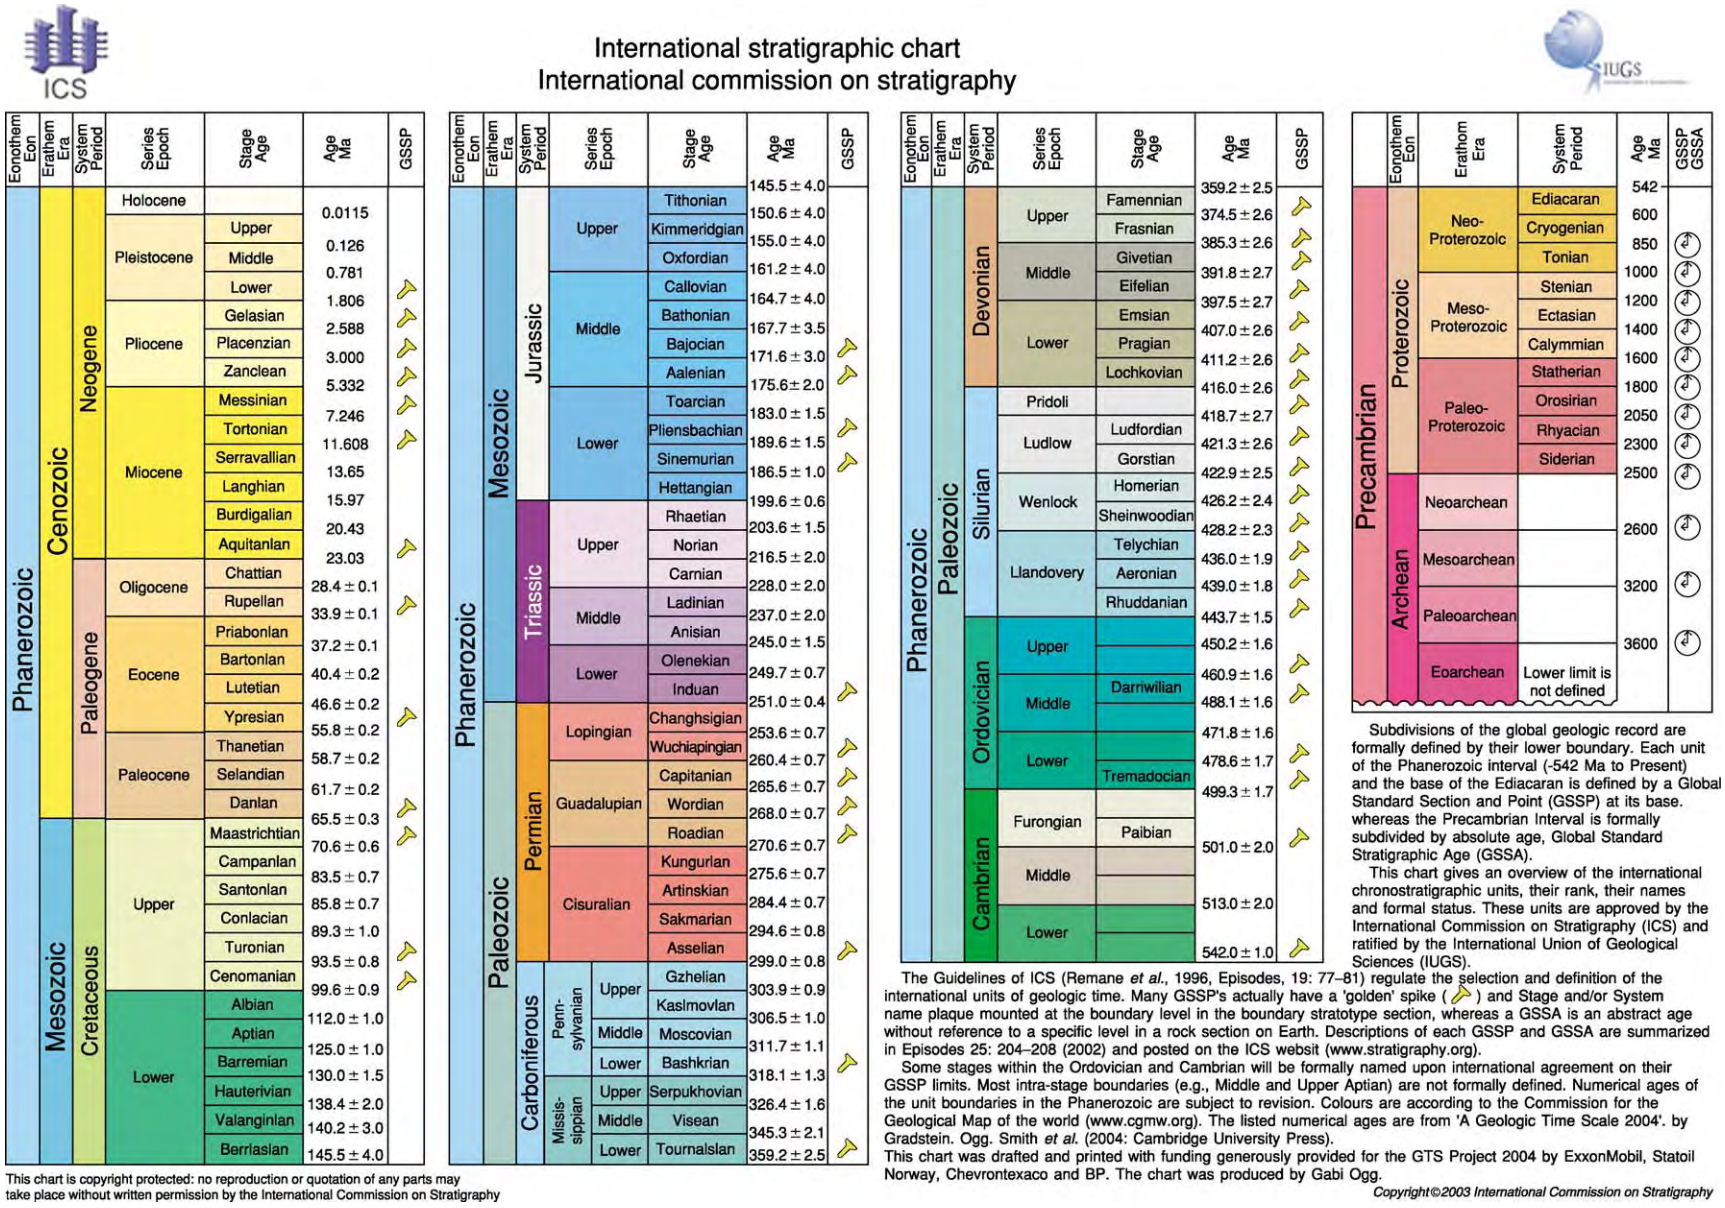

Figure 4 The international stratigraphic chart and time scale for the Phanerozoic, issued by the International Commission on Stratigraphy (ICS) (available on the Internet at http://www.stratigraphy.org). Reprinted from the International Commission on Stratigraphy (2003), with permission.

Greatly detailed counts these centimetre- to metre-thick cycles over land outcrops and in ocean drilling wells, combined with the additional correlation aids provided by magnetostratigraphy, oxygen isotope stratigraphy, and biostratigraphy, have been used to produce a very detailed Neogene sediment/orbital cycle pattern. The critical step is the direct linkage of each cycle to the theoretical computed astronomical scale of the 21 000-, 41 000-, and 100 000-year palaeoclimatic cycles. This astronomical tuning of the geological cycle record from the Mediterranean and Atlantic by earth scientists at Utrecht and Cambridge universities (e.g., Luc Lourens, Frits Hilgen, and Nick Shackleton) has led to unprecedented accuracy and resolution for the past 23 My. In New Zealand, Tim Naish and colleagues have calibrated the Upper Neogene record to the standard Neogene time-scale. Using the high-resolution land-based cycle, the isotope and magnetic record in the Wanganui Basin, these authors thereby transferred precise absolute ages to local shallow marine sediments and demonstrated the link between sequence and cycle stratigraphy.

Efforts are under way to extend the continuous astrochronological scale back into the Oligocene and Eocene by applying a combination of cycle stratigraphy, improved astronomical projections, oxygen isotope stratigraphy, and magnetostratigraphy to the deep-sea stratigraphic record. A special application of orbitally tuned cyclic sediment sequences is to 'rubber band' stratigraphically floating units, such as parts of the Paleocene, the Albian, and parts of the Lower Jurassic. A quantitative estimation of the duration of all cycles within a stratigraphic unit allows estimating their duration.

Decay of Atoms

For rocks older than the Neogene, the derivation of a numerical time-scale depends on the availability of suitable radioisotopic ages. Radioisotopic dating generally involves measuring the ratio of the original element in a mineral, such as sanidine feldspar or zircon, to its isotopic daughter products. The age of a mineral may then be calculated by means of the isotopic decay constant. Depending on the half-life of the element, several radioisometric clocks are available; $^{40}Ar/^{39}Ar$ and the family of U/Pb isotopes are the most common suites currently applied to the Phanerozoic, because of analytical precision and utility with tuffaceous beds in marine or non-marine sequences.

Radioisometric dating of sedimentary rocks follows several geological strategies:

1. Dating of igneous intrusions within sediments records the time of primary cooling, when the igneous rocks were emplaced and had cooled sufficiently (to a few hundreds of degrees centigrade) to set the radiometric decay clock in action. (Note: Because of uncertainty in the relation of the intrusion to the host sediment, such dates may be of limited stratigraphic use.)
2. Dating of volcanic flows and tuffs as part of the stratified sedimentary succession.
3. Dating of authigenic sedimentary minerals (mainly involving glauconite) found commonly in many marine sediments.

Note that mild heating or overburden pressure after burial may lead to loss of argon, the daughter product measured in the $^{40}K/^{40}Ar$ clock in glauconite. Another problem is that glauconite also contains an abundance of tiny flakes that allow diffusion of Ar at low temperatures. The result is that glauconite dates may be too young. Because of such problems, which may be difficult to detect, modern geological time-scales avoid dates based on glauconite.

Calibration of the decay constants or measurement standards can be enhanced by intercalibration to other radioisotopic methods, or by dating rocks of a known age (for example, a volcanic ash within an astronomically tuned succession). Astrochronological and interlaboratory recalibration of the $^{40}Ar/^{39}Ar$ monitor standard indicates that many of the $^{40}Ar/^{39}Ar$ ages used in previous Phanerozoic time-scales are too young by about 0.5–1.0%. For example, the age dating to 65.0 Ma that was assigned 10 years ago to the top Cretaceous is now 65.5 Ma.

Radioisotopic dating techniques with less than 1.0% analytical error are providing suites of high-precision U/Pb and Ar/Ar dates for the Palaeozoic and Mesozoic. The integration of this level of chronometric precision with high-resolution biostratigraphy, magnetostratigraphy, or cyclic scales is a major challenge to time-scale studies. Even the most detailed biostratigraphic scheme probably has no biozonal units of less than half a million years in duration, not to speak of the actual precision in dating a particular 'stratigraphic piercing' point, for which a U/Pb age estimate would be available with an analytical uncertainty of 100 000 years or more. Similarly, combining analytically less precise K/Ar dates with much more precise Ar/Ar or U/Pb dates in statistical interpolations creates a strong bias towards the latter, despite the fact that both may have equal litho-, bio-, and chronostratigraphic precision. Nevertheless, the combination of precise stratigraphic definitions through GSSPs and accurate radiometric dates near these levels is paving the way for a substantial increase in the precision and accuracy of the geological time-scale. The bases of Palaeozoic, Mesozoic, and

Cenozoic are bracketed by analytically precise ages at their GSSP or primary correlation markers – 542 ± 1.0, 251.0 ± 0.4, and 65.5 ± 0.3 Ma, respectively – and there are direct age dates for basal Carboniferous, basal Permian, basal Jurassic, basal Aptian, basal Cenomanian, and basal Oligocene. Most other period or stage boundaries lack direct age control. Therefore, the third step, linear interpolation, also plays a key role for development of the time-scale.

Interpolation and Statistics

Despite progress in standardization and dating, parts of the Mesozoic and Palaeozoic have sparse radioisotopic records. Ideally, each of the 90 or more stage boundaries that comprise the Palaeozoic, Mesozoic, and Cenozoic eras of the Phanerozoic should coincide with an accurate radioisotopic date from volcanic ashes that coincide with each of the stage boundaries. However, this coincidence is rare in the geological record. The combined number of fossil events and magnetic reversals far exceeds the total number of radioisotopically datable horizons in the Phanerozoic. Therefore, a framework of bio-, magneto-, and chronostratigraphy provides the principal fabric for stretching of the relative time-scale between dated tiepoints on the loom of linear time. For such stretching, interpolation methods are employed that are both geological and statistical in nature.

The outdated method of plotting the cumulative global thickness of periods against selected linear age dates was previously mentioned. Among the modern geological scaling methods, an assumption of relative constancy of seafloor spreading over limited periods of time is a common tool for interpolating the latest Cretaceous through Palaeogene relative scale. Magnetic polarity chrons – the units of magnetochronology – can be recognized both on the ocean floor, as magnetic anomalies measured in kilometres from the midocean spreading center, and in marine sediments, as polarity zones that contain biostratigraphic events and can be linked to linear time (*see* **Magnetostratigraphy**). Knowing the linear age of a few ocean crust magnetic anomalies (Earth magnetic reversals, or magnetochrons) allows interpolation of the ages of the intervening magnetic pattern, which, in turn, can be correlated to the fossil record and geological stage boundaries. The subduction of pre-Late Jurassic oceanic crust precludes such an interpolation approach for older Mesozoic and Palaeozoic strata.

A second geological method involves building a zonal composite to scale stages. Several outstanding examples are documented in the geological time-scale built by a large team of International Geological Congress (IGC) scientists in 2004. For this scale, Roger Cooper and colleagues have built a very detailed composite standard of graptolite zones from 200 or more sections in oceanic and slope environment basins for the uppermost Cambrian, Ordovician, and Silurian intervals. With zone thickness taken as directly proportional to zone duration, the detailed composite sequence was scaled using selected, high-precision age dates. For the Carboniferous through Permian, a composite standard of conodont, fusulinid, and ammonoid events from many classical sections can now be calibrated to a combination of U/Pb and $^{40}Ar/^{39}Ar$ dates. A composite standard of conodont zones was used for the Early Triassic. This procedure directly scales all stage boundaries and biostratigraphic horizons.

The two-way graphs of linear age versus scaled stages require a best-fit method, and that is where statistics comes into play, with cubic spline fitting and maximum-likelihood interpolation most suitable. On the time-scale of Figure 4, a majority of Phanerozoic stage boundaries for the first time show error bars; an exception is the Neogene Period, wherein analytical errors are negligible. These error bars reflect both radioisotopic and stratigraphic uncertainty. In addition, error bars were calculated on stage duration. Uncertainty in the duration of the age units is less than the error in age of their boundaries.

TRACE FOSSILS

P J Orr, University College Dublin, Dublin, Ireland

Introduction

Trace fossils and ichnofabrics offer an alternative source of data on the ecology of any palaeoecosystem to that provided by the body fossil record. Different preservational biases apply to the trace and body fossil records. 'Soft-bodied' organisms, i.e., those lacking biomineralized tissues, can produce trace fossils, yet their fossilization potential is minimal. Most trace fossils are emplaced into unconsolidated sediment, cannot survive reworking, and are thus autochthonous (in marked contrast to the vast majority of body fossils). The study of trace fossils and ichnofabrics has made a fundamental and growing contribution to our understanding of the evolutionary palaeoecology of the Earth's biosphere. Furthermore, bioturbation impacts on the physical and chemical properties of sediments, including their diagenesis. Key terms employed in the taxonomic, preservational, and ethological classification of trace fossils are defined; how trace fossils and ichnofabrics are used in palaeoenvironmental and community reconstructions is discussed.

'Trace fossil' is used herein to describe any discrete structure produced by the reworking of sediment or the bioerosion of lithic (rock) or xylic (wood) substrates by infauna or epifauna. Eggs and sedimentary structures produced by physical processes do not represent trace fossils. Some authorities include stromatolites within this term, on which basis

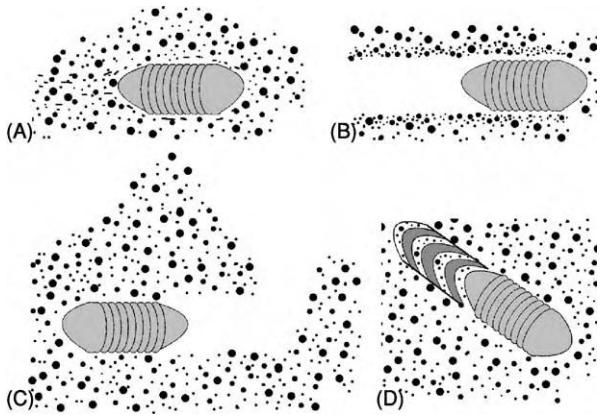

Figure 2 Style of burrowing reflects substrate consistency. (A) Intrusive burrowing typical of near surface soupgrounds. (B) Compression burrowing generates an open burrow and no spoils. (C) Excavation, yielding an open burrow and advected spoil. (D) Excavation, producing a backfilled burrow. In the latter case, the active infill, i.e., by the producer, may be structureless, but is often sorted; examples include separation into a distinct core and marginal or (as here) meniscate structures. The geom etry of individual menisci can vary from shallow and saucer like to sharply pointed cones; successive menisci are often defined by alternations in their colour and/or composition.

'suspect microbial structures' (e.g., wrinkle structures (Figure 1), roll-up structures, and elephant skin texture) would be included; these are attributed to the presence, including plastic deformation, of microbially bound crusts or veneers on the top of the sediment column. An ichnofabric, all aspects of the sedimentary texture that result from biogenic reworking, includes any remnant sedimentary structures, trace fossils, or indistinct structures produced by macrofauna ('sediment churning', 'burrow mottling', and biodeformational structures) that cannot be accorded formal taxonomic status. The poor definition of the latter usually reflects their emplacement in sediments with a high pore water content and low sediment shear strength (soupgrounds); it may be compounded by the employment of a different burrowing strategy (Figure 2). Intrusive burrowing in uncompacted sediment involves simple deflection of the sediment around the body; the sediment collapses behind the body to occlude any void immediately (sediment swimming). In more compacted sediments (softgrounds and firmgrounds), compression burrowing and, especially, excavation (accompanied by either advection or backfilling) produce more complex, open, and actively infilled structures. Cryptobioturbation, resulting from the activities of meiofauna and microfauna, may obliterate any primary sedimentary depositional fabric and homogenize sediment without producing either discrete trace fossils or biodeformational structures.

Taxonomy, Preservation, and Ethology

Taxonomy

Trace fossils are classified using ichnogenus and ichnospecies; the prefix 'ichno' distinguishes these ichnotaxa from either living organisms or body fossils. Some higher rank categories (ichnofamilies), or informal groupings, have been established, but are not used widely. As a sedimentary structure, the detailed morphology of a trace fossil reflects both the producer's behaviour and the properties of the host sediment; characteristics of the latter (such as water content or grain size) can vary between beds, or even the laminae of a bed (Figures 3A and 3B). The abundance, probably surfeit, of ichnotaxa, particularly ichnospecies, in the geological literature has its origin in the middle to late nineteenth century, when many trace fossils were interpreted as body fossils; every subtle variation in morphology was therefore considered to be significant, and the structure worthy of separate classification. Further, and more easily resolved by comprehensive study, the morphology of a trace fossil *in partim*, and thus the ichnotaxobases (the features used to classify it), may vary depending on the orientation in which it is observed (Figures 3B and 3C).

Identifying the producer Trace fossils are very rarely preserved in association with their producer; if they are, each should be named separately. The identification of the causative organism is not a prerequisite for the naming of a trace fossil. One organism may produce more than one trace fossil depending on its behaviour (Figure 4A). A structure may also be produced by different coexisting organisms (Figure 4B), or modified later by a different organism. Potential producers may be constrained (usually at the

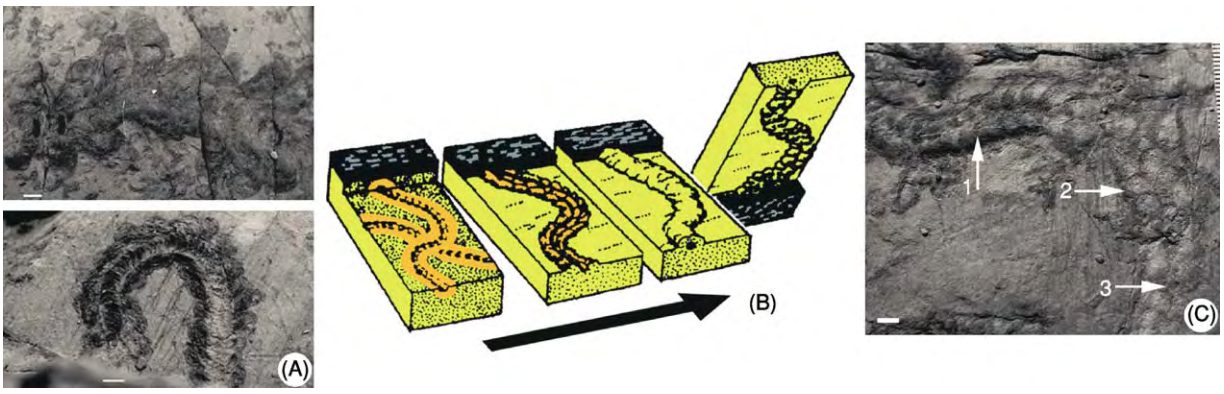

Figure 3 Key concepts in the study of trace fossils 1. (A) Preservational variants of the same ichnotaxon, reflecting emplacement in sediments of different consistency. resolution of phylum or class) by the morphology and inferred function of the trace fossil (e.g., 'arthropod-produced trackway'). The body fossil content of the same, or surrounding, lithologies may be suggestive; for example, the breadth of a trackway may correspond to that of one, but not other, potential candidates. The potential producers of trace fossils, however, include organisms with minimal preservation potential. Furthermore, the same trace fossil may be produced by a variety of animals, precluding extrapolation of the producer's identity between case studies. The resting trace *Rusophycus*, examples of which in Palaeozoic marine sediments are often attributed to trilobites (*see* **Fossil Invertebrates:** Trilobites), also occurs in Mesozoic strata (after trilobites became extinct) and in sediments from (non-marine) environments that were never colonized by trilobites (Figure 4C).

Preservation

Exogenic trace fossils are emplaced at the sediment–water or sediment–air interface, and endogenic traces within the substrate; intergenic trace fossils are those emplaced endogenously at the interface between two beds (Figure 5A). Exogenic trace fossils have limited fossilization potential; they must be covered and thus cast, not eroded, during later deposition. Splitting at the original interface will yield both epirelief and hyporelief views of the structure. Loading of the substrate during emplacement of exogenic traces may depress underlying sediment; in finely laminated lithologies, splitting a short vertical distance below the original interface may reveal such undertracks, the resolution of which is often poorer than that of the corresponding exogenic expression; furthermore, only those parts of the trace fossil where loading was greater may be expressed as undertracks. Endogenic trace fossils observed in three dimensions are in full relief; those exposed on bedding-parallel surfaces

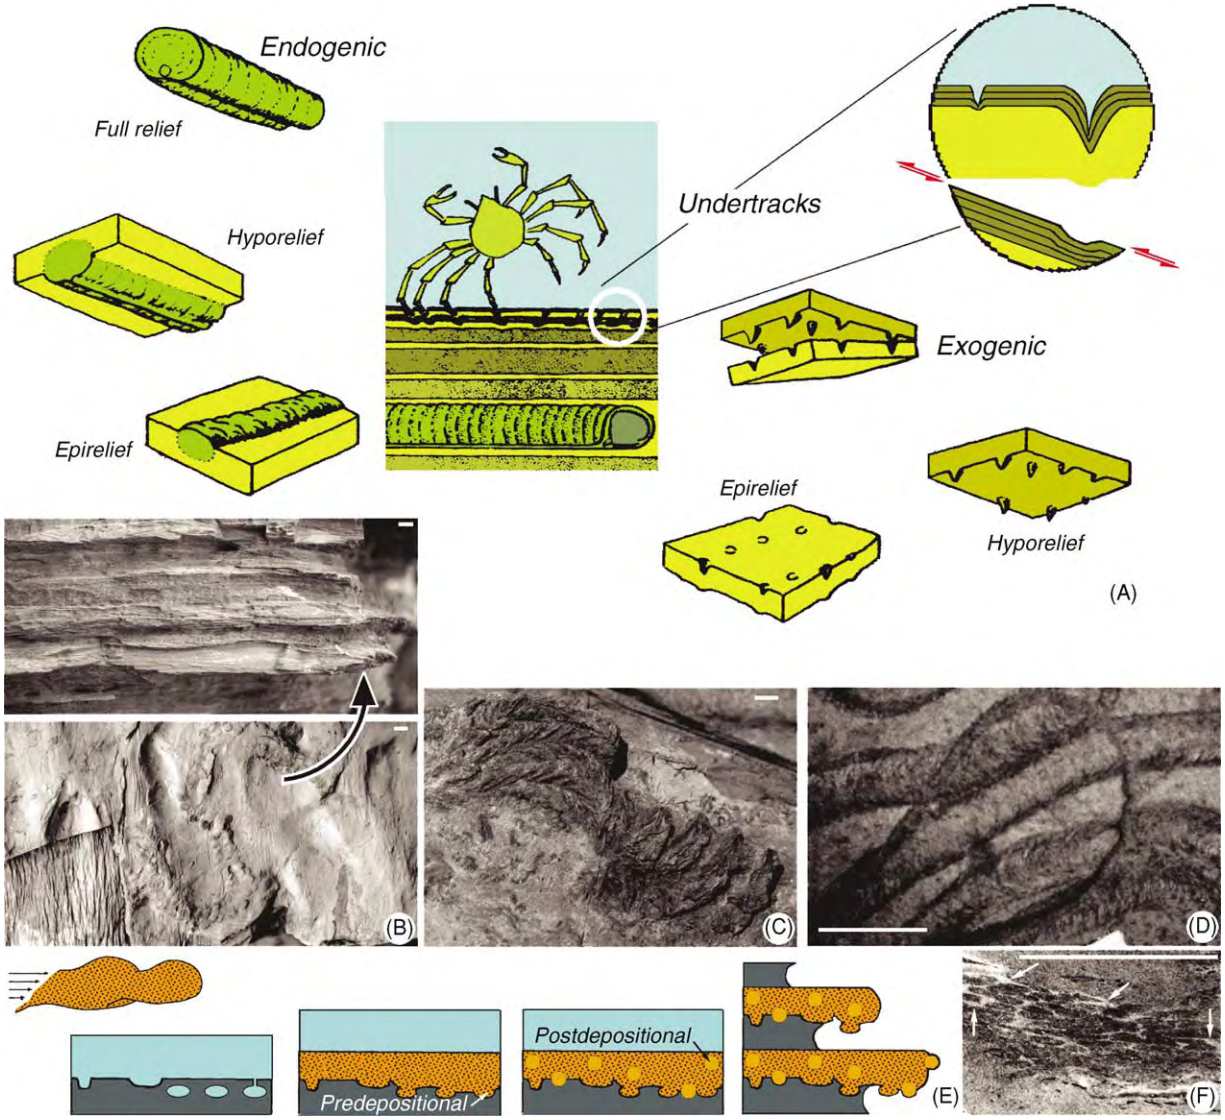

Figure 5 Key concepts in the study of trace fossils 3. (A) Preservational classification of trace fossils. Adapted from Ekdale AA, Bromley RG, and Pemberton SG (1984) *Ichnology. The Use of Trace Fossils in Sedimentology and Stratigraphy. SEPM Short Course No. 15.* Tulsa, OK: Society of Economic Paleontologists and Mineralogists. (B) The intergenic trace fossil is exposed in semirelief (positive hyporelief) on the sole of a bed of sandstone following preferential weathering of the underlying finer grained bed. (C) Positive epirelief view of *Lophoctenium* showing differential weathering of alternate menisci. (D) Polished horizontal cross section through an actively infilled burrow comprising a thick marginal wall structure and meniscate core. (E) Formation of predepositional and postdepositional trace fossils on the sole of an event bed. (F) Although the faecal pellets are the same colour and sourced from the host lithology, the light coloured sediment in the interstices between them indicates that the trace fossil is secondary. Scale bars, 5 mm.

are in semirelief; hyporelief and epirelief are used when the lower or upper surface, respectively, is that exposed. The orientation of specimens in the field should be determined at the time of their collection using independent criteria provided by sedimentary structures. The prefixes positive and negative describe the relief of the trace fossil relative to the host lithology. Full relief, and particularly semirelief, views can result from planes of splitting deflecting to follow the external surface of, rather than continuing across, a trace fossil. Semirelief views of intergenic structures are most common when successive lithologies have a different resistance to weathering (Figure 5B). Parts of an individual structure may weather differently; in the example in Figure 5C, alternate chevron-shaped menisci are either more sand-rich or mud-rich than, and thus have weathered positive and negative with respect to, the host lithology. Localized differences in the sedimentary fabric that result from bioturbation can be exacerbated during diagenesis. Trace fossils are often sites for the precipitation of early diagenetic minerals; this may be encouraged by the presence of mucus secreted during burrowing as an aid to locomotion, excretion, or to maintain an open structure. This can impact on economically important variables such as sediment texture, organic content, porosity, and permeability.

An open structure connected to either the air or water column may be later infilled gravitationally (passive infill) by sediment of a different composition and/or grain size. Active infill of a structure is by its progenitor. Modifications resulting from the reworking of sediment, for example during its ingestion and passage through the gut of an animal, include (1) excretion as pellets or a faecal string; (2) the exclusion or selection of grains by shape, size, or type; and (3) the reorientation of grains to produce a localized sedimentary fabric (Figure 5D).

Predepositional and postdepositional trace fossils Postdepositional trace fossils are emplaced after the deposition of a bed; the term 'predepositional' is used for trace fossils, now preserved on the sole of a bed, that were emplaced on the surface of, or within, the underlying bed. Thus, while an exogenic trackway in epirelief view is postdepositional, the secondary cast produced during deposition of the next bed, and exposed subsequently in hyporelief on the sole thereof, is predepositional. For exogenic trace fossils, the process requires there to be no erosion of the existing sediment. More extensive erosion, however, may expose endogenic open burrow systems, or wash away the active infill of burrows whilst preserving their outlines; infill of the voids created generates predepositional secondary casts (Figure 5E). The critical conditions, erosion closely followed by deposition, are often met during deposition of event beds, such as turbidites or storm deposits.

Postdepositional intergenic burrows may be emplaced later onto a surface containing predepositional secondary casts (Figure 5E). As well as the difference in their relative age, each suite may reflect different environmental conditions. Only the lower surface of a predepositional endogenic burrow system will be preserved; its infill will comprise the host lithology. Active infill of a postdepositional burrow may include modification of the host lithology (see above); in vertical cross-section, the outline of the burrow (whether infilled actively or, later, passively) will be complete.

Primary and secondary trace fossils Primary trace fossils represent either reworking of the host lithology *in situ* (but not necessarily at the time of its deposition), or the piping downwards of sediment of identical composition from one layer into another. Their identification relies on the properties of the host lithology being altered in the process (see above). Secondary trace fossils originate when sediment with different properties is 'piped' (usually downwards) into the host lithology; the evidence can be subtle (see example in Figure 5F).

Ethology

A behavioural, or ethological, classification of trace fossils is presented in Figure 6. Few trace fossils represent just one activity, and classification is thus on the basis of what is considered to be the dominant, most significant, behaviour. Cubichnia, temporary resting traces, are usually shallow, exogenic excavations (Figure 7A). Repichnia, locomotion traces, include both endogenic continuous burrows and exogenic structures. The latter may be continuous (trails), or comprise a series of discrete sequential footfalls (tracks or imprints) made by an appendage or limb (trackways) (Figure 7B). Pascichnia combine continuous locomotion parallel to bedding with feeding; emphasis is on the systematic extraction of food resources within an area (cf., strip mining). This is achieved by phobotactic (the avoidance of crossing previously formed parts of the structure), combined with strophotactic (episodic or periodic 180° turns) and/or thigmotactic (tendency to keep close to a previously formed part of the structure), behaviour patterns (Figures 7C and 7D). Trails in negative epirelief with similar geometries on the surfaces of modern ocean floors are exogenic structures with limited fossilization potential; at least, the vast majority of fossil pascichnia were actively filled endogenic burrow systems. Agrichnia are endogenic burrow

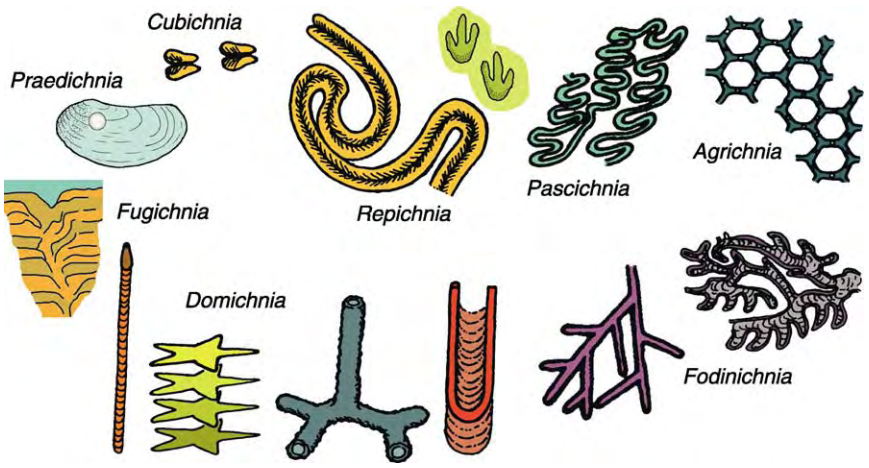

Figure 6 An ethological classification of trace fossils. Adapted from Ekdale AA, Bromley RG, and Pemberton SG (1984) *Ichnology. The Use of Trace Fossils in Sedimentology and Stratigraphy. SEPM Short Course No. 15.* Tulsa, OK: Society of Economic Paleontologists and Mineralogists.

systems that were maintained as open structures, and are therefore almost always preserved in positive hyporelief as predepositional secondary casts (Figures 5E and 7E). Their characteristic, complex geometries in plan view include fish scale-like, polygonal, and planispiral patterns. Spiralling patterns maintain a constant spacing between successive whorls, i.e., they do not exhibit thigmotactic behaviour. Many agrichnia are essentially two-dimensional, contained within a single plane parallel to the sediment–water interface; three-dimensional structures comprise several such levels, separated from each other vertically and connected by a more steeply inclined continuous open burrow. Agrichnia possessed single or multiple vertical connections to the overlying water column. As with domichnia (see below), the introduction of oxygenated seawater to depth within the sediment could have reduced the idealized vertical stratification of electron acceptors to a patchwork of biogeochemical microenvironments (Figure 8). Their exact function is unknown, but agrichnia may represent traps or 'microbial gardens'; microbes may be cultured on, and harvested from, the walls. Fodinichnia combine semistationary behaviour with deposit feeding. Geometries are highly variable and include two-dimensional, bedding-parallel, and three-dimensional forms. The key morphological element is the derivation of a series of branching, non-interpenetrating, straight or curved shafts, or spreiten-infilled lobes, from a common source (Figures 7F–7H). Domichnia are open burrow systems, or borings into xylic and lithic substrates (Figures 7I–7L), utilized on a semipermanent basis; most are for habitation, but structures specifically constructed for other functions (e.g., brood chambers) have been identified; some examples of the fossilized cases of caddis larvae contain pupae (Figure 7K). Domichnia in soft sediments often exhibit passive infill from the overlying layer and a thick marginal lining (to prevent collapse of the open burrow system); examples include the pelleted walls typical of *Ophiomorpha*. A domichnion in a firmground may have a bioglyph on its internal surface (Figure 7L). A 'spreite' (plural spreiten) is produced by shifting the position of a U-shaped vertical burrow in order to maintain its base a constant distance below the sediment–water interface. The spreite, which marks the former position of the basal part of the burrow, may be protrusive (occurring inside the limbs of the open burrow system in response to sediment being removed; Figure 7I), and/or retrusive (occurring below the active burrow in response to sediment aggradation). Equilibrichnia, formed by the regular, incremental shift upwards of burrows in response to the semicontinuous accretion of sediment, are considered here as a variety of domichnion. Rapid upward (attempted) escape, for example following burial by sediment, results in poorly structured escape traces, fugichnia (fugichnion). Unequivocal examples of praedichnia, trace fossils indicating predation, include the holes drilled in the shells of other molluscs by some gastropods by mechanical and/or chemical means (Figure 7M); the acid secreted by muricid gastropods can have a pH as low as 3.8. More equivocal examples in soft substrates include the intersection of two trace fossils, following which only one continues.

This classification scheme works well for the majority of trace fossils, although it has its limitations. Categories can grade into each other; for example,

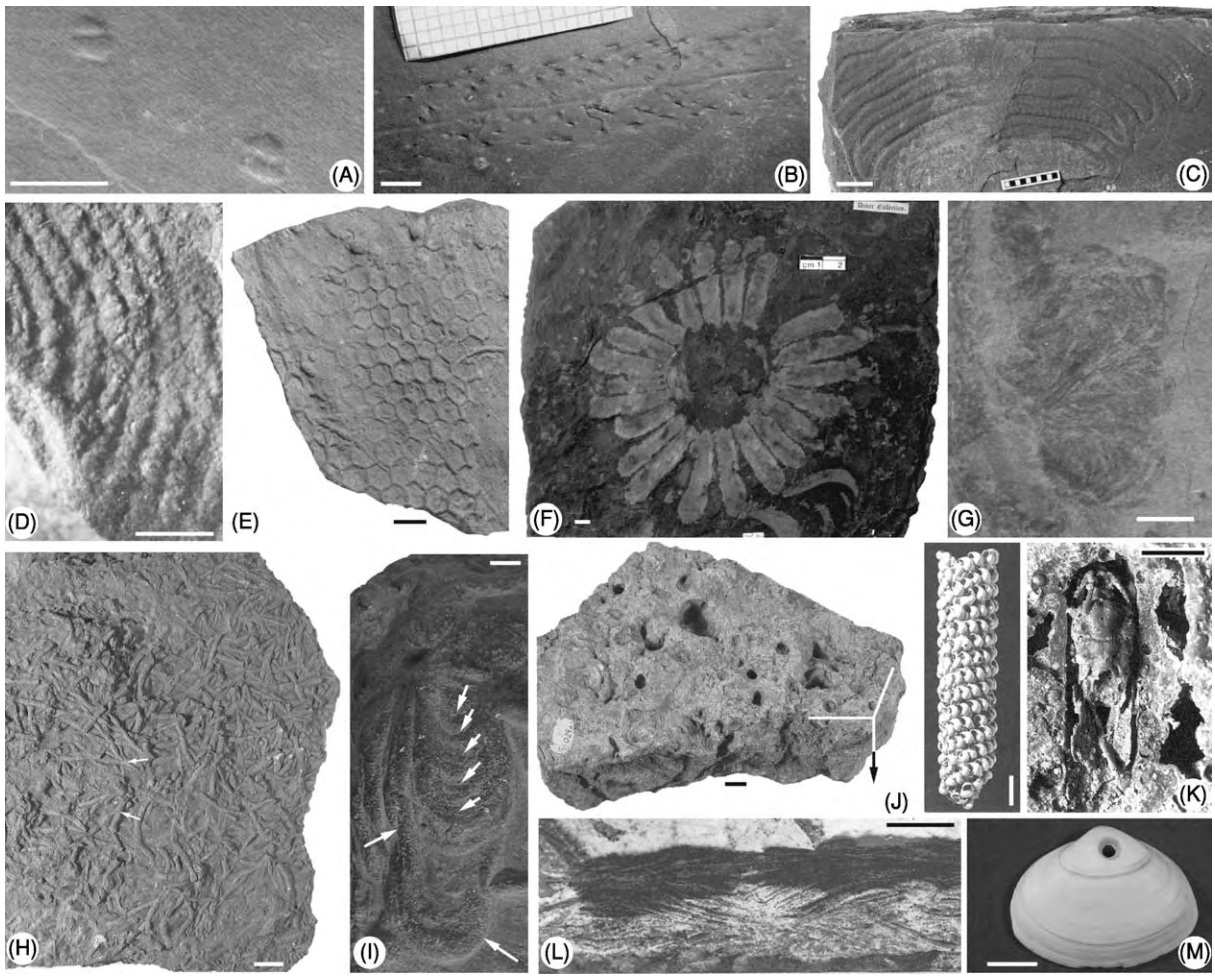

Figure 7 Variation in behaviour represented by trace fossils. (A) The cubichnion, *Rusophycus*. (B) An arthropod produced repich nion. at what point is a meandering pattern sufficiently regular to warrant the descriptor pascichnion, not repichnion? Opinions may vary between authors as to what the dominant behaviour is; the burrow *Planolites* has been considered a fodinichnion, pascichnion, and repichnion, as it involves reworking of the sediment whilst on the move in a straight to sinuous curve. Finally, each ichnospecies within an ichnogenus need not have the same ethology; more rarely, the ethology may vary (e.g., between a repichnion and a pascichnion) amongst a set of specimens of an ichnospecies.

Use as Environmental Indicators

Information from trace fossils and ichnofabrics can be incorporated into palaeoenvironmental reconstructions at scales ranging from the individual bed (reconstruction of a single endobenthic community) to depositional sequences tens to hundreds of metres thick (e.g., ichnofacies).

Ichnofacies

Ichnofacies are recurrent combinations of sedimentary facies and trace fossils; the Skolithos, Cruziana,

Zoophycos, and Nereites ichnofacies, emplaced within marine softgrounds, characterize successively greater water depths (Figures 9 and 10). The use of trace fossils as a palaeobathymetric indicator exploits the fact that many, particularly ichnogenera, have a long time range, but are restricted to, or most common in, specific environmental conditions. These conditions include wave or current energy, temperature, chemistry (including salinity and quantity of dissolved gases such as oxygen), light penetration, nutrient supply, competition for ecospace and resources, sedimentation rate, and substrate character (including the grain size and geotechnical properties of soft sediments). Changes in these conditions tend to correlate with changes in absolute water depth, and thus the palaeobathymetry is depth related rather than depth controlled. Environmental conditions are, however, far from uniform at any given water depth. Local factors may control the distribution of ichnofacies; for example, depositional conditions in the proximal or channellized parts of a submarine fan may resemble the high-energy, mobile substrates typical of nearshore environments, and the Skolithos ichnofacies occur in each. A change in environmental conditions can produce a succession of ichnofacies that mimics, but is not the product of, significant changes in water depth; progradation of the submarine fan in Figure 9A would result in lithologies with a Skolithos ichnofacies succeeding those with a Nereites ichnofacies, unaccompanied by any significant decrease in water depth. The Glossifungites, Trypanites, and Teredolites ichnofacies are emplaced into firmgrounds, lithic substrates, and xylic substrates, respectively (Figure 10); water depth is not a controlling factor (Figure 9B). Some authors recognize the Psilonichnus (between the foreshore zone and the terrestrial realm) and Arenicolites (opportunistic colonization of newly deposited event beds) ichnofacies. Originally identified as the Scoyenia ichnofacies, the heterogeneity of non-marine environments does not lend itself to classification; several alternative detailed subdivisions have been proposed, but no consensus has emerged.

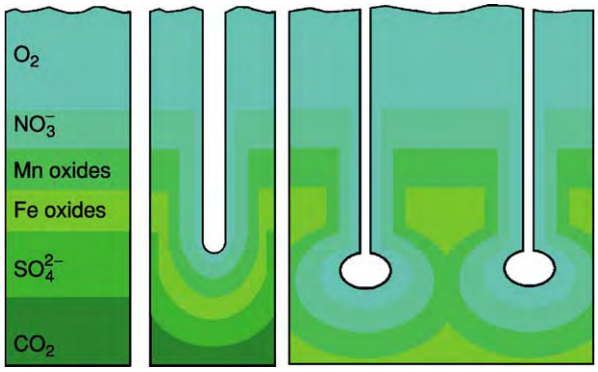

Figure 8 Modification of the idealized vertical stratification of electron acceptors via the emplacement of an open burrow structure at depth.

The presence or absence of an individual ichnogenus, even that after which the ichnofacies is named, is not strong evidence for a particular water depth. Furthermore, the bathymetric ranges of some ichnotaxa are known to have changed over

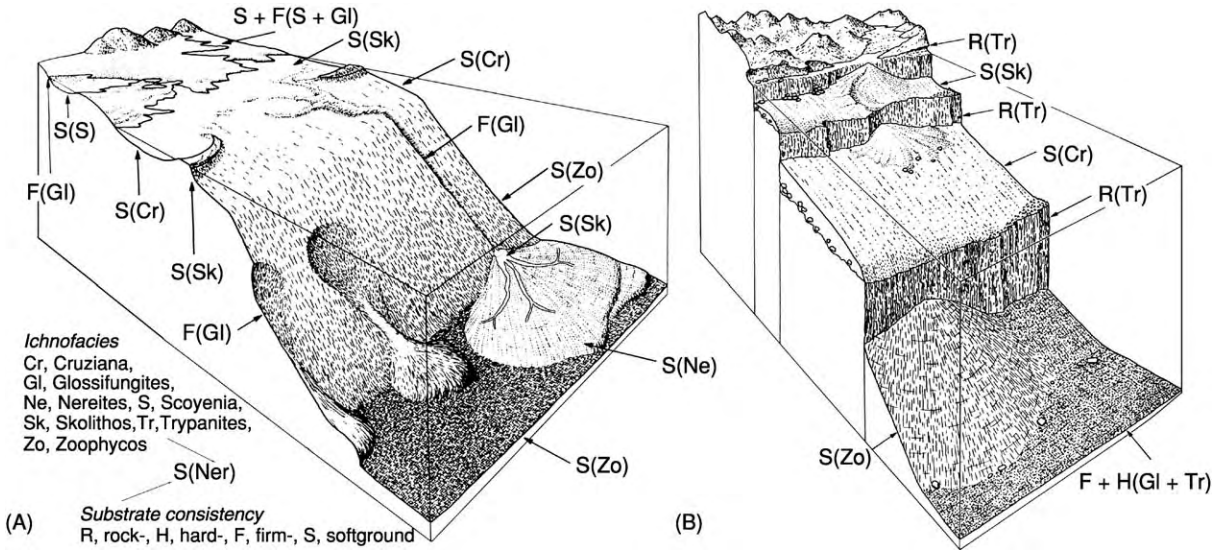

Figure 9 Schematic representation of the distribution of ichnofacies in marine environments. (A) Passive continental margin. (B) Sediment starved active continental margin. Skolithos ichnofacies

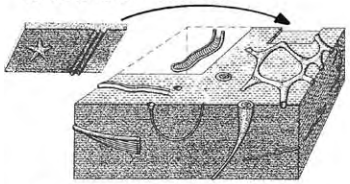
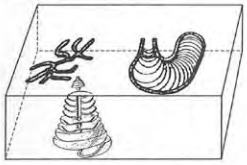
- *Typical environments:* moderate to relatively high energy conditions; muddy to clean, well-sorted, shifting substrates, subject to abrupt deposition and erosion.
- *Trace fossil content:* vertical, cylindrical, or U-shaped domichnia; latter may have protrusive and/or retrusive spreiten; also fugichnia.

Cruziana ichnofacies



- *Typical environments:* infralittoral to shallow circalittoral substrates; below daily wave base, but not storm wave base to offshore shelf; moderate to low energy; well-sorted to muddy silts and sands.
- *Trace fossil content:* varied; bedding-parallel epigenic and endogenic repichnia. Domichnia often with protrusive spreiten. Fodinichnia varied. Cubichnia common.

Zoophycos ichnofacies

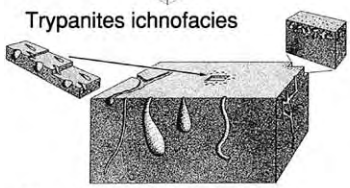


- *Typical environments:* circumlittoral to littoral; quiet-water, ?reduced oxygen; firm organic-rich sands and muds; sediment accretion continuous.
- *Trace fossil content:* simple to complex fodinichnia often with planar, inclined, or helicoidal spreiten; deposit feeding predominates; reduced diversity may reflect poorly oxygenated waters.

Nereites ichnofacies

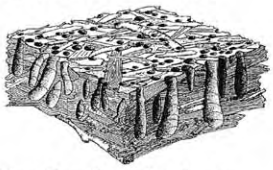
- *Typical environments:* bathyal to abyssal, quiet, oxygenated waters; episodic turbiditic deposition or continually accreting pelagic surfaces.
- *Trace fossil content:* bedding-parallel pascichnia and agrichnia dominate in distal parts of turbiditic fans; their distribution can be mutually exclusive reflecting partitioning into specific environmental niches. Proximal parts of turbidite fans often with vertical, cylindrical, or U-shaped domichnia; pelagic and hemipelagic sequences including inter-trubidite deposits usually dominated by fodinichnia and actively infilled repichnia.

Trypanites ichnofacies



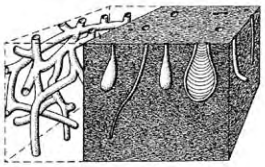
- *Typical environments:* lithic substrates, notably littoral omission substrates; also organic (shell, bone) substrates.
- *Trace fossil content:* cylindrical or vase-shaped endolithic domichnia; shallow cubichnia produced by epifauna; praedichnia in biomineralized tissues, e.g., shells.

Teredolites ichnofacies



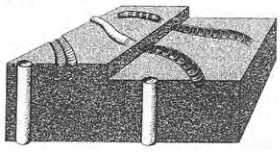
- *Typical environments:* xylic substrates, including forested marginal marine settings (mangrove swamps); high-density occurrence of allochthonous bored wood can be associated with flooding surfaces.
- *Trace fossil content:* lined or unlined domichnia, diversity often low or monospecific.

Glossifungites ichnofacies



- *Typical environments:* firmgrounds, often marine littoral and sublittoral omission surface; suitable substrates can also occur following incision into partially consolidated sediments.
- *Trace fossil content:* varied domichnia, including vertical, cylindrical, tear-shaped, or U-shaped burrows, and branching and gallery-like open networks.

Scoyenia ichnofacies



- *Typical environments:* terrestrial environments are extremely varied, but preservation potential highest in softgrounds and firmgrounds at margins of aquatic environments. Subdivisions or alternatives are available for specific environmental settings.
- *Trace fossil content:* bedding-parallel, meniscate burrows; vertical or gallery-like domichnia; invertebrate, particularly arthropod-produced, cubichnia and repichnia; vertebrate-produced repichnia.

time. During most of the Palaeozoic, the ichnogenus *Zoophycos* occupied a broad range of marine water depths; since the Early Permian, it has become progressively restricted to greater water depths and is only found in continental slope and deep basin settings today.

Use of Infaunal Ecospace: Endobenthic Tiering

Bioturbation in modern, fine-grained substrates undergoing accretion that is the work of a single community can be divided into three general levels: the surficial mixed and underlying transition layers in which bioturbation occurs, and the lowest historical layer which contains the ichnofabric preserved after diagenesis and lithification (Figure 11A). As sediment properties change progressively with depth, the boundary between the mixed and transition layers is gradational, not abrupt; it is convenient, however, to model the two as distinct layers. Mixed layer sediments are often soupgrounds and thus, although bioturbated completely, the trace fossils are often poorly preserved. Bioturbation in the transition layer is heterogeneous and occurs as discrete burrows. These are usually well defined because of the high shear strength of these more dewatered sediments (softgrounds or even firmgrounds); other progressive changes with depth include reductions in both the volume and degree of oxygenation of the interstitial pore waters. Vertical partitioning, tiering, of the transition layer infauna (and thus the trace fossils they emplace) occurs in response to such changes in the physical and chemical properties of the sediments (Figure 11A). Reconstruction of the tiering profile therefore provides a measure of the community complexity; this can include the depth to which sediments were bioturbated and thus the volume of ecospace exploited. As sediment accretes, organisms will move upwards to maintain the same level or ecological niche; trace fossils produced at shallower depths will thus be cross-cut by those emplaced at successively greater depths. Dominant to unilateral cross-cutting of one trace fossil by another implies that the latter belonged to a deeper tier; the mutual intersection of two or more trace fossils implies that they are

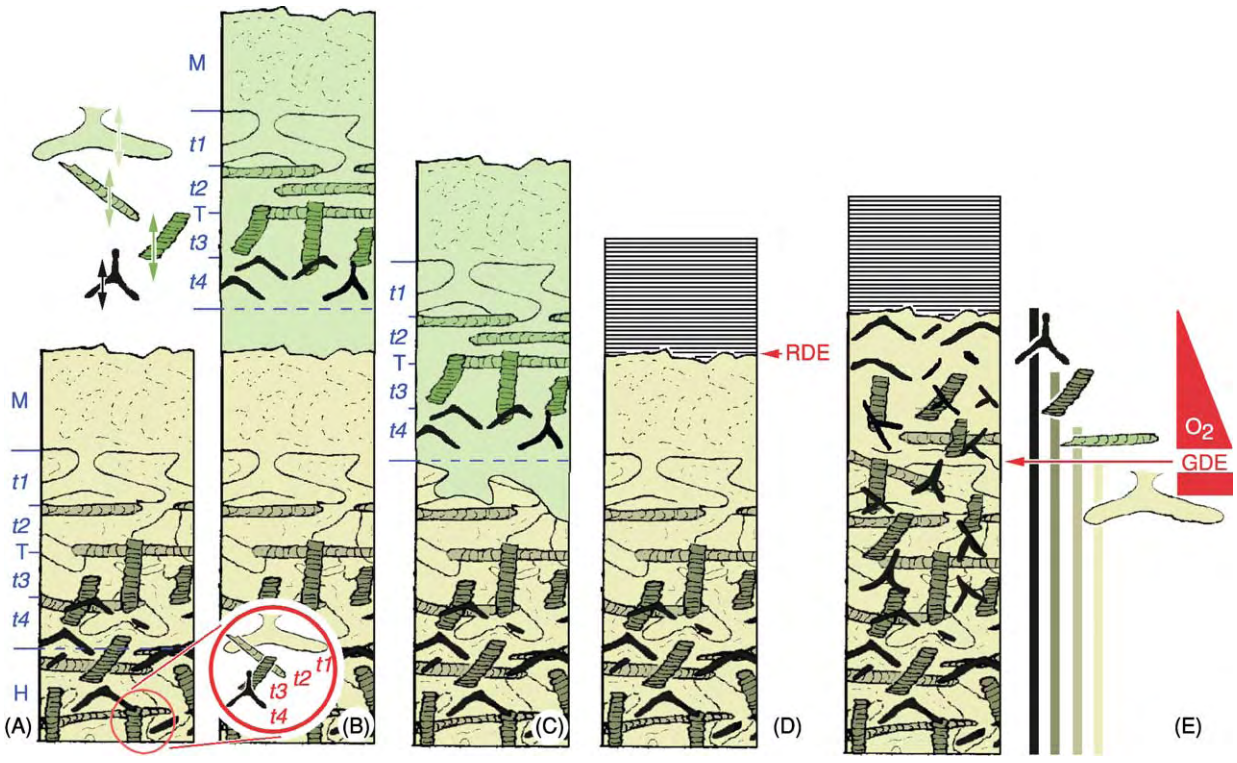

Figure 11 Endobenthic tiering revealed by the ichnofabrics produced 1. (A) Subdivision of the sediment column into the mixed (M), transition (T), and historical (H) layers; inset shows dominant to unilateral cross cutting relationships amongst the transition layer trace fossils allowing the identification of four tiers (*t1 4*). (B, C) Rapid relocation of the infauna following event bed deposition leaves a 'frozen profile' in the older sediments, all of which (B) or, if the event bed is erosively based, only the lower part of which (C), may be preserved. (D) Production of a 'frozen profile' resulting from the evacuation of the sediment column by infauna following a rapid deoxygenation event (RDE). (E) A gradual deoxygenation event (GDE), in which the oxygen content of the interstitial pore waters declines gradually, results in exclusion of the infauna of successively deeper tiers. Adapted from Savrda CE and Bottjer DJ (1986) Trace fossil model for reconstruction of paleo oxygenation in bottom waters. *Geology* 14: 3 6.

components of the same tier. In practice, deviations from the random cross-cutting of older structures by younger can occur; these include preferential re-exploitation as well as avoidance of earlier formed structures. Complete reworking of sediment at depth will obliterate the record of earlier activity in shallower tiers, and thus reduce the diversity of the trace fossil community (the palaeoichnocoenosis). The preservation of a complete tiering profile requires the intensity of bioturbation to decline with depth; earlier formed parts of the ichnofabric, including occasionally the mixed layer ichnofabrics, occur as relict patches between later structures.

The deposition of an event bed will result in a rapid upward relocation of the infauna; if this event bed is sufficiently thick, the base of the transition layer will be moved above the older sediments, leaving a frozen tiering profile preserved within them; the distance from the sediment surface to the base of the transition layer indicates the thickness of sediment occupied (**Figure 11B**). The upper part of the sediment column is often a soupground, and thus remobilized relatively easily; the upper parts of the frozen tiering profile, notably the mixed layer, may be eroded during the deposition of the next bed (**Figure 11C**). Evacuation of the sediment column following a rapid deoxygenation event, in which the redox threshold boundary is moved above the sediment–water interface, will leave a frozen profile preserved below the succeeding sediments (**Figure 11D**). Mixed layer ichnofabrics, rare in the geological record, are more likely to be preserved in this manner than by burial below an event bed.

Other means of reconstructing the tiering profile include the identification of the depth to which an intergenic postdepositional trace fossil penetrated the substrate. In a sequence of event beds of different thickness, the components of shallower tiers occur only on the soles of thinner beds (**Figure 12A**). Secondary trace fossils (see above) occur within a 'piped zone' (**Figures 12B and 12C**). The thickness of the piped zone indicates the volume of ecospace used by the endobenthic community; components of progressively deeper tiers occur closer to its base. In the simple model in **Figure 12B**, the secondary trace fossils were sourced from the immediately overlying layer whilst it was being deposited, and the piped zone is contained entirely within one layer. The example in **Figure 12C** shows a more complex situation; the lowest bed was rebioturbated during deposition of the second, not the first, overlying layer, but the latter was too thin to contain the piped zone entirely. In this idealized example, the colour of each layer is different, and the source of sediment in the piped zone is obvious. In practice, however, many hemipelagic

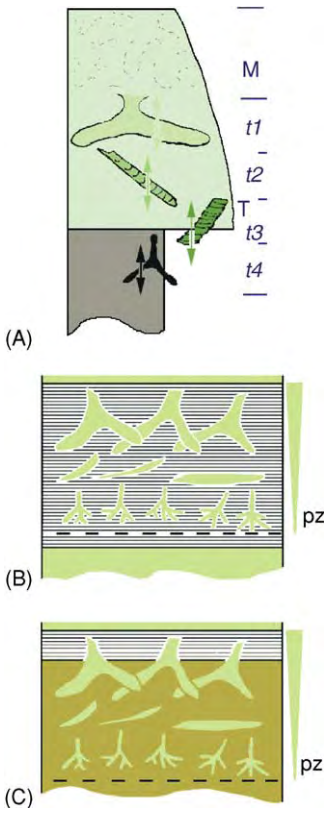

Figure 12 Endobenthic tiering revealed by the ichnofabrics produced 2. (A) The base of the event bed cannot be reached by the infauna of the shallower tiers; the trace fossils at its sole will comprise those of tier 3 and, if the accretion of sedi ment subsequently is gradual, tier 4. (B, C) Emplacement of secondary trace fossils defines a piped zone (pz), the thick ness of which is a measure of the volume of ecospace utilized. For clarity, earlier formed parts of the ichnofabrics have been omitted.

and pelagic sequences are characterized by alternating lithologies, the differences in colour and composition of which can be the result of orbital forcing. In such cases, trace fossils within the piped zone may be actively infilled by the same sediment as the host lithology.

Natural systems are obviously more complex, but more dynamic models can be produced by allowing variables, such as the rate of sediment accretion, including negative values (erosion), or the levels of oxygenation, to fluctuate over time. Not all circumstances will satisfy the assumptions within the model. Thin-bedded siliciclastic turbidites often exhibit a bipartite division into a sand-rich lower part and a mud-rich upper part, and infauna can position themselves with respect to the interface between the two, independent of its depth below the sediment–water interface. Cross-cutting relationships can also be generated by the superimposition of two successive

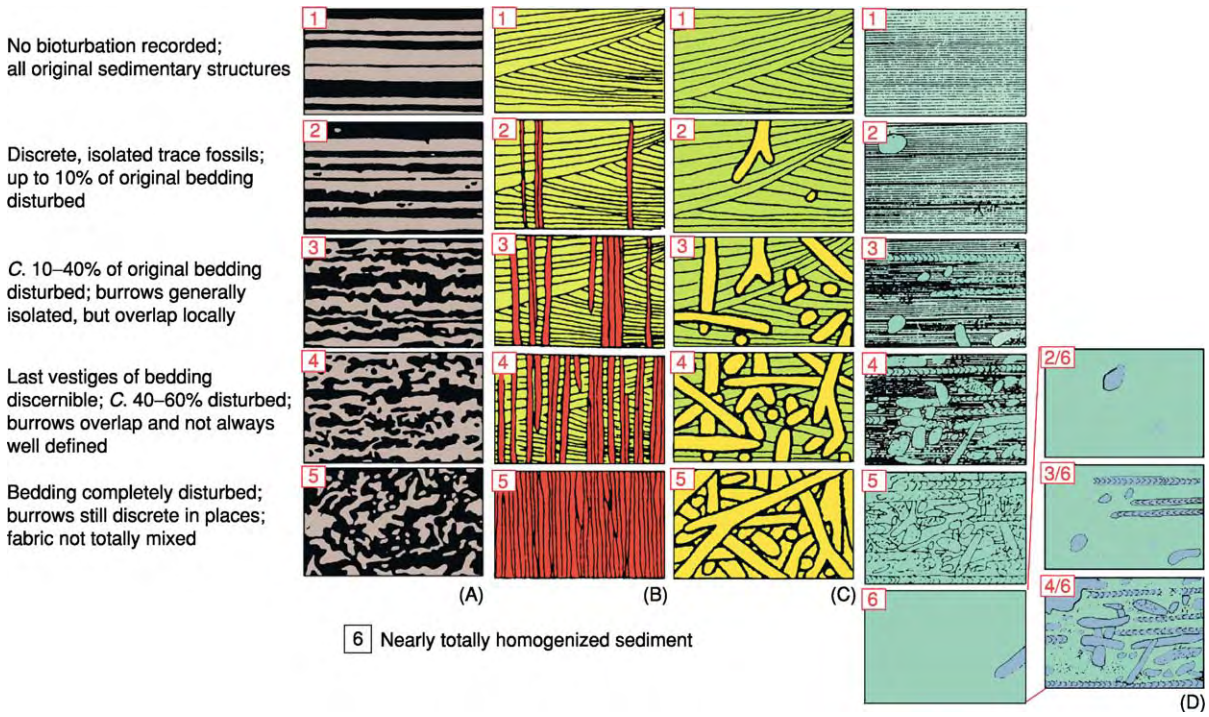

Figure 13 Definitions and schematic illustrations of ichnofabric indices for strata deposited in: (A) shelf environments; (B) high energy nearshore sandy environments dominated by *Skolithos*; (C) high energy nearshore sandy environments dominated by *Ophiomorpha*; (D) deep sea deposits, including examples of homogenized sediment that has been reworked subsequently. communities; following event bed deposition, it is not unusual for a short-lived opportunistic community to exploit the new ecospace and resources, before the longer term equilibrium community is re-established.

Palaeo-oxygenation

As bottom water oxygenation declines, the general tendency is for the thickness of the mixed and transition layers, and the size (reflected in the burrow diameter) and diversity of actively infilled transition layer trace fossils, to decrease (Figure 11E). It has been suggested that ichnofaunal assemblages dominated by domichnia, pascichnia, and fodinichnia indicate a progressive decline in pore water oxygenation. Related to this, certain ichnogenera, notably the fodinichnion *Chondrites*, especially if abundant in a low-diversity or monospecific assemblage, have been considered to be diagnostic of low oxygen conditions; however, this should not be assumed without supporting ichnological and sedimentological evidence. The shaft diameter is relatively large in the monospecific assemblage of *Chondrites* emplaced in a storm bed in Figure 7H, and an interpretation as an opportunistic colonization of newly deposited sediment is favoured.

Intensity of Bioturbation

The ichnofabric index (ii) is a semiquantitative measure of the intensity of bioturbation, based on the extent to which the original stratification is disrupted; as both the nature of bioturbation and host lithology will vary, the schematic illustrations are specific to certain environmental settings (Figure 13). The ichnofabric is observed in vertical sections; a standard horizontal field of view should be used and reported (500 mm is often used in outcrop studies).

ULTRA HIGH PRESSURE METAMORPHISM

H-J Massonne, Universität Stuttgart, Stuttgart, Germany

Introduction

Ultra high pressure (UHP) metamorphic rocks of common basic to felsic nature are defined by the occurrence of coesite, a silica polymorph that is denser than quartz. According to several experimental studies, the transition from quartz to coesite at 600°C requires a pressure (P) of around 27 kbar, a temperature (T) of conditions that occur on Earth at depths close to 100 km. Coesite in nature was detected first in rocks affected by impact metamorphism, but a coesite-bearing rock that had been subjected to regional metamorphism was described in 1983 by Chopin. Based on the coesite–quartz transition pressure and temperature curve, this rock, which was from the Dora Maira Massif of the Western Alps, must have been buried at depths of about 100 km or more. Transition curves of SiO_2 polymorphs show a moderate pressure (P) and temperature (T) slope, dP/dT, of only 10 bar °C^{-1} (Figure 1).

Prior to discovery of the Dora Maira Massif rock, it was thought that metamorphic rocks (excepting ultrabasites) that were formed during orogenic events, and now exposed at Earth's surface, represent, in general, a fossil record of pressure and temperature conditions only of Earth's crust, equivalent to maximum depths of 70 km and pressures up to ~18 kbar. Eclogites (basalts that have been metamorphosed under high pressure) were believed to have formed, depending on temperature, at pressures between 12 and 16 kbar, corresponding to the jadeite content of omphacite, the mineral that characterizes eclogites. However, these estimates are only justified when omphacite co-exists with plagioclase and quartz (but plagioclase is often only a retrograde product in eclogites, due to the breakdown of omphacite). Rare jadeite occurrences in felsic rocks with plagioclase supported the view of metamorphic pressures not exceeding 18 kbar for crustal rocks. In geodynamic models of subduction of oceanic crust under oceanic or continental plates, it was assumed that the return of subducted material was possible only for shallower regimes of the collision wedge. Such subducted material then became, for instance, part of an accretionary wedge complex. Within the framework of such a scenario, the discovery of coesite in regional metamorphic rocks was sensational and a real turning point in scientific thinking about deep burial and subsequent exhumation of crustal rocks. Soon after Chopin's report in 1983, it became evident that UHP rocks are more widespread than had been thought. Coesite was recognized in rocks of the Norwegian Caledonides, the Dabie Shan in China, and orogenic regions elsewhere. Moreover, in 1990, microdiamonds, another indicator mineral for UHP metamorphism, were reported by Sobolev and Shatsky in marbles and gneisses from the Kokchetav Massif, Kazakhstan. These diamonds provided evidence for burial of crustal rocks to depths of at least 130 km.

Identification of UHP Rocks

The discovery of UHP rocks at Earth's surface at a relatively late date in geological science history can be attributed to the nature of the processes involved. Retrogression of rocks during exhumation can result

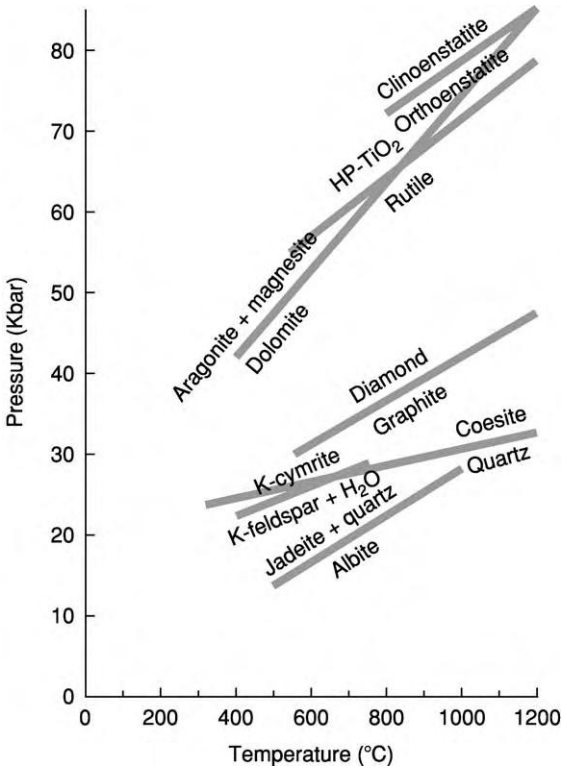

Figure 1 Pressure and temperature stability of various mineral phases that are of relevance to UHP metamorphism. Except for the transition curves below 30 kbar, the experimental error is even higher than is expressed by the thickness of the lines. The clinoenstatite orthoenstatite transition refers to a composition with 10 mol% of ferrosilite component.

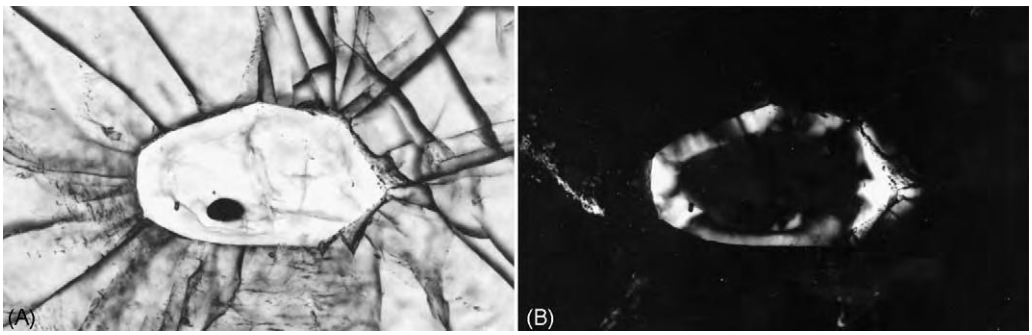

Figure 2 Photomicrograph of a coesite relic enclosed in garnet. Left hand side shows the appearance of palisade quartz using plane polarized light; the specimen is best seen under crossed nicols (i.e., a polarizing filter; right hand side). Typically, coesite has been partially replaced by the palisade quartz, causing radial cracks in the host mineral. Image width is 0.6 mm. The example is from a thin section of an eclogite from the central Saxonian Erzgebirge.

in a complete overprint of the UHP mineral assemblage, thus erasing the 'memory' (record) of the UHP event in the metamorphic rock. Therefore, it is important for the geoscientist working with such rocks to look for mineralogical hints of UHP metamorphism (e.g., tiny inclusions in resistant garnet porphyroblasts and unusual microfabric textures and appearances). Coesite, the 'indicator' mineral that points to UHP, has never been found to be a major constituent of UHP rocks. On the contrary, quartz dominates among the SiO_2 polymorphs, even in the best preserved UHP rocks, and coesite commonly occurs only as inclusions in minerals such as garnet and zircon (Figure 2). Even in such inclusions, coesite is normally partly decomposed to quartz. A typical decomposition fabric is formed of palisade quartz, with lamellae perpendicular to the replaced coesite. Cracks in the host mineral around the coesite inclusion form due to the volume increase during the decomposition of coesite to quartz. Thus, even completely replaced coesite can be recognized by such features. Tiny coesite relics can be identified by confocal micro-Raman spectroscopy even when the relics are not at the surface of a rock thin section.

Identifying UHP rocks on the basis of coesites is problematic when cracks around quartz inclusions in the host mineral are discernible but no coesite relic or palisade quartz is detectable. Palisade quartz formations may have recrystallized, forming polycrystalline quartz, but this cannot be considered a clear indication for UHP metamorphism. No doubt there have been a few reports in the literature of UHP rocks as a result of mistaken identification of unusual quartz inclusions as former coesite. Symplectites consisting of K-feldspar and quartz resemble quartz pseudomorphs of replaced coesite, and there are usually cracks in the host mineral, typically eclogitic omphacite, around such inclusions. Massonne, Dobrzhinetskaya, and Green have described such

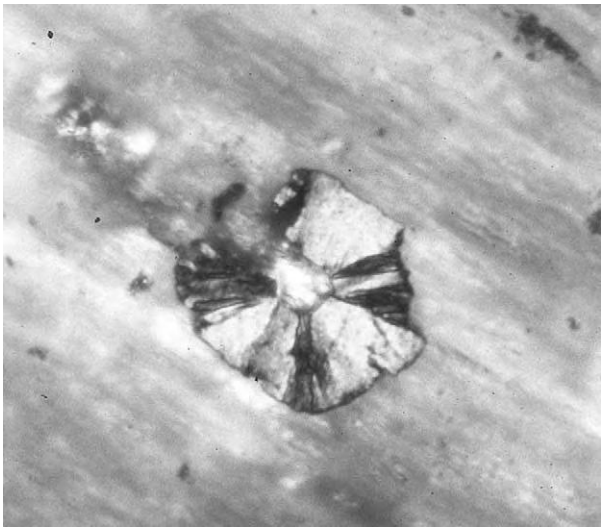

Figure 3 Inclusion of a pseudomorph of radially oriented graphite after diamond in clinopyroxene from a siliceous calcite marble of the Kokchetav Massif. A relic microdiamond is present in the centre of the pseudomorph. Image width is 0.11 mm.

symplectites as being decomposition products of K-cymrite ($KAlSi_3O_8 \cdot H_2O$). K-Cymrite has not yet been found as a relic, but it has potential for identifying UHP rocks due to its lower pressure stability limit (Figure 1), which is similar to that of coesite.

Another mineral that is diagnostic for UHP is diamond. Like coesites in UHP rocks, diamond can be easily transformed. During exhumation, unless it is enclosed as tiny grains in resistant porphyroblasts, diamond is transformed to graphite. Even when enclosed in porphyroblasts, diamond rarely survives, but it can react to form pseudomorphs of radially oriented graphite (Figure 3). Although microdiamonds are not as widespread in UHP rocks as coesite is, they are found in all kinds of UHP rocks, from ultrabasic to felsic or silicate to carbonate-rich rocks,

whereas coesite can occur only in felsic to basic rocks when SiO_2 is in excess. Phengite, a silicon-rich potassic white mica common in basic to felsic HP to UHP rocks, also has potential to be diagnostic of UHP rocks. In contrast to coesite and diamond, which are pure phases, potassic white mica is chemically complex. Mica compositions of the corresponding solid solution series can be stable at both high and low pressures, which is probably the reason that the potassic white mica that formed under HP to UHP conditions often remains in rocks during exhumation. However, phengite is diagnostic for UHP only if it is possible to detect its precise composition at UHP, and the compositions of its coexisting partners (e.g., garnet and omphacite). Although numerous experiments at high-pressure conditions have contributed to an understanding of the relationship between mica compositions and coexisting phases as a function of pressure and temperature, the degree of uncertainty in determining pressure conditions for phengite-bearing rocks is at less than 2 kbar, even when advanced thermodynamic calculation methods and suitable mineral paragenesis are considered. In any case, metamorphic temperature determinations are required using a well-calibrated geothermometer, such as the Fe^{2+}–Mg exchange reaction for different mineral pairs (e.g., garnet and omphacite). A problem arises when phengite inclusions or core compositions are used: for example, subduction of a basalt of the oceanic crust first reaches pressure and temperature conditions of the blueschist facies. At that stage, Si-rich phengites ($Si > 3.5$ per formula unit) can form and coexist with a typical blueschist facies assemblage. Further subduction at elevated pressure and temperature causes garnet growth. During this process, the blueschist-facies phengite is enclosed in garnet and thus survives the subsequent metamorphism, leading to a kyanite-bearing eclogite. At peak temperature conditions, Si contents of re-equilibrated phengites reach 3.3 per formula unit in the kyanite-bearing assemblage; this is typical for near-ultrahigh pressure conditions. If the blueschist-facies phengite is related to the peak temperature assemblage, pressures of the UHP regime would be indicated. Thus it is likely that in a few cases, rocks lacking coesite and diamond have been erroneously assigned to UHP metamorphism because a silicon-rich phengite was found in an ordinary high-pressure rock. This may have occurred with eclogite blocks in the low-grade metasediments of the Franciscan Formation in California, where phengites with high Si contents ($Si > 3.55$ per formula unit) were reported. Nevertheless, phengite geobarometry combined with geothermometers is a powerful tool and allows determination of pressure and temperature conditions in the UHP regime, whereas coesite and diamond can yield only minimum pressures. This is also true for tetrahedrally coordinated Al in clinopyroxene and orthopyroxene, which act as suitable geobarometers in the presence of garnet, especially for ultrabasic rocks lacking phengites.

In the known UHP regions of the world, minerals with specific exsolution fabrics have been observed and assigned to UHP conditions. Clinopyroxenes can contain rods of SiO_2. Garnets show clinopyroxene and orthopyroxene exsolution lamellae and precipitates (Figure 4). Both phenomena are explained by introduction of Si into the octahedral site of the corresponding mineral structure at UHP. Subsequent pressure release results in dissolution of the octahedrally coordinated Si and formation of specific minerals. Experimental constraints are related only to garnet, whereby small amounts of majorite component, $(Mg,Ca)_4Si_4O_{12}$, can be dissolved in the garnet structure at pressures exceeding 50 kbar. However, the dissolution products, clinopyroxene and orthopyroxene, can form from ordinary garnet by pressure release as well, but in that case, the pyroxenes should contain significant amounts of Tschermak's component, $CaAl_2SiO_6$. Titanite in marble from the Kokchetav Massif is yet another example for the likely introduction of Si into the octahedral site. This mineral contains coesite precipitates as dissolution product. Clinopyroxene from UHP areas can also show K-feldspar lamellae, which are interpreted as exsolution from K-bearing clinopyroxene. Such clinopyroxenes, with significant

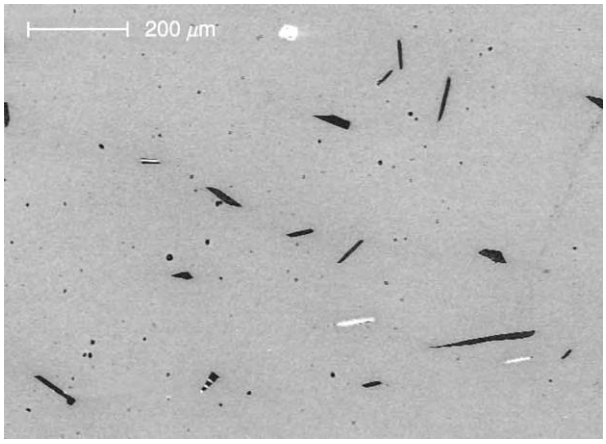

Figure 4 Exsolution of orthopyroxene and clinopyroxene from majoritic garnet, shown by a back scattered electron image (pyroxenes are darker than garnet). This sample is from the Western Gneiss Region of the Norwegian Caledonides. Reproduced with permission from Van Roermund HLM, Drury MR, Barnhoorn A, and De Ronde AA (2000) Super silicic garnet microstructures from an orogenic garnet peridotite, evidence for an ultra deep (>6 GPa) origin. *Journal of Metamorphic Geology* 18: 135 147.

amounts of K_2O (>0.5 wt.%), have been reported from diamondiferous siliceous marbles of the Kokchetav Massif. Experiments have proved that K is introduced into the clinopyroxene lattice at high pressures, but conclusions on the metamorphic pressures of the Kokchetav rocks have so far been only semiquantitative. In high-pressure experiments, TiO_2 with the α-PbO_2 structure is stable at high temperatures above 60 kbar instead of rutile (Figure 1). A nanocrystal of HP-TiO_2 was observed in a diamondiferous quartzofeldspathic rock from the Saxonian Erzgebirge, Bohemian Massif. Clinoenstatite lamellae in pyroxenes were reported from the Dabie Shan–Sulu terrane, China. This would point to pressures of 80 kbar and more (see Figure 1). Magnesite and calcite, probably former aragonite, in direct contact or separated by dolomite, were observed in the Dabie Shan. This allows the conclusion that the corresponding rocks experienced pressures of at least 60 kbar (Figure 1). Ilmenite rods in olivine were reported from several ultrabasic rocks of different UHP terranes. Relatively high concentrations of these rods were found in olivine from Alpe Arami, in the central Alps. Dobrzhinetskaya, Green, and Wang argued that this feature points to depths of more than 300 km as the origin of the corresponding rock. Certainly a number of other potential candidates, either minerals or specific mineral assemblages, could serve to diagnose UHP conditions; experimental studies and calculations of mineral equilibria using thermodynamic data have indicated this possibility, but corresponding observations have not yet been made.

Global Distribution

Following Chopin's 1983 report of finding the first UHP metamorphic rock of crustal origin in the Western Alps, several other finds were reported from around the globe, relating to more than 10 different orogens or far-distant sections of an orogenic chain. The locations of these rock finds are shown in Figure 5, together with some potential UHP terranes where, so far, no coesite or diamond relic has been found. There are certainly even more UHP potential terranes than are indicated in Figure 5 (note also that neither the Franciscan Formation in California nor Neoproterozoic areas with eclogites, for which geothermobarometrically derived pressure and temperature estimates lie in the UHP field, are indicated in Figure 5). Typically, the confirmed UHP areas worldwide are parts of young orogens resulting from

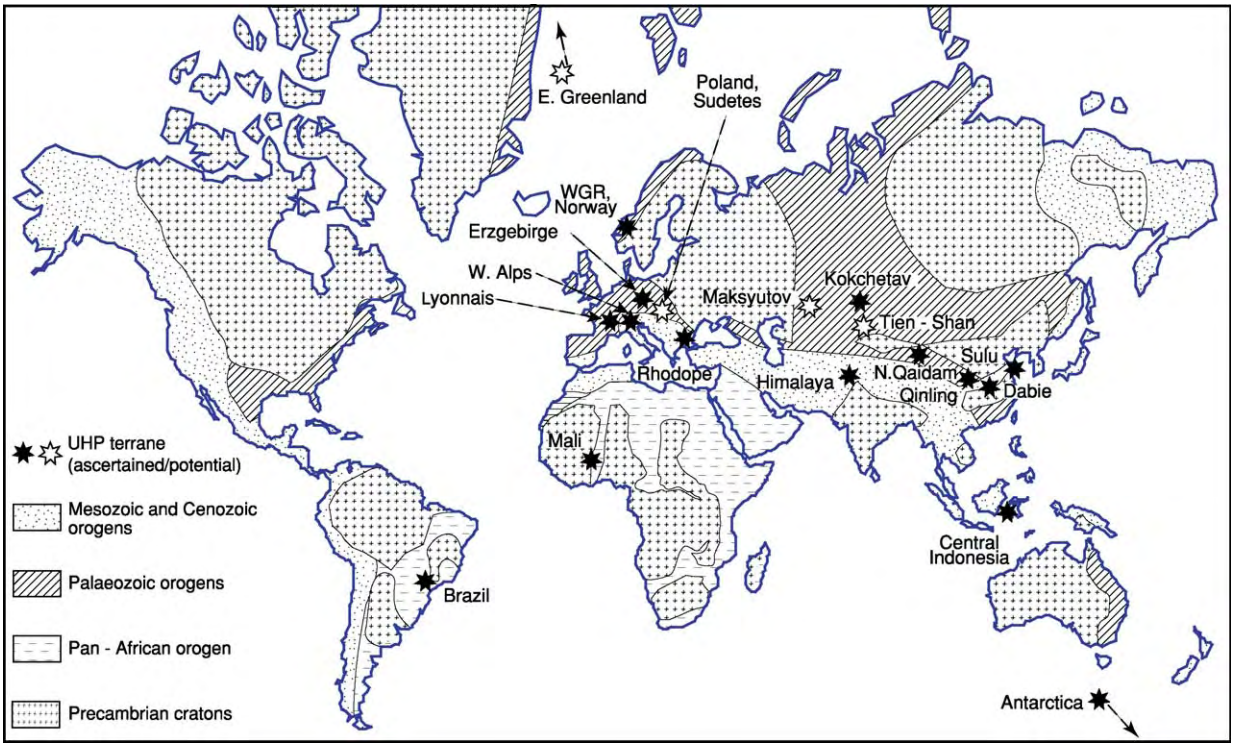

Figure 5 Occurrences of ascertained and potential UHP rocks worldwide. The group of potential UHP rocks includes pseudomorphs replacing coesite and/or diamond. WGR, Western Gneiss Region. continent–continent collision, but relatively few of these areas have been well explored for UHP rocks. Those areas that have been examined closely are in the European Alps, the Norwegian Caledonides, the Chinese Qinling Shan–Dabie Shan–Sulu Terrane belt, the Kokchetav Massif in northern Kazakhstan, the Mid- and West-European Variscides, and, to some extent, the Himalaya.

European Alps

UHP rocks in the Western and Central Alps occur exclusively in the Penninic unit. Potential UHP rocks also exist in the Eastern Alps; these rocks are mainly eclogites, whereas in the Western and Central Alps, different metapelites, metagranitoids, and ultrabasic rocks are also involved in UHP metamorphism. The lateral extent of UHP units in the Alps is in the range of several to a few tens of kilometres. The thickness of these units is commonly less than 1 km, because they are part of the nappe stack of the Alpine Orogen. Age dating of the UHP event yielded values close to 35 Ma. Potential UHP eclogites in the Eastern Alps were formed in the Cretaceous. The protoliths of felsic UHP rocks of the Western Alps can be at least partially assigned to former Variscan metamorphic and plutonic rocks. This implies that Variscan continental crust was subducted to great depths during a late Alpine continent–continent collisional event.

Geothermobarometric evolution has resulted in a pressure and temperature path for the majority of the UHP rocks that is characterized by a prograde branch along geothermal gradients, decreasing from 10 to 6°C km^{-1} towards the pressure and temperature climax, which is settled between 30 and 40 kbar and around 750°C. The retrograde path typically shows decreasing temperatures during pressure release, but the temperatures of the retrograde path are always higher than those of the prograde path at a given pressure. Age dating, for instance, on zoned zircon grains has demonstrated that significant exhumation from great depths happened within a few million years. Thus the uplift rates must be in the range of several centimetres per year. This rate and dating to 35 Ma for UHP metamorphism were also found for ultrabasic rocks, for instance, outcropping at Alpe Arami, Central Alps.

Norwegian Caledonides

Felsic, basic, and ultrabasic UHP rocks are widespread in the Western Gneiss Region (WGR) of the Norwegian Caledonides. Similar rocks also occur in the Caledonian Orogen further north (for instance, in the Lofoten range) and at the eastern coast of Greenland. The widely scattered occurrences of UHP rocks within the WGR may indicate the existence of a coherent UHP terrane of up to $350 \times 150\,km^2$. Prograde metamorphism is characterized by geotherms around 6°C km^{-1}, reaching peak temperatures of 550°C in the south-east inland area and more than 800°C in the north-west coastal area of the WGR. In the latter area, microdiamonds were found on the island of Fjørtoft. Age data obtained from UHP metamorphic rocks scatter between about 440 and 390 Ma, but it has been concluded that UHP metamorphism happened close to 400 million years after closure of the Iapetus Ocean. Early exhumation rates of 1 cm or more per year are assumed. The coeval garnet peridotites originated at mantle depths of about 200 km (60–65 kbar) and temperatures significantly above 1000°C. However, it is possibly that they had resided there since mid-Proterozoic times, until they were uplifted by a mantle diapir in the Lower Devonian.

Chinese Qinling Shan - Dabie Shan - Sulu Terrane Belt

In central and eastern China, the Triassic orogenic belt resulting from collision of the Yangtze Craton and the Sino-Korean Craton contains sections with UHP metamorphic rocks. Although intruded by enormous volumes of Cretaceous granitoids, these areas can be traced over 100 km and more, leading to the conclusion of the existence of wide, coherent UHP terranes. Under this scenario, orthogneisses with Proterozoic protolith ages would be the dominant UHP rock type there. The pressure and temperature conditions of the Chinese UHP rocks resemble those of the WGR in regard to spread of peak pressure and temperature ($\leq$600–$\geq$800°C) conditions. However, a significant difference between the WGR and the Triassic orogenic belt is related to the peak temperature conditions of ultrabasic rocks. Garnet peridotites of the Sulu Terrane were metamorphosed at only 800°C, and those of the Dabie Shan were metamorphosed below 800°C. In spite of the relatively low temperatures, pressure conditions were estimated to be as high as 55 kbar or even more, thus yielding geothermal gradients somewhat below 5°C km^{-1}. It is assumed that rocks as well as other UHP rocks of the Qinling Shan–Dabie Shan–Sulu Terrane belt dates close to 220 Ma.

Kokchetav Massif in Northern Kazakhstan

An enormous variety of identified UHP rocks is known to occur at local sites (e.g., close to Lake Kumdy Kol) of the Kokchetav Massif. Although the development of such rocks can be traced over several tens of kilometres, the recent view of a

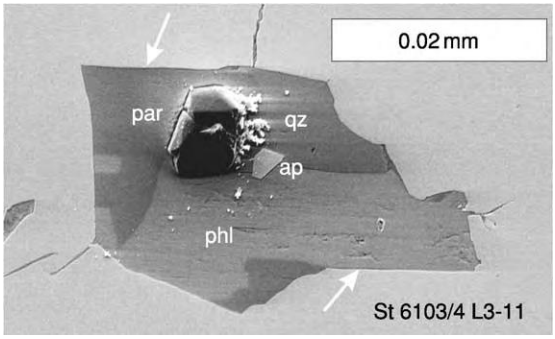

Figure 6 Scanning electron microscope image of a polyphase diamond bearing inclusion in garnet, interpreted as trapped sili ceous fluid or melt before crystallization. The example is a quart zofeldspathic rock from the Saidenbach reservoir, central Saxonian Erzgebirge. Arrows point to rational mica garnet inter faces. qz, quartz; par, paragonite; phl, phlogopite; ap, apatite.

'megamelange', including medium-pressure rocks, may best describe the geological situation. Nevertheless, two types of UHP rocks can be distinguished in terms of maximum pressure and temperature conditions. One type has experienced pressure and temperature conditions similar to those of UHP rocks of the Western Alps ($T_{max} \sim 750°C$). The other type, characterized by abundant microdiamond inclusions in various host minerals, was metamorphosed at pressures as high as 70 kbar. At these high pressures, temperatures exceeded 1000°C, probably resulting in partial melting. Polyphase aggregates (Figure 6), commonly containing microdiamonds, are enclosed in garnet and other phases. These aggregates serve as evidence for siliceous fluids or melts. The silica-rich material of these inclusions was probably trapped in growing minerals during exhumation of the (partially molten) rocks at decreasing temperatures. This happened at 530 Ma, as deduced from zircon dating, also indicating a fast uplift of the rock in the range of centimetres per year.

Mid- and West-European Variscides

An abundance of ascertained and potential UHP rocks have been detected in several crystalline complexes of the Variscides, including those later involved in the Alpine Orogeny. However, due to a significant fragmentation of specific major units by a late orogenic event, a former, possibly extended, coherency of UHP terranes has been broadly lost. Nevertheless, HP to UHP metamorphism cannot be related to a single event. For instance, in the Bohemian Massif, representing the north-eastern section of the Variscides, two major HP–UHP events can be discriminated from abundant age data. The earlier event, around 395 Ma, led to eclogites, probably former oceanic crust, which experienced maximum pressure and temperature conditions close to 700°C and 23–30 kbar. A common feature of these eclogites is the replacement of omphacite by amphibole porphyroblasts due to the influx of hydrous fluids, probably close to the pressure and temperature climax. In the younger UHP event, occurring about 340 Ma, felsic, basic, and ultrabasic rocks were involved. Peak temperature conditions can exceed 1000°C–1200°C and 80 kbar are indicated by a diamondiferous quartzofeldspathic rock from the Saxonian Erzgebirge; this rock has polyphase inclusions in garnet (Figure 6), similar to rocks from the Kokchetav Massif. The anatectic evolution of the Erzgebirge rock is inferred to be similar to that of diamondiferous rocks from the Kokchetav Massif, in addition to the fast exhumation. The diamondiferous rock from the Erzgebirge forms lenses up to 1 km long, like other UHP rocks in the Variscides. The surrounding gneisses display a medium to high pressure signature, but also a clear peak pressure contrast to the UHP rocks.

Himalaya

UHP rocks in the Himalaya are very rare, but their geodynamic context is much clearer compared to other UHP regions. The protoliths of coesite-bearing eclogites and surrounding metasediments in the north-western Himalaya were part of the continental margin of India that was subducted beneath Asia. The prograde metamorphism during this event followed a geothermal gradient of $6°C\,km^{-1}$ reaching peak pressure and temperature conditions at depths between 90 and 120 km about 50 Ma ago. Amphibole blastesis at the expense of clinopyroxene is common. The subsequent exhumation of the UHP rocks is characterized by moderate cooling at uplift rates in the range of centimetres per year, slowing down to millimetres per year for the past 40 million years.

Mechanisms

The known UHP rocks at Earth's surface can be subdivided into two groups. One group suffered from metamorphism along geothermal gradients of about $7°C\,km^{-1}$, reaching maximum pressures generally below 40 kbar (Figure 7). Frequently observed peak pressure and temperature conditions are 30 kbar at 650–700°C. Moderate cooling and uplift rates in the range of centimetre per year characterize the exhumation of this group of UHP rocks, commonly starting with the influx of hydrous fluids (for instance, into eclogites). The subduction of oceanic crust under continental crust, including the exhumation within a subduction channel, best explains the characteristics of these UHP rocks. However,

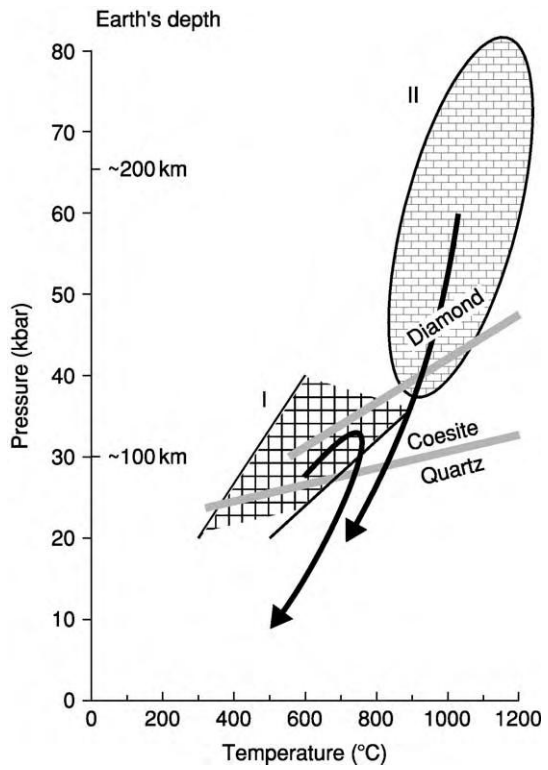

Figure 7 Range of peak pressure and temperature conditions of UHP rocks (patterned areas). The typical shapes of common pressure and temperature paths for UHP/ near UHP (I) and UHP (II) are depicted.

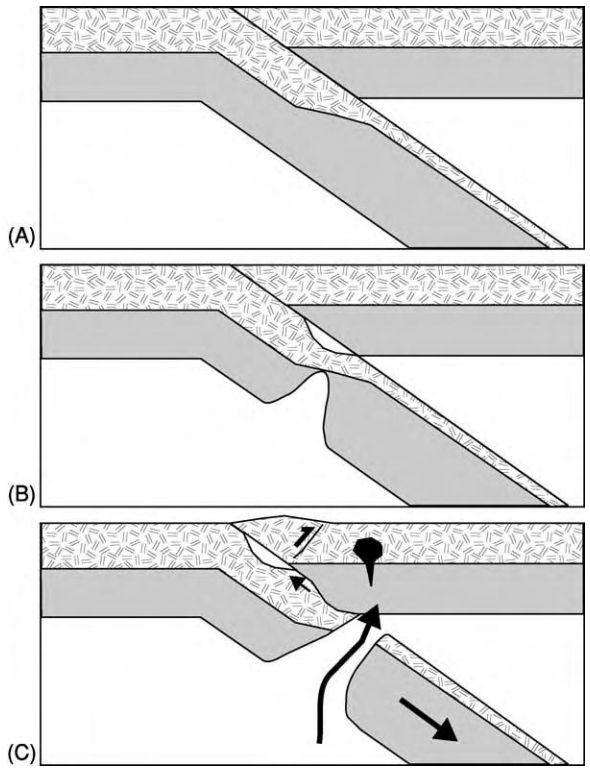

Figure 8 The slab breakoff model, evolution (from top to bottom). (A) Subduction; (B) slab weakening and narrow rifting; (C) slab breakoff, magmatism, and uplift of UHP sheets. formation of larger coherent UHP terranes consisting broadly of continental crust, as inferred from the WGR in Norway and the Triassic UHP belt in China, cannot be explained by this mechanism alone. If continental crust adherent to a slab of subducted oceanic crust is drawn into depth at the beginning of a continent–continent collision, as suggested by the slab-breakoff model (Figure 8), extended regions of continental crust can be affected by UHP metamorphism. Fast exhumation is caused by buoyancy forces exerted by continental material that is less dense than eclogites and garnet-bearing ultrabasic rocks, after the oceanic slab has been broken off to be subducted further down.

A second group of UHP rocks experienced significantly higher temperatures, or at least higher pressures (Figure 7). Often both groups of UHP rocks occur together in one crystalline complex. Moreover, both crustal material and mantle material were metamorphosed at peak pressure conditions, between 60 and 80 kbar, as has been proved at least for the UHP regions of the Kokchetav Massif and the Bohemian Massif. The slab-breakoff model may explain this situation as well, because it is believed that continental crust can be dragged to depths of about 200 km by the adherent oceanic slab, despite the buoyancy forces of the continental material. An alternative explanation, however, is delamination of continental lithosphere after continent–continent collision and significant thickening of continental crust, a process that is currently observable in the range of the Himalaya and in the Tibetan Plateau. Modelling experiments suggest that material from the continental crust can be involved in the delamination process and deeply submerged into Earth's mantle. There, anatectic processes in the continental material are caused by the hot environment before fast uplift starts. Because there is limited coherency among the hot-temperature UHP rocks of the Bohemian Massif or the Kokchetav Massif, the debate continues as to whether the slab-breakoff model, lithospheric delamination, or any other process can sufficiently explain the UHP rocks there.

Conclusions

Continent–(micro)continent collision leads to the formation of UHP rocks. Such rocks, although a

minority among metamorphic rocks in crystalline basement areas, are common in denuded Phanerozoic orogens. UHP rocks that originate from crustal protoliths are difficult to detect and it seems that they did not appear at Earth's surface until about 600 Ma ago. What could be responsible for that? Crustal thickening during continent–continent collision over a wide lateral area, resulting in a crust 60–70 km thick, may have been uncharacteristic in Proterozoic and Archaean times, thus limiting lithospheric delamination with continental crust involved. The magnitude of crustal thickening might have been influenced by the thermal structure of the (lower) crust and lithospheric mantle, where geothermal gradients are presently lower than they were a long time ago. The present thermal structure could also be responsible for lower geothermal gradients in subducted and metamorphosed oceanic crust, compared to those in pre-Phanerozoic times. Thus, dipping into the UHP field before melting would have been possible for oceanic crust only since the beginning of the Phanerozoic. This would also apply to continental crust adherent to the subducted oceanic crust when the slab-breakoff model would mirror the true process in overprinting continental material at UHP conditions.

UNCONFORMITIES

A R Wyatt, Sidmouth, UK

Introduction

An unconformity is a surface that separates rocks of significantly different ages. This was at one time an exposed part of the Earth's land surface or the rock surface below a body of water (for example, a lake or the sea), and the younger rocks were deposited on this surface. Juxtaposition of rocks of different ages caused by faulting does not give rise to an unconformity. An unconformity represents a substantial break or gap in the local or regional depositional record. In modern usage this break or gap may have been caused by the erosion of previously deposited rocks or by a long period of non-deposition of sediments (that is, a long enough period that the absence of sediments of the relevant age can be recognized).

Early workers confined the use of the term unconformity to places where the older rocks had been deformed and eroded, so that the unconformity cut across the truncated beds of the lower deposits. The idea that structural discordance is an essential feature of an unconformity continued for much longer in the UK than in many other parts of the world, such as, for example, the USA. Other terms were introduced for breaks where there was no structural discordance. In the Phanerozoic these would normally be identified by gaps in the expected fossil sequence. For the simple case of non-deposition, the terms diastem and non-sequence were used. Although these terms have often been considered to be synonymous, some workers have suggested that a diastem is a break of shorter duration than a non-sequence. Where the break can be shown to be associated with erosion but the upper beds are still parallel to the lower beds, the term disconformity was used. The disconformity surface is often parallel to the bedding surfaces, but it may also show major relief.

Terms such as unconformity and disconformity refer to the surface (and, by implication, the time) that separates the older from the younger rocks. Terms have also been introduced to refer to the relationship between the bedding of the upper (younger) rocks and that of the lower (older) rocks. Where there is no structural discordance, so that the attitude of the upper beds is the same as that of the lower beds, the upper beds are said to be conformable. When there is structural discordance, the upper beds are unconformable.

Where there is structural discordance, as we follow the base of the overlying bed we find that it moves from one to another member of the lower, truncated, series. This is known as overstep (see **Figure 1A**, side face of block). The term is chiefly used when the angular nature of the unconformity is not obvious but is made evident by detailed mapping. One of the earliest recorded examples was the overstep of the base of the Cretaceous across the underlying Jurassic

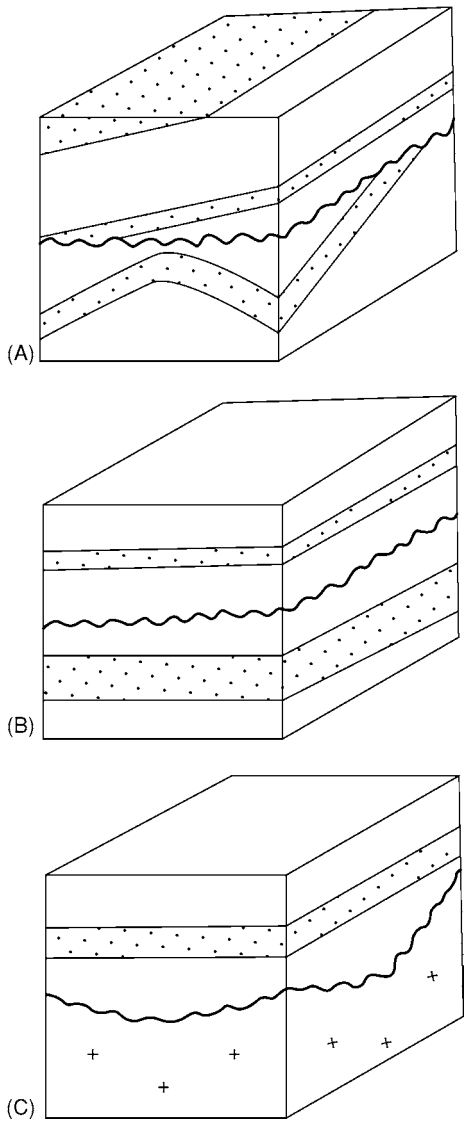

Figure 1 Types of unconformity. (A) Angular unconformity. The front face of the cube shows overlap, caused by onlap from the right. The side face shows overstep of the base of the overlying beds over the dipping lower beds. (B) Disconformity. (C) Heterolithic unconformity.

formations in Yorkshire, which was first noticed in the late eighteenth century.

The rocks overlying an unconformity often show features that record changes in the areal extent of deposition through time, particularly when looked at on a regional scale. For example, where the sea transgresses over the land each bed will cover a slightly greater area than the bed below. This process is known as onlap, and the result, as seen in the rocks, is referred to as overlap (see **Figure 1A**, front face of block). In recent years many authors have failed to distinguish between the process and the product, using the term onlap to describe both. In traditional usage the opposite of onlap – that is, the successive contraction in the lateral extension of beds in an upward succession – is known as offlap. It should be noted that offlap has been used in a very different sense by seismic stratigraphers (for reflection patterns generated by strata prograding into deep water).

History of the Concept

Some early workers published sketches of what would later be called unconformities, although they did not discuss their significance. Nicolaus Steno (1638–1687) (*see* **Famous Geologists:** Steno) produced a series of diagrams suggesting how unconformable beds in Tuscany could have been produced by cave formation and the subsequent collapse of the roof of the cave. John Strachey (1671–1743) published a diagram showing a sequence of horizontal Triassic and Jurassic rocks overlying inclined Carboniferous Coal Measures in Somerset. Some of his other diagrams suggest that he had a very vague understanding of what he was showing. Jean Etienne Guettard (1715–1786), working in northern France, produced some of the first geological maps, and two of the published maps included sections that clearly show unconformities. Unfortunately, no explanation of the observations was published.

James Hutton (1726–1797) (*see* **Famous Geologists:** Hutton) was the first author whose writings show that he understood the significance of unconformities (though he did not name them). In 1785 he presented his theory of the Earth at a meeting of the Royal Society of Edinburgh. Included in this theory was the concept of geostrophic cycles: the idea that the denudation of the landmasses produces sediments that are deposited on the seafloor and that these sediments are consolidated into rocks, elevated, folded, and denuded. Hutton theorized that there should be places where rocks from one cycle are overlain by rocks from a younger cycle, but there is no evidence that, at the time of giving his paper, Hutton had either seen or read about actual examples. If he had seen the work of Steno, Strachey, or Guettard, he would have been able to point to their diagrams as evidence for his theory.

Over the next few years Hutton searched for, and eventually found, field examples. In 1787 he discovered the unconformity at North Newton, near Lochranza, Arran (**Figure 2**). Here, reddish and yellowish sandstones, associated with some bands of caliche palaeosol, probably of Late Devonian age, rest with a marked discordance on Dalradian Schists of Late Cambrian age.

Almost immediately after finding the Arran locality, Hutton discovered horizontal beds of the Upper Old Red Sandstone lying on highly inclined (almost vertical) Silurian greywackes near Jedburgh. In the spring of the following year (1788) he found another example of almost horizontal Upper Old Red Sandstone unconformably overlying highly inclined Silurian greywackes at Siccar Point, north of Berwick.

Other examples were found by Hutton's friend John Playfair (1748–1819), whose book *Illustrations of the Huttonian Theory*, published in 1802, did much to draw attention to Hutton's work. Both Hutton and Playfair lacked a simple term to name what they were describing. The term unconformable was introduced in 1805 by one of their geological opponents, Robert Jameson (1774–1854), as an English translation of the German expression *abweichende Lagerung* ('deviating bedding or stratification') used by followers of Abraham Gottlob Werner (1749–1817). For some decades after 1805 geologists described examples of unconformable rocks, without, it appears, paying much attention to the cause of the relationship. It was only in the late 1830s, after Charles Lyell (1795–1875) (*see* **Famous Geologists:** Lyell) started publishing his extremely popular books, that the concept of, and name, unconformity really became incorporated in the thinking and language of geology.

For the rest of the nineteenth century the term unconformity was used to describe an angular discordance between two sets of strata. It was in 1905 that Amadeus William Grabau (1870–1946) extended the use of the term to include cases where there was an obvious erosional break in otherwise parallel strata. Grabau called this a case of disconformable strata, which soon became known as a disconformity.

In 1909 Eliot Blackwelder (1880–1969) suggested that the contact between sedimentary rocks and underlying igneous or metamorphic rocks should also be called an unconformity. Some authors began to apply the term nonconformity to this type of unconformity. Unfortunately, the term nonconformity was already in use as an alternative name for an angular unconformity. To try to avoid this confusion later authors used the term heterolithic unconformity. (Although at first

Figure 2 Hutton's unconformity at North Newton, near Lochranza, Isle of Arran, Scotland. The arrows mark the obvious change from steeply dipping Dalradian Schists in the lower part of the photograph to sub horizontal Devonian sandstones in the upper part.

sight 'heterolithic' (Greek for unlike rocks) may appear to be an appropriate term, it could also apply to clastic rocks overlying carbonates or to marine rocks overlying non-marine rocks. In some parts of the world heterolith is used to refer to interbedded sandstones, siltstones, and mudstones).

In all of the cases discussed above there was an assumption that the surface of unconformity represented a subaerial erosion surface. If we look at many parts of the world today, we see that the land surface is not a smooth plane. It is therefore not surprising that many unconformities that originated as subaerial surfaces are also irregular. This is often referred to as a buried-landscape type of unconformity. A good example is the Torridonian unconformably overlying the Lewisian in north-western Scotland.

In 1910 Bailey Willis (1857–1949) included surfaces of non-deposition in marine sediments as a variety of unconformity. Over the next few decades several authors stressed the importance of subaqueously formed breaks, but it was not until 1957 that John Essington Sanders (1926–1999) proposed a complex Greek-based nomenclature that attempted to distinguish clearly between subaerial and subaqueous breaks. It is, perhaps, not surprising that most people were put off by the nomenclature or thought that it was all an elaborate joke. But in ignoring the terms many people also ignored the attempt to refine geological thinking.

It was inevitable that the expansion of the use of the term unconformity would give rise to some nomenclatorial confusion (Table 1). The same word was used by different authors to describe different concepts, and the same concept was given different names. In recent years there has been some convergence of views on the nomenclature. Authors have tended to use the descriptive terms angular unconformity, disconformity, and heterolithic unconformity (Figure 1). This consensus has, however, been challenged by the specific definition of unconformity that has been used by the proponents of seismic and sequence stratigraphy (see below).

Lateral Variation

One descriptive term is usually adequate to describe an unconformity at a single exposure, but when the surface is traced over wide areas it is common to see the nature of the unconformity vary. A good example is the North Sea Unconformity Complex, often called the 'base-Cretaceous unconformity' or the 'Late-Cimmerian unconformity'. This is perhaps the most easily identifiable surface of the Phanerozoic succession of the Norwegian continental shelf. It displays great local complexity and great variability on a regional scale, such that in different places it has been classified as a nonconformity (in the sense of heterolithic unconformity), a disconformity, and an angular

Table 1 Names that have been given to different types of unconformity

Angular	*Parallel*	*Non depositional*	*Overlying igneous or metamorphic rock*
Angular discordance	Accordance	Concordant leuroatmodialeima	Heterolithic unconformity
Angular unconformity	Concordant trachyatmodialeima	Concordant leurodiscontinuity	Nonconformity
Clinounconformity	Concordant trachydiscontinuity	Concordant leurohydrodialeima	
Discordance	Concordant trachyhydrodialeima	Diastem	
Discordant atmodialeima	Disconformity	Marine unconformity	
Discordant discontinuity	Eroded surface	Nonevident disconformity	
Discordant hydrodialeima	Evident disconformity	Non sequence	
Nonconformity	Parallel unconformity	Paraunconformity	
Unconformity	Paraunconformity	Surface of non deposition	

unconformity. This variation in the nature of the surface reflects local differences in the processes of formation.

The unconformity complex developed during the transition from the synrift stage (active stretching) to the post-rift stage (thermal subsidence and sediment loading) in the development of the northern North Sea basin. A transgression coincided with the transition. This combination of differential subsidence, block rotation, changing patterns of sediment input, and sea-level rise caused local differences in patterns of erosion and sedimentation, which are reflected in the spatial variation of the type of unconformity.

Although varied in detail, there is a general distribution pattern of the different types of unconformity. At the rift margins the rising sea covered the previously exposed basement, producing nonconformities. On the rift flanks, where faulted blocks subsided and rotated, angular unconformities were normally developed. In the centre of the rift, subsidence dominated, generally giving rise to disconformities.

This example, produced during the development of a passive margin, helps to demonstrate that unconformities can originate in a variety of tectonic and sedimentary settings and are not just products of erosion at the end of a geostrophic cycle.

Unconformities and the Stratigraphic Record

Once the Huttonian theory of geostrophic cycles became commonly known, geologists started to apply the reasoning in their efforts to understand and classify the rock record. It became clear that there were major periods of deformation, uplift, and erosion, known as orogenies, which could be recognized over large areas, and the consequent unconformities were used to subdivide the geological column. It soon became apparent that much of Britain and Scandinavia had been affected by the Caledonian orogeny, which was originally thought to have culminated in the Late Silurian. The three classic unconformities discovered by Hutton were all produced by deposition after Caledonian deformation. South-western Britain, and much of the adjacent continent, had been affected by an orogeny that culminated in the Late Carboniferous, which was variously termed the Armorican, Hercynian, or Variscan (*see* **Europe:** Variscan Orogeny). Geologists in North America recognized a similar pattern of orogeny. It was also apparent that there is an ongoing Alpine–Himalayan orogeny.

Although the causes of these orogenic episodes were unclear and were to remain so until the development of plate-tectonic theory in the 1960s, the practical result was the rapid development of the broad outlines of the stratigraphic column. In addition to the major unconformities associated with the final phases of uplift and erosion, other unconformities were discovered that helped in the processes of subdivision and classification. Stratigraphers and palaeontologists could then look in more detail at the rocks bounded by these unconformities.

In many cases the first rocks deposited on an unconformity surface are conglomerates, often containing pebbles eroded from locally weathered rocks. These pebbles can give us information about the rocks that were exposed at that time. For example, the basal Carboniferous conglomerates that lie unconformably on Silurian shales in the east of the English Lake District contain distinctive fragments of the Shap granite. We know that the granite is intrusive into the Silurian (up to and including the Upper Ludlow), so we have some constraints on the timing of cooling, crystallization, uplift, and erosion of the granite.

At a higher stratigraphic level, although in the same area of England, we find the Lower Brockram of Permian age unconformably overlying the Carboniferous Limestone. The Lower Brockram is formed of pebbles that are mostly Carboniferous Limestone. The Upper Brockram, found slightly higher in the

succession, contains a large proportion of fragments of Ordovician and Silurian sedimentary and volcanic rocks, demonstrating that by the time the Upper Brockram was deposited an area of these older rocks was exposed and being eroded.

With the development of stratigraphic thinking and knowledge it became clear, however, that unconformities were a poor choice for defining widely correlatable boundaries. An unconformity necessarily implies that there is a gap in the record. This gap may represent different durations of time in different areas. For good correlation, detailed information about fossil occurrences and other temporal markers, such as ash bands, is needed. A gap cannot provide this kind of detail. So a lot of effort was put into searching for areas where a continuous sedimentary record, deposited during the time-span represented by the gap, could be demonstrated. In many cases this involved looking outside the European area, where most of the stratigraphic units had first been defined.

Unconformities and Sequences

For many practical problems, the refinements of stratigraphy are less important than the local rock distribution, so not all geologists abandoned the use of unconformities. From the 1930s onwards Arville Irving Levorsen (1894–1965) interpreted the geology of the mid-continent region of North America in terms of large-scale unconformity-bounded tectonostratigraphic units. Levorsen did not propose names for these units, referring to them as layers of geology, but he demonstrated their importance in petroleum exploration. It was in the late 1940s that Laurence Louis Sloss (1913–96) began to use the term sequence for such major unconformity-bounded units, eventually proposing a formal name for each sequence. In order to distinguish these sequences from standard chronostratigraphic units they were given the names of Indian tribes (Table 2).

Sloss, and many other North American stratigraphers, had encountered problems when attempting to apply the mostly European-based stratigraphic divisions to North American rocks. However, a small number of major craton-wide unconformities could be recognized, based on an integrated study of outcrop and subsurface data. Sloss stressed that at the scale of an individual exposure there was no obvious characteristic by which these inter-regional unconformities, which were used to separate sequences, could be distinguished from the many local unconformities. This was graphically illustrated when the unconformity at the base of the Absaroka Sequence was redefined.

The inter-regional unconformities represented major breaks in the depositional record and were associated with a great degree of overstep and overlap. For example, the rocks at the base of the Sauk Sequence range in age from latest Precambrian to Late Cambrian. They were deposited on an unconformity that cut across rocks of a great range of Precambrian ages. The boundary at the top of a sequence was interpreted as representing a time of major regression of the sea from the continental craton, with associated subaerial erosion. The base of the next sequence represented the re-flooding of the craton. Local unconformities were thought to be produced by minor fluctuations in the rate of sea-level rise or fall, by local tectonics, or by local changes in sediment supply.

Sequences, as promoted by Sloss, are major units, with demonstrably diachronous boundaries. Although they are useful as major subdivisions of North American strata, they were not intended to replace the standard chronostratigraphic units. They were erected because of the perceived differences between the rock record in North America and that in Europe. By no means all stratigraphers agreed with this approach, arguing that better-defined chronostratigraphic boundary sections and improved techniques of correlation would eventually help to solve the difficulties.

Unconformities, Seismic Stratigraphy, and Sequence Stratigraphy

The development of high-quality seismic-reflection profiles, primarily as a result of the intensive search for hydrocarbons, and the calibration of these profiles

Table 2 North American sequences

Sequence name	*Age of rocks included in the sequence*
Tejas	Late Paleocene to Holocene
Zuni	mid Jurassic to mid Paleocene
Absaroka	latest Mississippian (post Chesterian) to Early Jurassic[a]
Kaskaskia	late Early Devonian to Late Mississippian
Tippecano	mid Ordovician to Early Devonian
Sauk	latest Precambrian to Early or possibly early mid Ordovician

[a]The Absaroka was originally defined as from the Chesterian.

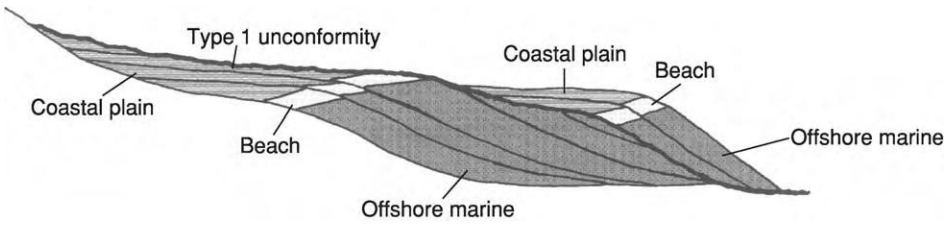

Figure 3 A type 1 unconformity, produced during a rapid relative fall in sea level, when the rate of eustatic fall exceeded the rate of basin subsidence. The diagram shows the erosion associated with the sea level fall, the ongoing subaerial erosion, the basinwards shift in facies, the downward shift in coastal onlap, and the abrupt change in facies. Only parts of the sequences above and below the unconformity are represented, but minor marine flooding surfaces show how the sequences can be subdivided into parasequences.

by geophysical logging techniques applied to relevant boreholes, has stimulated a major development of interest in unconformities. Seismic stratigraphy was originally developed by members of an Exxon research team and was presented and promoted to the worldwide geological community from the mid-1970s onwards. Seismic stratigraphy is simply the geological interpretation of seismic data. Its basic premise is that primary seismic reflectors represent either major bedding surfaces (with the assumption that the reflections are following isochronous horizons) or unconformities. By the 1980s the originators had broadened their concepts and were talking about sequence stratigraphy rather than seismic stratigraphy (*see* **Sequence Stratigraphy**).

Data analysis is based on the identification of stratigraphic units composed of genetically related strata, known as depositional sequences. The lower and upper boundaries of these depositional sequences are unconformities or their correlative conformities. When sequence stratigraphy was first promoted, an unconformity was defined as a surface of erosion or non-deposition that separates younger rocks from older rocks and represents a significant hiatus. A conformity was defined as a surface along which there is no evidence of erosion or non-deposition and along which no significant hiatus is indicated. (Purists might point out the difficulty of correlating a gap with a surface or argue whether theoretically there needs to be a correlative conformity, but most workers seem to accept the overall concept). The sequences of seismic and sequence stratigraphy are much smaller units than the North American sequences named by Sloss, and the time-transgressive nature of their bounding unconformities is not considered to be significant.

By the late 1980s the originally proposed concept of sequences was being refined and extended. Two types of sequence were now recognized, which are known as type 1 and type 2. They are differentiated on the basis of their lower boundaries, which have come to be called type 1 and type 2 unconformities. A type 1 unconformity is characterized by subaerial exposure and erosion associated with stream rejuvenation, a basinwards shift in facies, a downward shift in coastal onlap, and an abrupt change in facies, for example non-marine or very shallow-water marine rocks overlying deeper-water marine rocks (Figure 3). It is interpreted to form when there is a relative fall in sea-level at the depositional shoreline break, i.e. when the rate of eustatic fall exceeds the rate of basin subsidence. A type 2 unconformity lacks both subaerial erosion associated with stream rejuvenation and a basinwards shift in facies (Figure 4). It is interpreted to form when no relative fall in sea-level occurs at the depositional-shoreline position, i.e. when the rate of eustatic fall is less than the rate of basin subsidence.

Sequences were now subdivided into parasequence sets and parasequences. A parasequence is a relatively conformable succession of genetically related beds bounded by marine-flooding surfaces and their correlative surfaces. A parasequence set is a succession of genetically related parasequences that form a distinctive stacking pattern bounded, in many cases, by major marine-flooding surfaces and their correlative surfaces.

These definitions require a clear distinction to be made between a marine-flooding surface and an unconformity. A marine-flooding surface is defined as a surface that separates younger strata from older strata across which there is evidence of an abrupt increase in water depth. The deepening is commonly associated with minor submarine erosion (but no subaerial erosion or basinwards shift of facies) and non-deposition, and a minor hiatus may be indicated. An abrupt increase in water depth implies a transgression at the basin margins, with marine sediments overlying an exposure surface.

An unconformity is now defined as a surface separating younger strata from older strata, along which there is evidence of subaerial erosional truncation (and, in some cases, correlative submarine erosion) or subaerial exposure, with a significant hiatus. This use of the term unconformity is obviously more restrictive than that used when seismic stratigraphy was

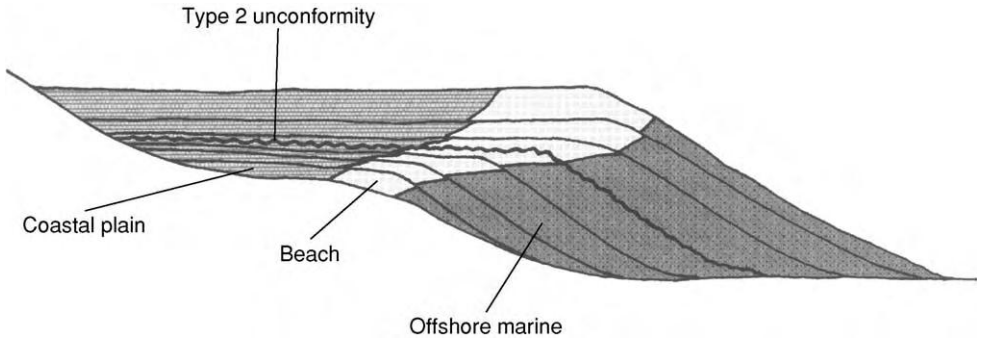

Figure 4 A type 2 unconformity, produced when the rate of eustatic fall is less than the rate of basin subsidence such that there is no relative fall in sea level. There is no major erosion of the underlying sediments. A major feature associated with a type 2 unconformity is a change from prominent progradation below the unconformity, caused by an increasing rate of regression, to prominent aggradation above the unconformity as the rate of regression slows.

first proposed and is also more restrictive than traditional use. This definition is required to differentiate between sequence and parasequence boundaries. Although the promoters of sequence stratigraphy proposed this restricted definition only in the context of their work, their definition has been applied more widely by some workers.

Although Hutton's original concept of an unconformity was based on his geostrophic theory, subsequent workers have tended to use the term to describe what has been observed, with explanations and hypotheses being separated from the observation. To restrict the use of the term to fit a particular hypothesis, as has been done by the promoters of sequence stratigraphy, is, to some people, a retrograde step. With such a well-known term as unconformity it can also lead to confusion, as many workers continue to follow traditional usage.

One early product of the sequence-stratigraphic model was a series of charts of global cycles of relative change in sea-level through time, based on the interpretation of unconformities and marine-flooding surfaces as products of eustatic sea-level change. Much of the data from which the charts were developed came from North America, with a small number of regional studies from elsewhere. The fact that many of the unconformities on these global cycle charts do not match traditional stratigraphic-unit boundaries, many of which were originally erected based on unconformities, does suggest a rather more complex interplay between local, regional, and global events than that proposed in the model.

Despite these caveats, work on seismic and sequence stratigraphy has promoted a huge increase in our knowledge of unconformities. Although much of this data remains in confidential commercial files, there is sufficient in the public sector to keep geologists arguing and theorizing for years to come.

UNIDIRECTIONAL AQUEOUS FLOW

J Best, University of Leeds, Leeds, UK

Introduction

Unidirectional water flows are vital agents of erosion, transportation, and deposition in many Earth surface environments and can occur in a wide variety of depositional settings from continental rivers to flows in the deep sea. Unidirectional flows move in one principal direction, with no time-averaged reverse flows within the depth-averaged fluid and, apart from any local deviations caused by bed topography, experience no reverse or oscillatory motion, such as may be produced by waves and tides. Unidirectional flows can be either uniform, where the flow does not vary in velocity or cross-sectional area along its path, or non-uniform, where the fluid velocity and cross-sectional area do change spatially. Non-uniform flows show convective acceleration, where the cross-sectional area decreases and velocity increases, or convective deceleration, where the cross-sectional area expands and the flow slows. In addition to this spatial change in flow properties, unidirectional flows may vary temporally in their behaviour. Flows that show no temporal change in their behaviour are termed steady, whereas those whose velocity changes over time are termed unsteady. Unsteady flows show temporal increases and decreases in velocity, which are often related to the passage of a discrete event such as a flood.

Water flowing over a boundary, whether solid or mobile, develops a flow structure that depends on the velocity and depth of the fluid together with its density and viscosity. The surface over which the fluid moves exerts a frictional drag on the flow, and the region of flow near the bed that is retarded by this friction is termed the boundary layer. Minor friction at the upper atmospheric interface can also cause a small decrease in velocity at the top of the flow in open channels, whereas in unidirectional flows that have solid boundaries all around the flow (such as flow in ice-covered channels or flows through conduits and pipes) significant boundary layers develop from all surfaces. Additionally, unidirectional flows that propagate within another fluid, such as unidirectional density currents, experience significant mixing at their upper boundary owing to shear at this surface. The boundary-layer structure near the surface (or wall) generates a stress on the bed, which initiates and causes sediment transport and ultimately the development of bed morphology. However, the sediment in transport and exact shape and nature of the topography also exert significant feedbacks upon the flow.

Flow Types

Unidirectional flows may be either laminar or turbulent. Laminar flows are dominated by viscous forces rather than the inertial forces acting on the fluid, whereas turbulent flows are dominated by inertial forces. The laminar or turbulent state of flow is expressed by the Reynolds number, Re, where

$$\mathrm{Re} = \frac{\rho \overline{u} Y}{\mu} = \frac{\textit{inertial forces}}{\textit{viscous forces}}$$

and ρ is fluid density, $\overline{u}$ is a characteristic velocity of the flow (such as the depth-averaged mean downstream velocity), Y is a characteristic length scale (such as the flow depth), and μ is the molecular viscosity of the fluid. Flows are termed laminar when $\mathrm{Re} < 500$ and any mixing that occurs is on a molecular scale, turbulent when $\mathrm{Re} > \mathrm{O}2000$ and mixing occurs through the action of turbulent eddies or coherent flow structures at various scales, and transitional when $500 < \mathrm{Re} < 2000$. Many aqueous flows are fully turbulent in their behaviour, although it should be remembered that, owing to their small size, many organisms living in unidirectional flows may experience the overwhelming effects of viscosity and thus live in laminar worlds. Additionally, changes to the turbulent nature of flow can be caused by increasing concentrations of fine suspended sediment, which may modify the nature of the velocity profile and mechanisms of turbulence generation.

Additionally, unidirectional flows are significantly affected by the relative influence of gravitational forces compared with inertial forces, as expressed through the Froude number, Fr.

$$\mathrm{Fr} = \frac{\overline{u}}{\sqrt{gY}} = \frac{\textit{inertial forces}}{\textit{gravitational forces}},$$

where g is acceleration due to gravity. Flows are termed subcritical when $\mathrm{Fr} < 1$, supercritical when $\mathrm{Fr} > 1$, and critical when $\mathrm{Fr} \cong 1$. This dimensionless number expresses the relative celerity of a gravity wave ($\sqrt{gY}$) on the flow: subcritical flows are able to experience the upstream effects of the wave, which has a velocity greater than the flow velocity, whereas the effects of the wave are felt only downstream for

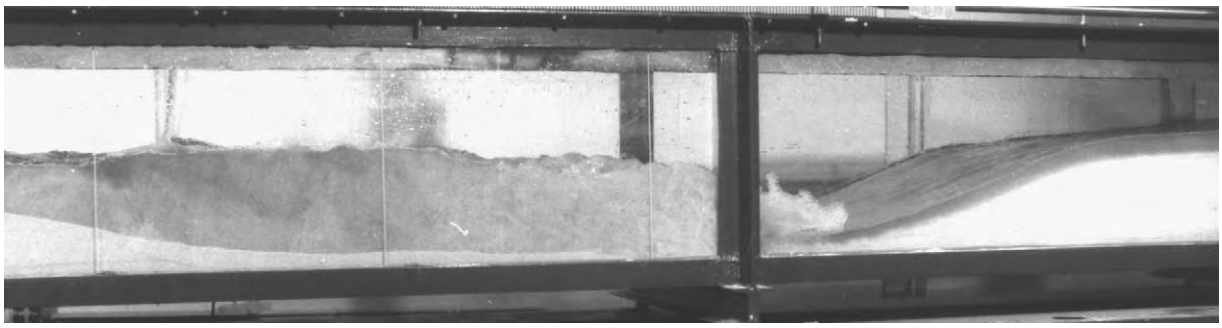

Figure 1 Flow in a laboratory channel, showing the transition from supercritical flow (Fr > 1, right) to subcritical flow (Fr < 1, left) through a hydraulic jump. Image courtesy of John Bridge.

supercritical flows. The form of the Froude number is slightly different for unidirectional density-current flows, where one fluid flows into another, as the effects of reduced gravity must be taken into account. However, the behaviour of the flow, and especially the interaction between the bed and the flow surface and hence the nature of energy loss within the flow, is strongly linked to the Froude number, as exemplified by the transition from supercritical to subcritical flow through a hydraulic jump (Figure 1).

In addition to these properties of flow, unidirectional aqueous flows can show a range of behaviours dependent on their rheology, or how their internal rate of strain responds to an applied external stress (Figure 2). Newtonian fluids, such as pure water, show a linear relation between applied shear stress and strain rate, and hence their viscosity is invariant with respect to the applied stress. Non-Newtonian fluids, however, do not behave in this manner, and either strain rate changes with applied stress (pseudoplastic and dilatant behaviours; Figure 2) or there is an initial yield stress with a subsequent linear stress–strain relationship (Bingham plastic; Figure 2). Although the majority of aqueous flows behave in a Newtonian manner, the addition of significant quantities of fine sediment can cause a change in behaviour and result in flows that have non-Newtonian characteristics, eventually leading to mud or debris flows in which the percentage of water may be very low and the rheology markedly non-Newtonian.

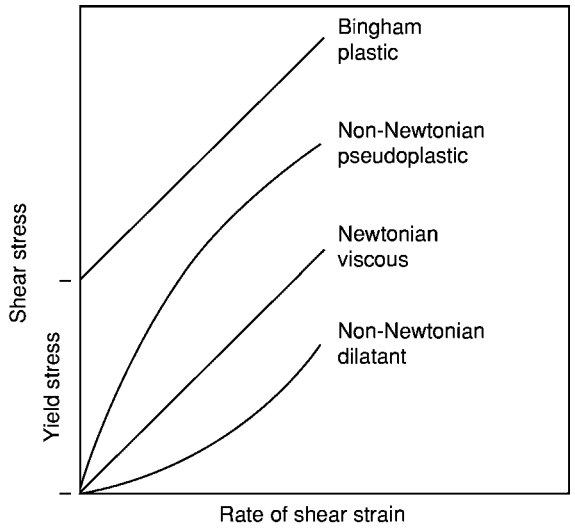

Figure 2 The relationship between the shear stress applied to a fluid and its strain rate, illustrating the various types of behaviour. The viscosity of the fluid is given by the slope of the line.

Velocity Profiles and Boundary Layer Structure

Unidirectional aqueous flows moving over a solid impermeable surface develop a distinct velocity profile away from the wall (Figure 3), and the boundary layer extends into the outer flow until the effects of wall friction become minimal (where the velocity at a point is approximately 95% of the maximum velocity

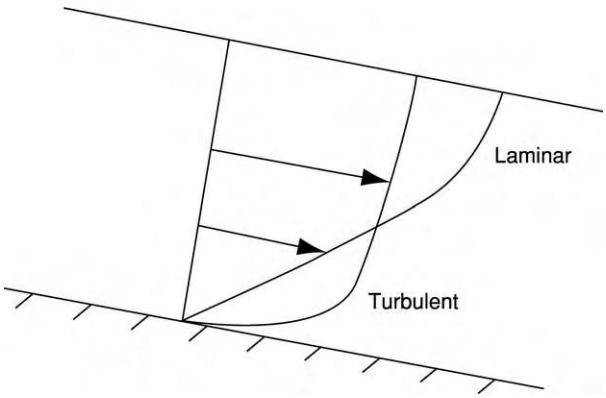

Figure 3 Comparison of a laminar flow and a turbulent flow over an impermeable flat surface. Both flows have the same mean discharge through a cross section, but they adopt different velocity profiles. (After Middleton GV and Southard JB (1984) *Mechanics of Sediment Movement*. SEPM Short Course Notes 3. Tulsa: Society of Economic Paleontologists and Mineralogists).

in the profile). Turbulent flows, since they possess appreciable mixing between adjacent fluid layers, have a steeper velocity gradient near the wall than do laminar flows (Figure 3). The stresses generated in a laminar flow, τ, are a product of the diffusion of momentum within the fluid on a molecular level and can be expressed as

$$\tau = \mu\left(\frac{\partial \overline{u}}{\partial y}\right)$$

where $\overline{u}$ is the time-averaged velocity at a point and y is the vertical height above the boundary.

However, for turbulent fluids the flow at each point can be broken down into a mean flow velocity, $\overline{u}$, and the deviation from that mean, u' (i.e. $u = \overline{u} + u'$ for the downstream component of the flow). This decomposition of the turbulent-flow signal can be applied to all three components of velocity (i.e. $u = \overline{u} + u'$, $v = \overline{v} + v'$, and $w = \overline{w} + w'$, with u, v, and w denoting the downstream, vertical and spanwise components of velocity, respectively, in the x, y, and z directions). The stresses within turbulent flows are thus a function of both transfer of momentum on a molecular level (the viscous shear stress) and mixing caused by the movement of turbulent eddies within the flow, such that shear stress within a turbulent flow, τ, is given by

$$\tau = (\mu + \eta)\frac{\partial \overline{u}}{\partial y}$$

where η is the so-called eddy viscosity.

The effect of turbulent mixing is that packets of low-momentum fluid from near the bed may be mixed upwards in the flow and relatively faster parcels of fluid from higher in the flow may be carried downwards towards the bed. This exchange of downstream momentum is expressed by $-\rho u'$, and, for a parcel of fluid moving upwards or downwards in the flow (considering the x–y plane with u and v as the components of velocity), the rate of change of downstream momentum through a given area is expressed by $-\rho u'v'$. Hence, the time-averaged shear stress in a turbulent flow can be given by

$$\tau = \mu\left(\frac{\partial \overline{u}}{\partial y}\right) - \rho\overline{u'v'}.$$

Similar expressions can be written for the shear stresses exerted by the combination of the velocity fluctuations between the three components of flow, and these are termed the Reynolds stresses.

The velocity profile of a turbulent boundary layer developed over a smooth surface can be divided into several distinct regions (Figure 4): the viscous sublayer, in which the influence of viscosity is dominant but in which some turbulent eddies are initiated (there is a linear increase in velocity with height within the viscous sublayer); the turbulence-generation layer (or buffer zone), which is the region of largest velocity gradient and where the majority of turbulence is generated, which is characterized by a logarithmic velocity distribution with height above the bed; and an outer zone, which is characterized by the dissipation of turbulent eddies generated near the boundary.

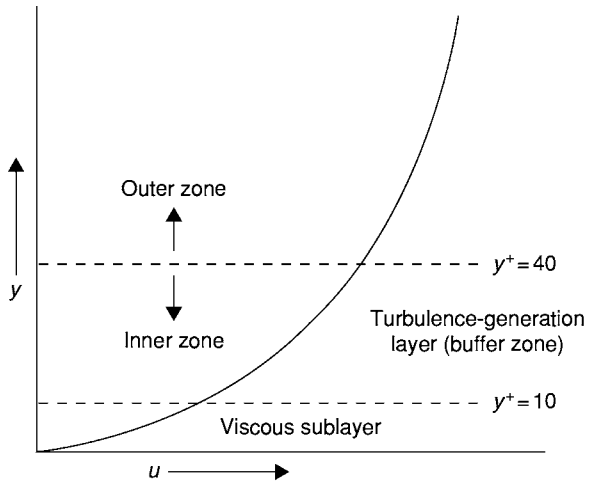

Figure 4 The different regions of a turbulent boundary layer.

The Estimation of Boundary Shear Stress

A key aim of understanding and quantifying boundary-layer structure is to enable prediction of the boundary shear stress exerted on the wall, in order that erosion thresholds and sediment transport can be estimated. Six methods are commonly used to estimate the mean value of the shear velocity, u_*, which is related to the boundary shear stress, τ_B, by $\tau_B = \rho u_*^2$.

1. The slope method uses the slope of the water surface, S, and flow depth, Y, such that $u_* = gYS^{0.5}$.
2. The best fit to the linear velocity profile within the viscous sublayer, $u^+ = y^+$, where $u^+ = U/u_*$ and $y^+ = yu_*/v$, where U is the mean velocity at a point and v is the kinematic viscosity of the fluid (μ/ρ).
3. The best fit to the logarithmic 'law of the wall', which describes the logarithmic shape of the downstream velocity profile in the lower part of a flow (up to the top of the turbulence-generation layer), such that $u^+ = (1/\kappa)\ln(y^+) + C$, where κ is the von Kármán constant (*ca.* 0.40 in clear-water flows) and C is a function of the roughness of the bed.

4. Using linear extrapolation of the Reynolds stress profile to the bed at a height of $y = 0$, such that $-(\overline{u'v'})/u_*^2 = 1 - (y/Y)$.
5. Adopting the spectral method, which uses estimated values of the turbulent dissipation rate, ε, in the inertial region of the spectral domain, such that $u_* = (\varepsilon\kappa y)^{1/3}$.
6. Using the normalized vertical flux of turbulent kinetic energy, which has been proposed to adopt a universal value irrespective of wall roughness, such that $0.5q^2\nu/u_*^3 \approx 0.30$, where q is the turbulent kinetic energy $(q = 0.5(\overline{u'}^2 + \overline{v'}^2 + \overline{w'}^2))$.

The Structure of Turbulent Boundary Layers

The nature of mixing within a turbulent boundary layer depends on the exact nature of the turbulent eddies, or coherent flow structures, that are present within the flow. These coherent flow structures are generated within the viscous sublayer and turbulence-generation region, and can be investigated through their velocity signatures and their temporal and spatial length scales. If a two-dimensional flow is considered, four quadrants of flow behaviour can be defined based on the deviations of the u and v components of flow (downstream and vertical velocities) from their respective mean values (Figure 5). This allows recognition of regions of relatively slow downstream-momentum fluid moving upwards within the flow (quadrant 2 events; Figure 5); relatively fast downstream-momentum fluid moving downwards within the flow (quadrant 4 events; Figure 5); and outward and inward interactions of flow (quadrants 1 and 3 events, respectively; Figure 5). This simple quadrant analysis has been widely used in turbulent-boundary-layer research and is appropriate if the flow is largely two dimensional; in fully three-dimensional flows, all three components of velocity should be considered, and octant analyses may be required to characterize truly the fluctuations in fluid flow.

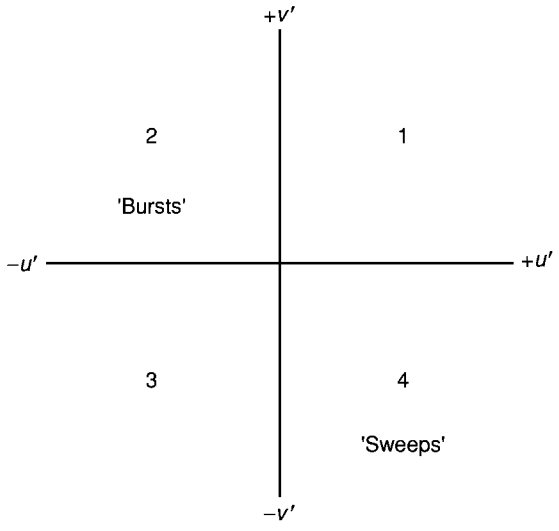

Figure 5 Quadrant classification of a turbulent flow, according to the deviations from the mean values of downstream (u') and vertical (v') velocity.

Much research over the past 40 years has been devoted to elucidating the form of coherent flow structures within turbulent boundary layers, linking these structures to their velocity signatures, and assessing their contributions to both the Reynolds stresses and turbulent kinetic energy budget. Studies have progressed from largely qualitative flow visualizations to quantitative measurements and more recent numerical simulations. Coherent flow structures within a flat-bed turbulent boundary layer are principally composed of:

- low-speed streak areas in the region $0 < y^+ \leq 10$ (where $y^+ = yu^*/\nu$), which are areas of relatively low downstream velocity that are aligned parallel to the flow and form a series of spanwise areas separated by regions of slightly higher flow velocity,
- ejections of low-speed fluid away from the wall (quadrant 2 events; Figure 5),
- sweeps of relatively high-momentum fluid towards the wall (quadrant 4 events; Figure 5), and
- vortical structures of several different kinds, including larger-scale structures, which may occupy a significant fraction of the flow depth and could be generated by amalgamations of smaller groups of vortices originating near the wall.

These structures have been visualized and modelled as a series of longitudinal vortices near the bed, which link through to the legs of 'horseshoe'-, 'hairpin'-, or 'arch'-shaped vortices higher in the flow, which constitute the ejections (quadrant 2 events) (Figure 6). The majority of the Reynolds stresses, approximately 70% in a smooth-wall boundary layer, may be linked to these quadrant 2 and quadrant 4 events, which may be critical in both the suspension of sediment (quadrant 2 events or 'bursts') and the entrainment of sediment as bedload (quadrant 4 events), although several studies have also highlighted the significance of quadrant 1 and quadrant 3 events. The transition from laminar to turbulent flow also appears to be linked to the generation of small 'packets' of vortices near the wall, which first appear as 'turbulent patches' near the bed (Figure 7). These 'patches' or 'turbulent spots' bear a striking resemblance to the groupings of hairpin vortices generated in fully turbulent boundary layers, which extend through a significant percentage of the flow depth.

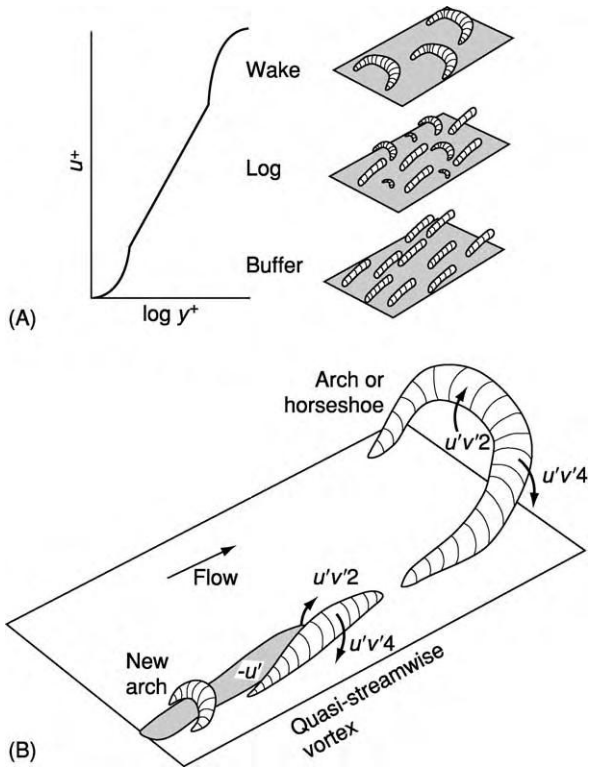

Figure 6 (A) Idealized model of populations of vortices in dif ferent regions of a turbulent boundary layer. (B) Schematic model of the links between ejection and sweep motions and streamwise vortices and 'arch' or 'horseshoe' shaped vortices in a turbu lent boundary layer 2 and 4 refer to quadrant 2 and 4 events (see Figure 5); Reproduced from Robinson SK (1991) Coherent motions in the turbulent boundary layer, *Annual Review of Fluid Mechanics* 23: 601 639.

Flow Separation

If a flow encounters a marked change in the gradient of the wall over which it is flowing or is subject to an adverse positive pressure gradient (for example, as a result of injection of fluid through a porous wall), then the fluid may be forced away from the wall and separate from the boundary, with subsequent re-attachment of the flow to the bed at some distance downstream, creating a zone of recirculating, or separated, flow near the bed (Figure 8). Flow separation is a key process under most unidirectional water flows and frequently occurs at both positive and negative steps or changes in bed topography. Such areas of flow separation are critical in many unidirectional flows, occurring at a range of scales from, for example, separation behind individual grains, bedforms (Figure 8), and bars to larger-scale features such as those associated with changes in channel

Figure 8 Flow separation visualized behind a dune bedform. Flow right to left. Flow is visualized by the path of neutrally buoyant particles within the water, which shows the recirculating flow within the dune leeside.

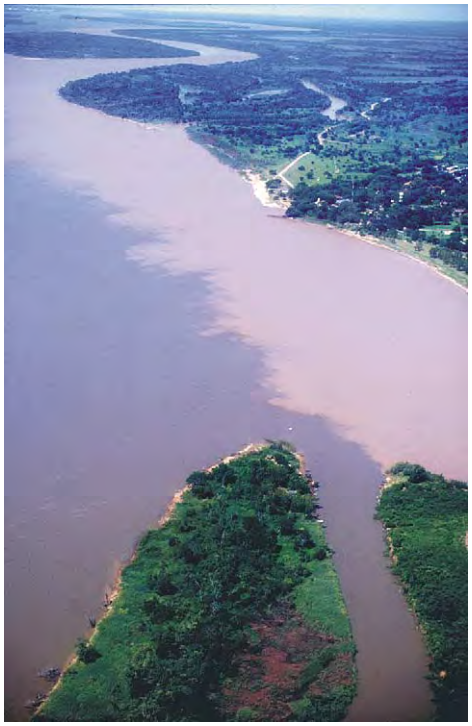

Figure 9 Large scale Kelvin Helmholtz instabilities generated along the mixing layer between the Rio Paraná (left, clearer water) and Rio Paraguay (right, higher sediment concentration), Argentina. Flow is away from the viewer, and the width of the image is approximately 1.5 km.

curvature, abrupt gradient changes at the edge of subaqueous slopes, and subaqueous topography. One key consequence of flow separation is that a steep velocity gradient and shear layer are generated between the separation zone and the faster free-stream fluid outside: large-scale coherent vortices, termed Kelvin–Helmholtz instabilities, are generated along this shear layer. Such large-scale vortices are highly turbulent and may be responsible for generating large instantaneous Reynolds stresses, which are often critical in erosion of the bed and sediment transport.

Free Shear Layers

In addition to shear layers associated with flow separation, zones of distinct differential velocity and rapid change in velocity may be present within the body of a unidirectional flow, owing to flow convergence around topography or in combining channels or to shear at the top of a subaqueous density current, for example. Turbulence and mixing across such 'free' shear layers depend on the velocity differential across the shear layer and the relative densities and viscosities of the two incoming flows, but these free shear layers often create large-scale Kelvin–Helmholtz instabilities (Figure 9), which dominate both fluid mixing and the instantaneous Reynolds stresses. For example, fluid mixing at channel confluences (Figure 9) has been shown to be greatly influenced by the shear-layer dynamics between the incoming flows, and interactions between free shear layer and bed topography are thought to control the downstream dispersal of suspended sediments and pollutants.

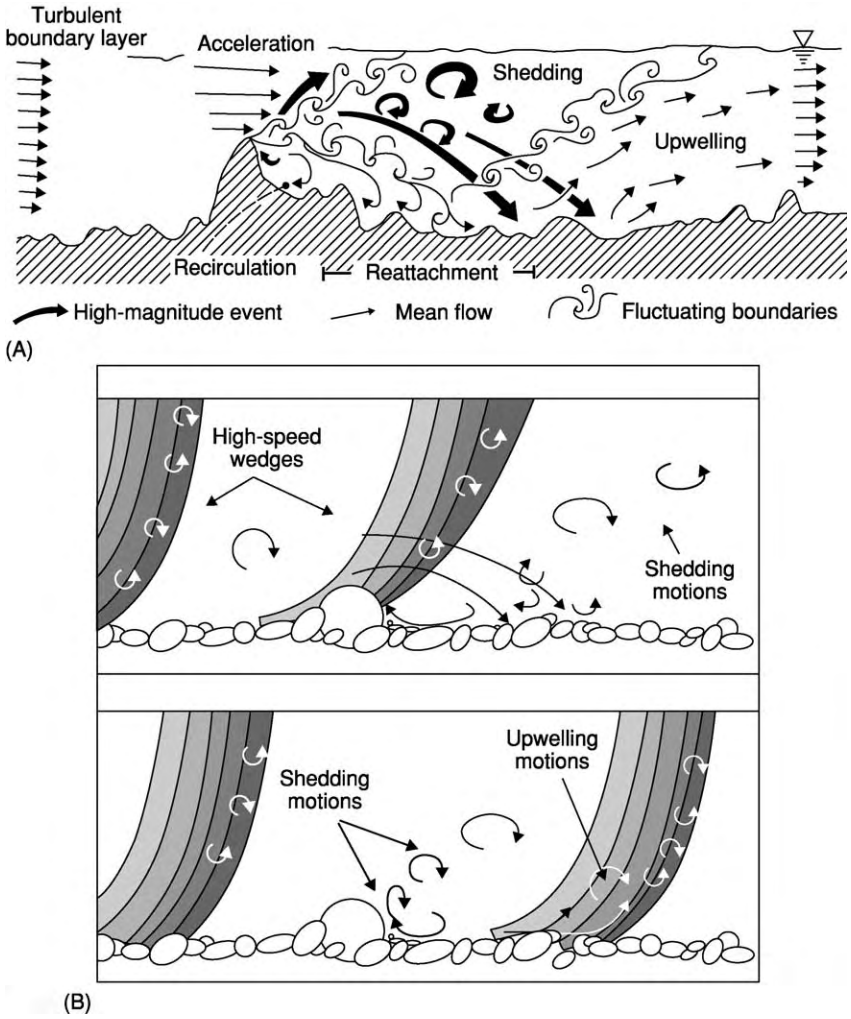

Figure 10 (A) Flow regions associated with the presence of a pebble cluster on the turbulent flow field. (B) Schematic diagram of the large scale flow structures proposed to develop over a rough gravel surface, showing (top) how the passage of a large scale high speed flow structure expands the flow separation zone in the lee of the clast and (bottom) how this generates vortex shedding from the separation zone and upwelling in the region of flow reattachment. Both A and B are reproduced from Buffin Belanger T and Roy AG (1998) Effects of a pebble cluster on the turbulent structure of a depth limited flow in a gravel bed river. *Geomorphology* 25: 249 267.

Reproduced from Nelson JM, McLean SR, and Wolfe SR (1993) Mean flow and turbulence fields over two dimensional bedforms. *Water Resources Research* 29: 3935 3953, with permission from American Geophysical Union.

Other Factors Influencing Boundary Layer Structure

In many unidirectional aqueous flows, the precise nature of the mean and turbulent flow is influenced by a range of variables that can significantly alter the flow structure, bed shear stress, patterns of sediment transport, and, hence, development of bed morphology. Some of the most significant influences on the characteristics of unidirectional aqueous flows are described below.

The Nature of Bed Grain Roughness

Particle roughness significantly increases the potential for turbulent mixing near the bed and often results in an increase in the gradient of the near-bed velocity profile, with a concomitant increase in the bed shear stresses derived from the velocity gradient, Reynolds stress, or turbulent kinetic energy budget. Grain roughness may destroy the viscous sublayer and also increase the generation of turbulence near the bed, through either encouraging intensified bursting (quadrant 2 events) from between the grains (and thus larger-scale return quadrant 4 events) or generating regions of flow separation around individual grains or groups of particles, which may both create significant velocity gradients near the bed and generate large-scale coherent vortices, associated with flow separation both in front of and behind the particles, which can penetrate the entire flow depth (Figure 10).

The Presence and Type of Bedforms

Many bedforms such as ripples, dunes and larger-scale bar forms, create their own flow field through topographic, convective accelerations and decelerations of fluid that may significantly change the nature of a unidirectional flow. In addition, many bedforms are also associated with flow separation on their upstream stoss side or downstream lee side, which generates appreciable turbulence and a boundary layer that is recovering from flow separation downstream of the region in which the flow reattaches to the bed (Figure 11).

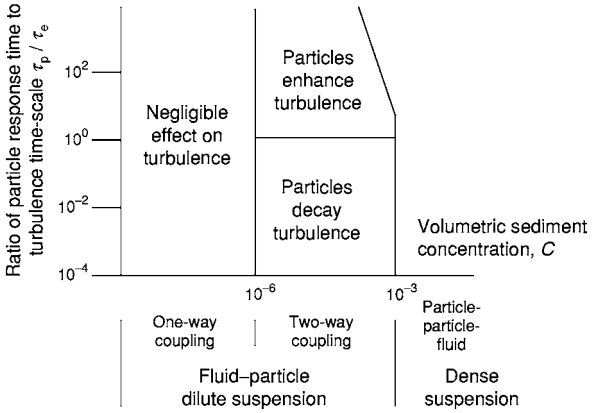

Figure 12 Schematic diagram of the attenuation or enhancement of turbulence due to the presence of sediment in a flow as a function of the volumetric sediment concentration, C, and the ratio of the particle response time to the turbulence time scale, τ_p/τ_e (after Elghobashi S (1994) On predicting particle laden turbulent flows. *Applied Scientific Research* 52: 309 329).

The Type and Quantity of Suspended Sediment

Many turbulent flows transport appreciable quantities of suspended sediment, with the suspended concentration in some flows reaching levels at which the flows become markedly non-Newtonian, such as in the Huanghe River in China, where concentrations of up to 1290 kg m ^{3} have been recorded. Suspension

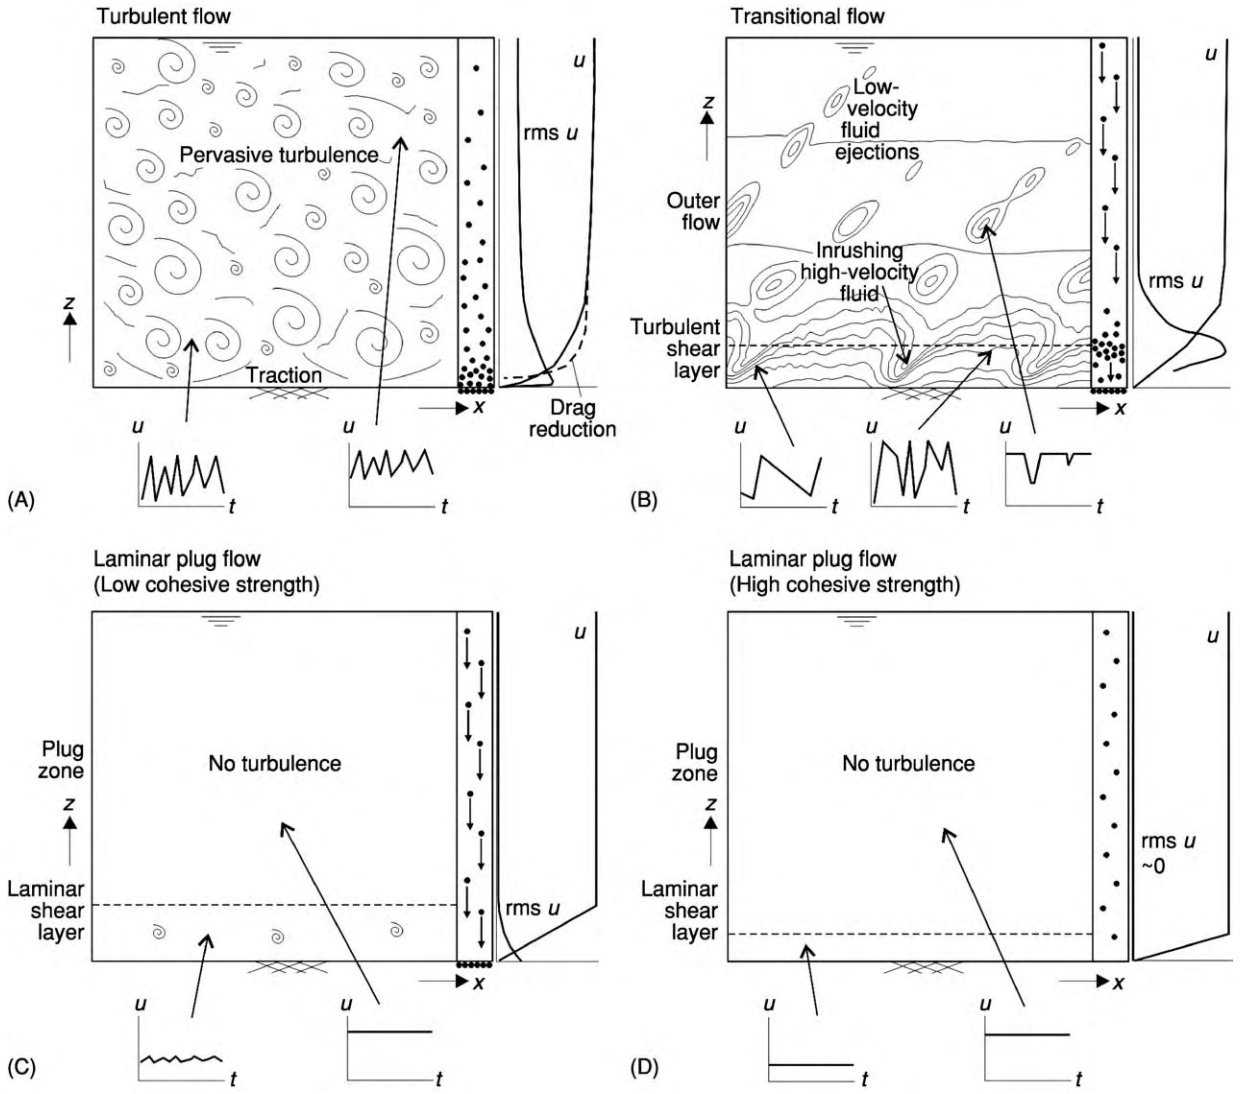

Figure 13 Schematic model for flows with increasing clay concentrations. Each model depicts the characteristic velocity profile and nature of flow, a vertical profile of the rms *u*, representative time series at several heights, and a representation of sediment settling. rms refers to the root mean square value of the downstream velocity component, or level of turbulence, within the flow, and indicates the principal regions of turbulence generation within each profile. (A) Turbulent flow with a logarithmic velocity profile and turbulence generation near the bed. At low clay concentrations, drag reduction may begin to occur. Coarser sediment is supported through turbulence, and sedimentary structures can develop. (B) Transitional flows with a developing shear layer, which separates a lower region of high velocity gradient from an upper layer of reduced shear. Sketch of flow depicts streamlines. Turbulence is strongest in the shear layer, along which Kelvin Helmholtz instabilities are developed with a distinctive velocity signature (see inset sketches). Sediment entrained into the basal region is trapped, and parallel lamination may be produced by the variable shear stresses induced by the shear layer instabilities. (C) Laminar plug flow without turbulence and with low cohesive strength. The cohesive strength of the flow is unable to support coarser sediment, which settles to the bed. (D) Laminar plug flow with high cohesive strength is able to support coarser sediment suspended within the flow. Reproduced from Baas JH and Best JL (2002) Turbulence modulation in clay rich sediment laden flows and some implications for sediment deposition. *Journal of Sedimentary Research* 72: 336 340. SEPM (Society for Sedimentary Geology).

of sediment requires turbulence within the flow, but a feedback is exerted where at some point the turbulence begins to be modified by the sediment in suspension. This complex feedback mechanism is poorly understood, with factors such as the concentration of sediment and ratios of grainsize: turbulent length and time scales thought to be important in causing either a decrease or increase in turbulence (turbulence attenuation and enhancement respectively) within the flow (Figure 12). Turbulence modulation is thus a key feedback mechanism within many unidirectional flows, acting to both enhance and suppress turbulence production, and is also known to change the downstream velocity profiles significantly with subsequent implications for sediment transport and sorting (Figure 13).

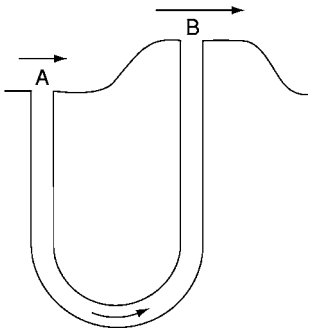

Figure 14 Flow acceleration above the raised limb of a burrow creates a lower pressure at B than at A, inducing flow within the tube (after Vogel S (1994) *Life in Moving Fluids*. Chichester: Princeton University Press).

The Porosity of the Bed Surface

Many studies of unidirectional flows have assumed that the bed is impermeable and that the subsurface flows exert little influence on the overlying boundary layer. However, this assumption is invalid, and the flow within porous beds, which comprise the surface of most sedimentary environments, can significantly alter the nature of the overlying boundary layer. This is especially true in the presence of bed morphology, which may generate differential velocities and fluid pressures around the topography. Such flow is seen, for instance, out of relict burrows that have a raised rim (Figure 14), where flow through the burrow and towards the area of raised topography results from lower fluid pressure associated with increased velocities at this raised opening. However, flow within porous beds may also lead to modification of the near-bed velocity profiles, and it has been suggested that the presence of a porous bed can decrease near-bed velocities and cause the velocity profile to deviate from a logarithmic form, with turbulence penetrating the top part of the porous bed.

URBAN GEOLOGY

A W Hatheway, Rolla, MO and Big Arm, MT, USA

Introduction

Most of the world's population lives in relatively crowded conditions in urban areas, affording them immediate contact with all forms of sustenance. At the same time, these teeming populations require huge imports of potable water, treatment of sanitary wastes, and export of solid, special, and hazardous wastes, along with a degree of infrastructure that impinges on and relies heavily on the constraints represented by the geological setting. Four major geological themes govern the application of geology to human life in cities and urban centres. First, although an abundance of regional geological information is applicable to urban development and life, the integration of most of such data is not readily discernible by the majority of the regional population. Second, urban life is concentrated such that there is 'loading' of the geological environment under various types of 'footprints' of engineered structures. Third, as the trend of importance of urban life for people continues to expand, 'megacities' become the centrepiece of new form of urban geology. Last, the concentration of urban populations in coastal regions interfaces with growing concerns over sea-level rise and global climate changes.

Cities historically have grown and developed around geological core areas where geological conditions were favorable to defense or security of construction. Although the form of these settings may seem geographical in nature, it is the underlying geology that has created such conditions. The following geological situations and the cities with which they are associated exemplify this:

- Natural, hard-rock sheltered seaports (Plymouth, England; Hong Kong; San Francisco, California; New York City).
- Confluences of major rivers (Pittsburgh, Pennsylvania).
- Mouths of major navigable rivers (Alexandria, Egypt; New Orleans, Louisiana; Para, Brazil).
- Heads of navigation of major rivers (Minneapolis–St. Paul, Minnesota).
- Confluences of rivers and pre-railroad trails (Paris; Rome).
- Defensive positions, underpinned by bedrock (Seoul; Rome).
- Sea-lane confluences for early trade (Singapore; Capetown, South Africa; Boston, Massachusetts).
- Confluences of pre-railroad trails (Kansas City, Kansas; Santa Fe, New Mexico; Edmonton, Canada).
- Mouths of mountain passes (Salt Lake City, Utah; Denver, Colorado; Reno, Nevada; Missoula, Montana).

Geoscience is a major potential contributor to maintenance of the health and welfare of cities and their populations. Successful implementation requires planning parameters for growth and redevelopment of the built environment and assessments of least-impact and least-cost alignments (e.g., the constantly needed improvements for rapid transit to move people around and in and out of cities). Geoscience plays an important role in the location, development, and delivery of potable water supplies and in the effective disposal of wastewater effluents. Previously used land must be characterized with respect to toxic contamination and its remediation, and risk from death, injury, and property losses stemming from geological hazards must be mitigated. Geological science is critical to understanding the potential for flooding, earthquakes, volcanic eruptions, ground collapse, mass movements, and seismic sea waves in densely populated areas. In the twenty-first century, yet another application of geoscience is in the consideration of how certain geological conditions might serve to enhance acts of terrorism.

Geological Influences on Urban Development

Modern engineered works in the urban environment represent relatively large and high-magnitude impacts on the substrate on which they are built. Geological site characterization of regional earth materials is thus an absolute necessity before laying the foundation for any large engineered structure, for economic reasons (i.e., to reduce construction costs) as well as for successful structure operation and maintenance and for basic environmental acceptability (Figure 1). Most of the high-impact concerns for site characterization are devoted to a few simple themes. The physical nature of foundation earth materials (soil, weak rock, or rock) must be identified as being able to support engineered works without unacceptable structural deformation or outright collapse. Geological anomalies that might compromise the integrity of building components or entire engineered work must be detected and delimited. Furthermore, 'bad ground' that would require premium foundations or difficult construction efforts and higher building costs must be recognized and presented to planners (Figure 1).

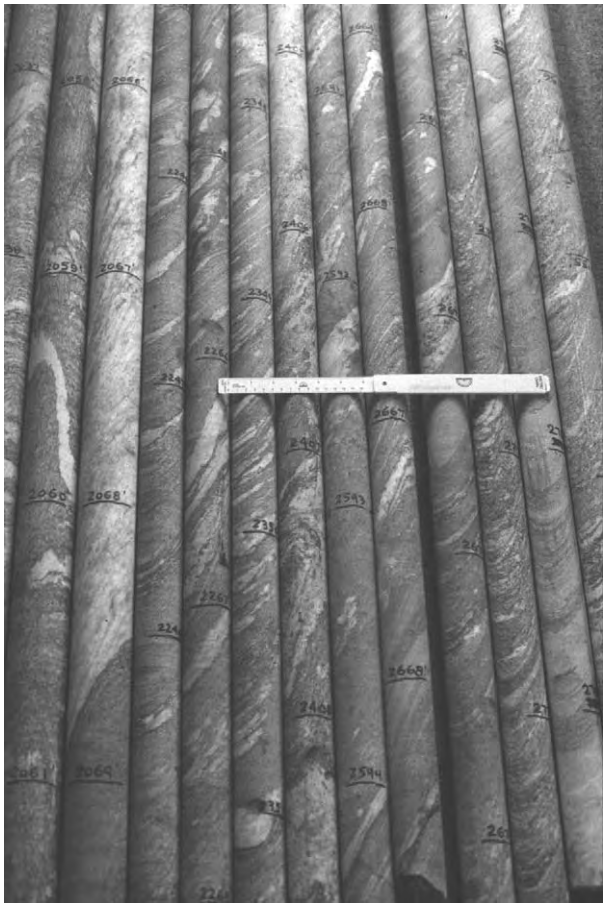

Figure 1 NX size (2.125 inches) rock core recovered by oriented, triple tube coring technique from more than 650 m below Kennedy International Airport, Long Island, New York City, at the site of a proposed liquefied natural gas storage cavern planned by the Brooklyn Union Gas Company (now Key Span Energy Co., Inc.). The rock is complexly mixed Fordham Gneiss and Manhattan Schist and these are select segments of 3 m lengths, all unbroken by natural discontinuities. The photograph shows the generally excellent foundation and deep cavern characteristics of New York City bedrock. Ruled portion of scale is 15 cm in length; depth marks on core are in metres. Photograph by the author.

Cities of The World Literature Series

For more than 20 years, the Association of Engineering Geologists (AEG) has fostered the incorporation of geoscience within urban development by publishing an international series of papers (*Cities of The World*) dedicated to the memory of the outstanding efforts of the late Canadian geological engineer, Robert F Legget (1904–94). The quarterly journal of the AEG (now a joint effort with The Geological Society of America), *Environmental and Engineering Geology*, seeks and publishes detailed accounts of urban geology, utilizing a standard format (Table 1; see also www.aegweb.org) that serves as a codification of the important elements of urban geology.

Problematic Conditions of Urban Construction

Construction in the built environment has to address a variety of geological 'constraints' that may be hidden from view during general observation of the existing ground surface. Without accurate geological information at the planning and design stages, new construction and urban renewal efforts will almost certainly encounter cost overruns, regulatory compliance infractions, and some type of construction failure. Three primary geological considerations (soil, groundwater, and geological dicontinuities) are integral to avoiding such difficulties. The nature and thickness of soil units that will bear the dead and live loads transferred downward from the intended construction must be established. Likewise, the presence, depth, and potential fluctuation of the groundwater surface below the intended engineered works must be evaluated and related to needs for dewatering without detriment to stability of existing nearby engineered works. The soil and groundwater profiles may pose potential excavation problems when deep basements are required to accommodate vehicle parking. The presence of and adverse geometrical orientation of geological discontinuities (bedding, joints, shear zones, and faults, to name a few) may

affect the stability of basement excavations and the integrity of surrounding buildings and other structures. These aspects of engineering geology require the geological team to interface with urban historians, archaeologists, architects, urban planners, insurers, financiers, and others related to the design and construction processes (Tables 2 and 3).

Role of the Engineering Geologist

Geological information is critical to the siting, design, and construction of all engineered works. This is particularly important in the urban environment, where all physical aspects of construction are compounded in their effects by mandates in scheduling

Table 2 Geotechnical influences on urban construction

Geotechnical influence	*Emphasis*	*Key considerations*
Site geological knowledge reduces the risk of unknown ground conditions	Unknown, undetected, or undisclosed geological conditions can compromise scheduling, cost, and operational performance of engineered works	Capacity of foundation soils to support loads of the structure; stability of surrounding facilities; excessively 'weak' or 'strong' ground exacerbates the construction effort
Some earth materials have undesirable properties or characteristics	Avoidance of constraints or slowdowns to construction process	Detection in the site exploration process, notification of owner and design engineer; incorporation into the design and construction specifications
'Faces' across which geologic character of construction ground changes	When not anticipated by the contractor, can cause unwanted perturbations in schedule and in project cost; where spanned by one 'bay' (segment) of construction, may lead to unacceptable differential settlement of portions of the foundation	Avoidance requires adequate site characterization, funding by the owner, and judicious selection of geological and geotechnical support consultants
Pockets or zones of 'bad' ground	Three dimensional bodies of degraded earth material not able to support design, construction, or operational efforts or roles of project	Generally related to geomorphic or tectonic considerations of origin and may have characteristics detrimental to construction or of performance of the facility
Near surface groundwater	Always a problem	Generally interferes with construction, particularly in placing the foundation; may require dewatering, which may affect performance of surrounding existing foundations
Perched water or groundwater is generally detrimental to the construction process	Control and removal without impairment of construction or with performance of completed facility	When truly 'perched', drains into the construction excavation within hours and does not replenish
Nature of site preparation or construction 'spoil' (soil) or 'muck' (tunnel spoil)	Must be removed from the construction site and reused in some worthwhile manner acceptable to the community	Spoil and muck have geotechnical characteristics that must be heeded in considering their reuse

Table 3 Engineering geological contribution to urban geology

Contribution	*Purpose*	*Important considerations*
Stratigraphy	Define the nature and bounds of soil types and of geological formational units	Controls the suitability and relative cost of siting and dimensional design of virtually all projects
Engineering properties of the foundation soil or rock	Must be capable of bearing the combined live and dead loads of the engineered works to be constructed	Acceptability measured in terms of nil compressibility and sufficiently high shear strength to support the loads of the project
Geological structure of bedrock exposed in construction	Locate and define fault displaced geological units and discontinuities that are of sufficient length of exposure to cross any one dimension of site excavation	Avoidance of adverse geological structures, premium foundation conditions, and expensive or 'bad' ground in terms of underground construction
Occurrence of groundwater	Protection from damage by human activities; avoidance of premium costs for foundations	In no way can groundwater be of beneficial consequence to the construction process
Surface water hydrology	Using geological evidence to define the nature of flooding as an economic and human welfare concern	Mainly involves interpretation of present geomorphic features that control the path, depth, and velocity of low frequency/high impact flood events
Avoidance of surrounding unstable ground	Protect from what may slip onto the site or move down slope from the site	Mainly ground that is unstable under gravitational and slope water conditions, along with rock falls
Avoidance of existing subsurface voids	Avoid presence of abandoned tunnels, mine shafts, mines in general, and natural voids such as karst caverns	All subsurface voids suffer from decreasing 'stand up' time, which is the ability to span loads imposed at the ground surface, and from the surrounding overburden weight of the geological column of materials

Table 4 Problems of urban construction: naturally troublesome geological conditions

Condition	*Impact*	*Geological considerations*
Soft and/or otherwise compressible soils	When detected will lead to engineering selection of medium to deep foundations, in turn leading to premium foundation costs	Afflicted typically by clay mineral rich soils such as glacial, glaciomarine, and glaciolacustrine clay soils, as well as a variety of slack water fluvial clays, silts, and 'muds'; learning to expect the presence of such conditions is based on regional and local geological knowledge
Certain marine silts and clayey silts are geotechnically 'quick' (unstable) by virtue of collapse prone 'card house' structure brought about by flocculated structure under saline depositional conditions	Can become unstable and can collapse under dynamic shock of earthquakes and a variety of man made shocks such as pile driving, blasting, and dropping of large loads	Where bordering river and stream banks and other steep terrain; type formation is the Leda Clay of Quebec Province and the marine clay soils of Scandinavia where encountered on land
Clay ('mud') 'plugs' formed as still water deposits of truncated river meanders	Creates unacceptable differential settlement of foundations, roads, and bridge abutments and piers	Endemic geotechnical problem in the Lower Mississippi River Valley of the United States
Organic soil of all types (notably peat)	Causes foundation deformation of all manner of engineered structures with all but the lightest bearing loads	Tends to have irregular but often oval to elliptical bounding contacts in the lateral sense; two type occurrences for this problem are the Newport Beach Fountain Valley areas of the Los Angeles basin, especially at the Pacific Ocean mouth of the ancestral Santa Ana River and the southern metropolitan area of Edmonton, Alberta, Canada
'Highs' in bedrock surface	Escalates costs of site preparation for construction	Sites must be 'brought to grade' as a preparation for installation of foundation; rock can cost ten times or more to remove, compared to soils
Buried zones of degraded bedrock	Increased costs of tunnels for water supply, sewerage, and rapid transit	Often the most difficult to anticipate; some are due to fault movement and displacement, others are due to geochemical cation exchange by water
Buried valleys	Channels of unconsolidated, porous earth material ('soils'), with preferential movement of groundwater	May place earth materials of vastly different engineering properties in the line of linear projects such as roads and tunnels, representing unanticipated design/construction conditions
Near surface groundwater	Calls for dewatering of basement excavations	Avoidance of disturbance of adjacent foundations and alteration of static ground surface, the latter leading to rot in older driven timber piles
Dumps of organic debris	Excessive settlement of foundations of successor buildings	Early residents routinely filled all topographic declivities with refuse, most of which is vertically compressible with time
Dumps of industrial (hazardous) wastes	Threats to health, construction workers, nearby residents, and occupants of the new facility	Mainly from low level, chronic emissions of toxic vapors from semivolatile and volatile organic compounds
Floodplain development	Unwise development of land subject to poorly predictable low frequency flooding	Geomorphic evidence of past flooding often crucial in defining the need for zoning against development
Proximity to seismically active faults and fault zones	The major seismotectonic zones are now well known throughout most of the world	Avoidance of high density human occupancy along known, 'active' fault traces and in areas of 'bad ground' subject to loss of foundation stability in large magnitude earthquakes
Proximity to major volcanoes	Ashfalls and lahars (volcanically induced mudflows)	In mild and humid climates, geochemical weathering rapidly produces volcanic soil, which attracts people because of cultivation advantages; geological evidence can predict rough levels of risk by time and location, for future exposure

and in costs of construction. The process by which geological input is discovered and provided to permitting officials, planners, owners, designers, and construction contractors is termed 'site characterization', and this task must include the discovery and description of man-made wastes (perhaps of archaeological/historical importance) left from previous site occupation. Site characterization as a concept generally arose in about 1900, but has taken on the particular meaning described here only since about 1980. It is a well-accepted practice in the field of engineered construction and environmental permitting.

Engineering geologists are generally tasked with planning and conducting site and waste characterizations, and the most important aspects related to the effort are experience, training, and professional competence of the geologist and the provision of adequate exploration funding by the builder/owner. In this respect, there has been a truly unfortunate trend towards unwarranted price-driven selection ('bid-shopping', or commoditization) of site-characterization consultants, by owners and some engineers, worldwide, since about 1980. Suffice it to say that the geologist who will perform the site characterization should be selected on the basis of qualifications and experience, rather than on the cost (budget) accorded to the effort.

Engineering Geological Site Characterization

Each construction site needs to be characterized for its geological, hydrological, and waste conditions, so that architects and design engineers have the necessary parameters when considering feasibility and design. In some cases, when geological constraints (the preferred term for 'geological hazards') are identified, the proposed construction may be shifted to a geologically 'less expensive' site in terms of building costs, operation, and maintenance of the proposed works. More often, however, for a variety of reasons, the owner of the planned construction, public or private, is committed to the site and the geological knowledge becomes essential to the success of the project.

Engineering geologists generally begin site work with a walkover of the site, attempting to 'peer' below the ground surface to generate a working hypothesis and conceptual geological model of what is likely present and what may be hidden. The ultimate goal is to assess how geotechnical factors could impact the construction or performance of the engineered works. Tables 4 and 5 provide a summary of geological conditions that might be expected to impact project feasibility, design, and construction processes

Table 5 Problems of urban construction: societal pressures causing geological impacts

Condition	*Impact*	*Geological considerations*
Cities require off street vehicle parking for a significant percentage of building occupants and visitors	Above ground space is too valuable for parking vehicles, hence deep basements are required	Hardrock excavation costs are extreme; bedded sedimentary and jointed or foliated crystalline rock present slope stability problems for the basement excavation during construction; stability of adjacent buildings is a constant concern
Water must be supplied to the city	Need for conveyance projects and tunnels; importation of the water for the distribution system	Linear projects such as pipelines, aqueducts, highways, and railroads are particularly susceptible to earthquake ground motion
Transportation routes must not interfere with much of the existing ground surface infrastructure	Reliance on tunnelling to achieve minimal grades between stations and minimal depth below ground for people movement	Places geological information at a premium for design and construction of stations; keeps transit tunnel alignment in sound rock, free of major ground support considerations
Abandoned waste dumps of all types	Organic debris will naturally compress as much as 300% vertically (becoming as little as one third of its preconstruction thickness, hence causing considerable settlement)	Use archival records, old topographic maps, historic aerial photographs, and confirming geophysical traverses
Previous quarrying, mining, and other mineral extraction activity	Many cities once relied on extraction of coal, building stone, gypsum, clay mineral, or mineral ore, leaving unstable ground	Present day hazards include rotting support timber, collapse prone workings, and movement of contaminated groundwater in workings
Excessive abstraction of groundwater	Causes rotting of historic timber foundation piles; these may also rise on termination of water abstraction	Saline intrusion in coastal areas, activation of non seismic 'growth' faults in post Cretaceous coastal embayments

Figure 2 An example of a zone of 'bad ground' discovered and delimited in an engineering geological site characterization ex ploration. This zone represents poor engineering properties of foundation materials in terms of their ability to support structural loads that would be imposed by engineered works. Shown is a shear zone of ancient tectonic origin, as it perpendicularly enters the foundation excavation for the Lahey Medical Clinic, urban Boston, Massachusetts. Such features are important when they are planar to and cross one or more dimension of the foundation excavation, because they have the potential to induce instability of the surrounding ground and existing buildings. Timbers are 200 mm^2 in section; survey tape in midview. Photograph by the author.

and therefore must be incorporated into the site engineering geological characterization process.

Geological conditions decidedly influence geotechnical design measures to transfer dead and live loads of proposed structures into the foundation soil or rock (Figure 2). Transfer of load to geological horizons is integral to ensuring adequate structural support for engineered works. During the site characterization process, appropriate site exploration techniques must be incorporated to determine the engineering geological conditions likely to adversely impact the project.

Summary

The struggle to provide decent living conditions for humanity on earth is characterized to greatest degree by the interwoven impact of geology on the human habitat and the impact of humans on geologic conditions that serve to support that life. Cities are the focus of human activity and this activity takes place on and in the ground, which is itself only a complex of geologic conditions. Of all of the qualities of human life in the cities is its dynamism, all of which tends to obscure and often obliterate the delicate evidence of the nature of geologic conditions supporting the city. For this reason, we must turn to urban geologic observations and recording in order to compile a sequence of snap-shot views and vignettes of urban geology. When recorded, this information is invaluable in the continual struggle to accommodate the great demands.

VENUS

See **SOLAR SYSTEM: Venus**

VOLCANOES

G J H McCall, Cirencester, Gloucester, UK

Introduction

Volcanoes are a major component of the Earth's present surface geology, both active and extinct; volcanic processes can be recognized throughout geological history and are important in generating certain types of mineral deposits (e.g., metallic sulphides, sulphur). They are studied in their relationship to both mantle (*see* **Earth:** Mantle) and crustal (*see* **Earth:** Crust) processes of igneous rock generation and plate tectonics. Volcanic eruptions comprise one of the most important of natural hazards (*see* **Engineering Geology:** Natural and Anthropogenic Geohazards) threatening populations living close to them. Volcanoes have been recognized on other bodies of the solar system – Venus (*see* **Solar System:** Venus), Mars (*see* **Solar System:** Mars) and Jupiter's satellite Io (*see* **Solar System:** Jupiter, Saturn and Their Moons) – the latter is the most volcanically active body in the solar system. Mars has the largest single volcano, Olympus Mons (440 km diameter; 24 km altitude). Venus, which we can only study from radar images on account of its dense volcanogenic CO_2-rich atmosphere, appears like Mars, to have no active volcanoes now, though there are many inactive ones.

Volcanoes and the Mantle

Liquid rock, poured out from volcanoes as lava (*see* **Lava**), makes up only a small portion of the planet, though a large part of the core is molten metal. The outer layer of the Earth, the lithosphere, is relatively cool, but the mantle below is so hot that rocks lose their cohesion. Indirect evidence obtained from seismology suggests that they move very slowly; and the theory of plate tectonics requires such movements to take the form of convection currents and localized upwellings (hot spots, mantle plumes) (*see* **Mantle Plumes and Hot Spots**). However, there is no agreement among geoscientists as to the depth of the lower boundary of these circulations. The hot, soft, solid material of the mantle, of peridotite and related compositions, only partially liquifies when the temperature exceeds the melting point of minerals in the rock. Because it is lighter than the solid rock above it, it will rise towards the surface, entering the lithosphere. It may pass through the crust directly and swiftly appear at the surface as a volcano, or it may be halted and form a large concentration of molten rock down in the crust, a magma chamber: from this it may later burst out to the surface as a residue, changed after some crystallization in the magma chamber. In narrow conduits to the surface, it may cool and crystallize, forming wall-like intrusions (dykes) or sheet-like intrusions (sills). Intrusive rocks formed by crystallization of the magma in the magma chamber, dykes, and sills, form the underworks of volcanoes, and may be all that is left after erosion: they frequently comprise ring complexes as on the Isle of Rum in Scotland. A quirk of erosion has left these underworks exposed, surrounded by Precambrian granite, in a hollow central to the remains of the lava and tuff pile in the 100-km wide Miocene Kisingiri volcano in western Kenya – Howel Williams called this the best preservation yet seen of a volcano complete with its upper- and under-works.

Distribution of Volcanoes

Volcanoes do not occur everywhere on the Earth's surface. The global distribution shown in **Figure 1** reflects the present distribution of more than a dozen tectonic plates, rigid plates of the lithosphere, which move laterally across the Earth's surface at minute velocities in the order of centimetres per year. Of course, they cannot do this indefinitely without colliding with each other and this pattern is controlled by upwelling of magma on the lines of separation (the mid-ocean ridges) and either the diving down of the spreading oceanic plate under the one it spreads against (subduction) or, where continental parts of plates meet, collisions such as formed the Himalayas. In subduction there is both

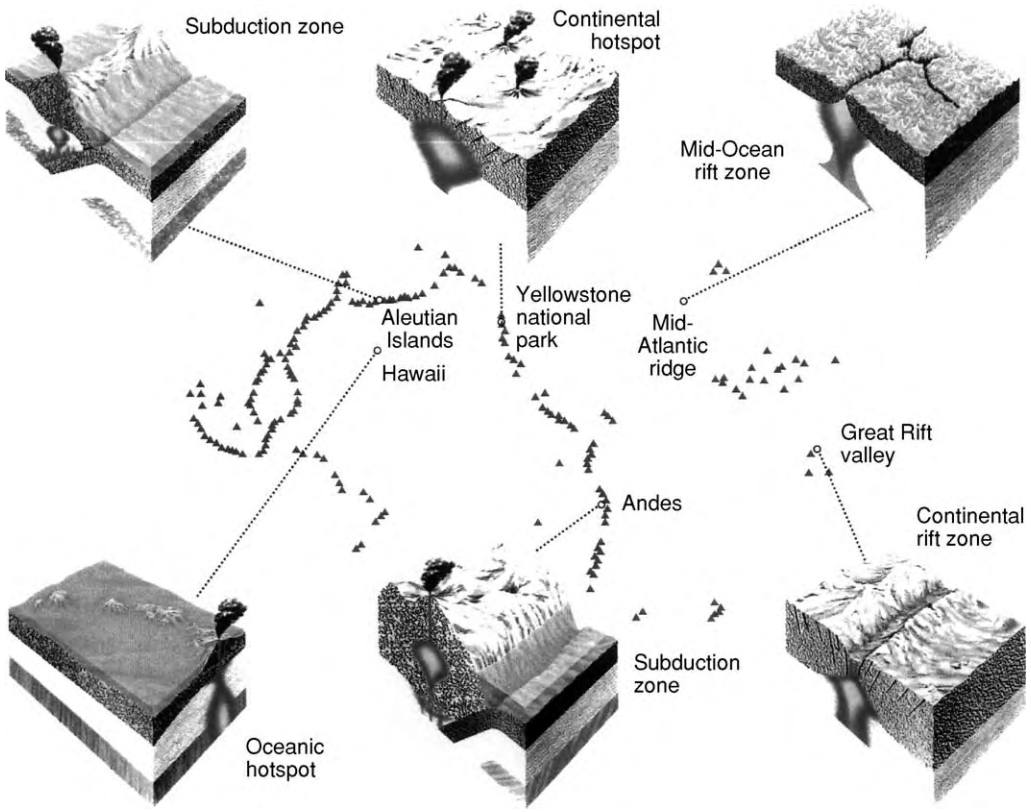

Figure 1 The global distribution of volcanoes and their geotectonic setting (after Scarth (1997)).

upwelling of magma from the mantle and melting in the lithosphere, after the descending oceanic plate has penetrated to some depth, and volcanic arcs are so formed, not at the surface boundary between the plates (the oceanic trench), but at some distance beyond it within the overriding plate.

As shown in Figure 1, most of the existing volcanoes of the Earth are concentrated in the arc zones; the ridge zones of upwelling produce much eruption deep under the oceans, but few subaerial volcanic piles occur on them: exceptions being the volcanoes on Iceland and Tristan da Cunha. Some volcanoes occur in the oceans unrelated to either type of plate tectonic zone, but are attributed to hot spots or plumes in the mantle: the Hawaiian Islands and the Galapagos are examples of these. Seamounts are stumps of such volcanoes. There are also volcanoes in rift zones within continents, for example Lengai, Tanzania, in the eastern rift and the volcanoes of the western rift (e.g., Nyiragongo), but such rift valleys are really aborted oceanic ridges, where the updoming and eruption has occurred, but the two flanks never spread and diverged away from the rift.

Classification of Volcanoes

There are two types of eruption:

Fissure Eruption

Concentrated in long, narrow fissures, the lava generally spreads to form extensive lava plateaus. If the eruption is explosive, plateaus of ash flows may form. Most fissure eruptions are, however, associated with fluid basalt lavas, which have given rise to the terms flood basalts and plateau basalts, but phonolites in Kenya also form extensive lava plateaus. Such eruptions have not been common in historical times, though the Laki fissure eruption in 1783 was of this type: however, extensive plateaus hundreds of kilometres wide of superimposed, quite thin fluid flows were formed in the geological past (e.g., the Deccan Plateau in India).

Central Eruption

Volcanic activity is more commonly concentrated in a central vent and gives rise to volcanic cones or, in the case of some viscous lavas, domes or necks with no summit crater. Single volcanoes, clusters, or chains are formed in this way. The chains may be associated with belts of extreme seismic disturbance (e.g., the Aleutian islands, Chile). Central volcanoes may have satellite cones superimposed on them: these are said to be nested (Figure 2) if they occur within the crater, parasitic or adventive if they occur on the outer slopes.

Central volcanoes of substantial dimensions may develop large circular cavities, calderas, focused on their summits: these may be circular, or of rather irregular annular shape; they may even be multiple, one inside or superimposed on the other. The Suswa caldera in Kenya is annular, a central plateau being preserved. Calderas may be formed either by subsidence, due to withdrawal of magma/lava support, or volcanic explosion. Calderas are evident on Mars and Io.

There are three types of central volcanic pile, all of which may develop calderas:

i. shield volcanoes: all lava flows
ii. ash cones: all pyroclastic
iii. composite or strato-volocanoes: alternating lava and pyroclastic (Figure 3).

The material that flows out as lava is termed effusive. Extrusive includes both lavas and pyroclastic rocks.

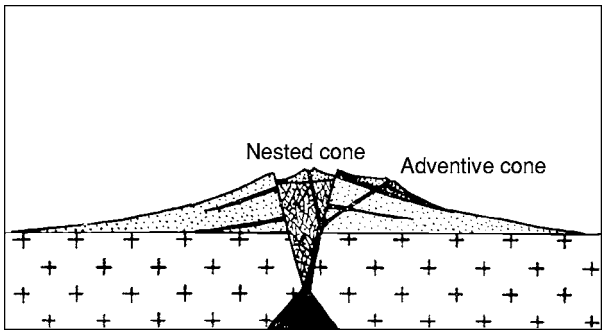

Figure 2 Diagram of a composite volcano: lava (black) and tephra (stippled) interbedded (from Green and Short (1971)).

There are seven types of volcano, classified according to the nature of the eruption. Four of the names stem from southern Italy, a field of classical study which can be termed the 'Birthplace of Vulcanology'; and which has lately been described by Guest *et al*. in modern terms. Iceland, Hawaii, and Martinique supply the remaining names. The list is given in Table 1.

This scheme is a very useful subdivision, but most volcanoes show some departure from these classical definitions derived from a handful of famous volcanoes. No other volcano, for example, matches Stromboli, where explosions occur every 10 minutes and activity has been continuous for 2500 years. Other types can be long dormant, Mt Pelée in Martinique, lay dormant for centuries, only, in 1902, to send off sudden blasts lasting a few minutes separated by weeks of relative inactivity while the plug in the vent built up into a spine (Figure 5).

A very useful table of explosivity of volcanoes was published in 1982 (Table 2):

Products of Volcanoes

Lavas

Magma erupted from volcanoes as lava consists of molten rock, crystals, and gas – carried as bubbles, mainly water, and carbon dioxide. The less siliceous lavas such as basalt flow freely and build up extensive shield volcanoes as in Hawaii. Other lava types may flow freely – a phonolite flow forming the Yatta Plateau in Kenya followed a valley for >300 km from its source. Less fluid flows such as trachyte

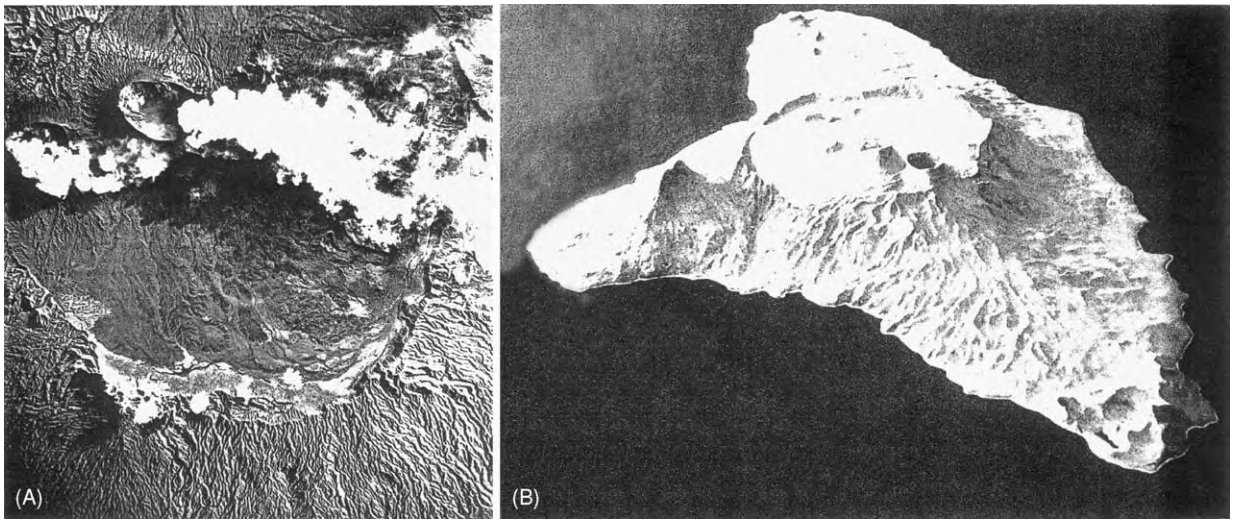

Figure 3 The 13 km diameter basaltic Ambrym volcano, Vanuatu. (A) Plaster model (by Jon Stephenson) (B) Air photo showing the caldera with two active craters nested within (Benbow and Marum).

Table 1 The seven types of volcano

Type	*Characteristics*
Icelandic	Fissure eruptions, releasing free flowing basaltic magma; quiet, gas poor; great volumes of lava flowing as sheets over large areas to build up plateaus
Hawaiian	Fissure, caldera, and pit crater eruptions: mobile lavas with some gas; quiet to moderately active eruptions: occasional rapid emissions of gas charged lava produce fire fountains; mainly basaltic; minor amounts of ash; builds up lava domes
Strombolian	Stratocones (composite) with summit craters: moderate, rhythmic to nearly continuous explosions, resulting from spasmodic gas escape; clots of lava ejected producing bombs and scoria; periodic more intense activity with lava outpourings; light coloured clouds, mostly steam reach only to moderate heights
Vulcanian	Stratocones: central vents; associated lavas more viscous; lavas crust over vent between eruptions, allowing gas buildup below surface; eruptions increase over long period of quiet until crust is broken up, clearing vent and ejecting bombs, pumice, and ash; lava flows from the top of flank after main explosive eruption; dark ash laden clouds, convoluted and cauliflower shaped, rise more or less vertically to moderate heights, depositing ash along the flanks of the volcano (note: other types, such as Hawaiin can produce similar effects when they suffer interference with groundwater, and phreatic eruption ensues, large steam clouds carrying fragmental material)
Vesuvian	More paroxysmal than the above two: extremely violent expulsion of gas charged magma from stratocone vent; eruption occurs after long interval of quiescence or mild activity: vent tends to be emptied to considerable depth: lava ejects in explosive spray (glow above vent), with repeated clouds (cauliflower) that reach great heights and deposit ash
Plinian	More violent form of Vesuvian eruption (**Figure 4**): last major phase is uprush of gas that carries cloud vertically upward in a column for kilometres; narrow at base but expands outwards at upper elevations; cloud generally low in ash
Peléan	Results from high viscosity lava and delayed explosiveness, conduit of stratovolcano being usually blocked by dome or plug (**Figure 5**); gas (+ some lava) escaped from lateral (flank) openings or by destruction/uplift of plug; gas, ash, and blocks move with high velocity downslope in one or more blasts as nuees ardentes or glowing avalanches, producing directed deposits

After Guest *et al.* (2003).

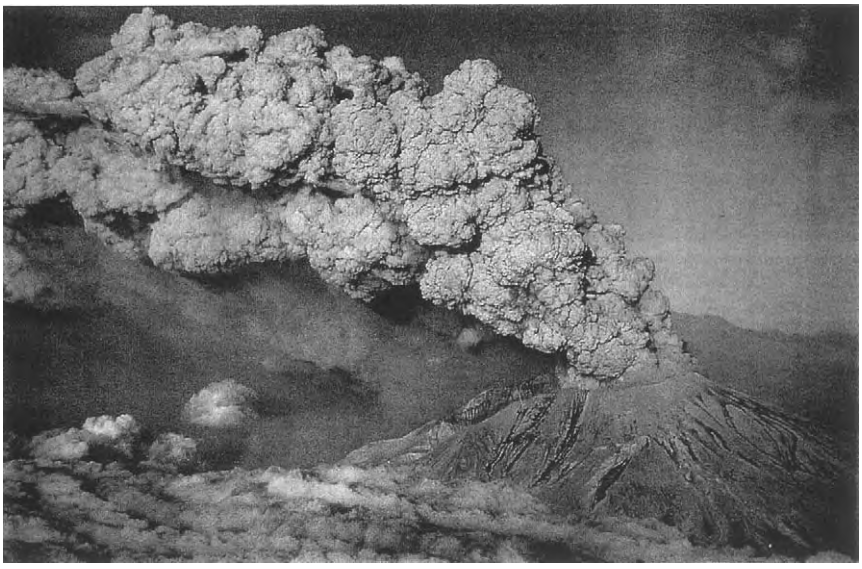

Figure 4 Plinian eruption of Mt St Helens, Oregon: ash, gas, and pulverized rock shooting out directionally (second eruption, July 1980) (from Pyle, 1998).

may terminate close to the vent (Figure 6). Even more siliceous lavas, such as rhyolite (equivalent in composition to granite), are sticky and form heaps close to the vent, or block the vent as plugs which may slowly extrude as spines. Lavas of this type are very dangerous as the plug finally breaks and there is a sudden explosive outburst which cannot be predicted. Both basalts and rhyolites tend to break up as they crust over, yielding slaggy flows. The solidified crust may be arrested and the molten lava flow underneath

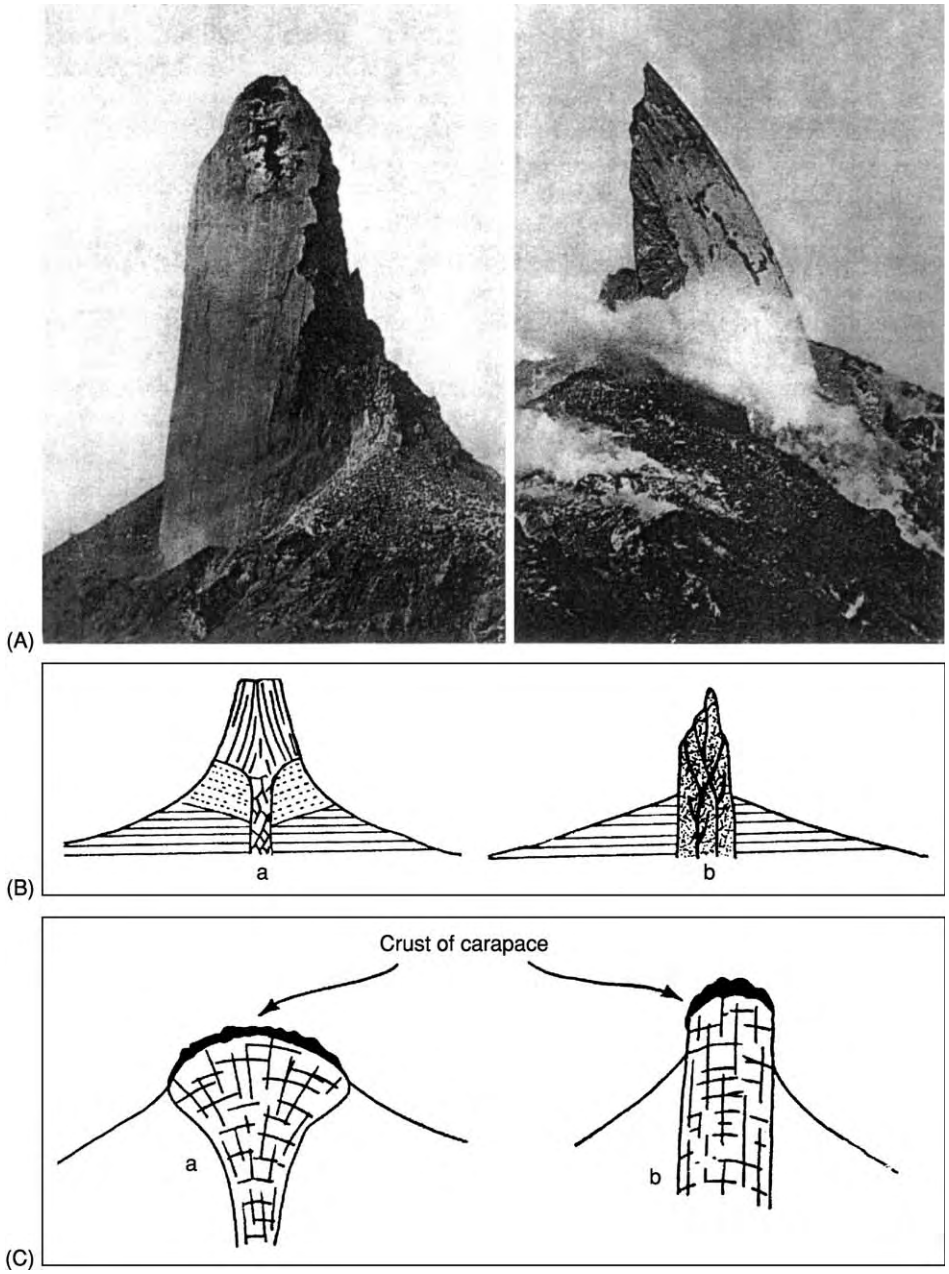

Figure 5 Mt Pelée, Martinique, (A) Two views of the rhyolite spine that plugged the vent prior to the catastrophe in 1902. (B) Types of lava domes: with spreading and no spreading. (C) Volcanic necks left behind by the above (from Green and Short (1971)).

it in a lava tube. There are four types of flow distinguished: pahoehoe (ropey), a'a' (slaggy); block lava; and pillow lavas (Figure 7). The latter form when the lava flows into water: sack-like glass covered bodies form, with concentric zones of vesicles or varioles (gas concentrations): they fissure radially and tend to break up easily, forming angular hyaloclastite breccias, containing pillow fragments. Fine fragmental glassy material formed in water or by deposition on wet surfaces is called peperite.

Some volcanoes erupt quite unusual peralkaline lavas; the Miocene 60 km diameter Kisingiri volcano in the Kavirondo Rift Valley, Kenya, erupted nephelinite and melilitite lavas; the magma chamber rocks below are nephelinitic ijolites and melilitic uncomprahgrites and turjaites, and the throat of the eroded volcano is a huge plug of carbonatite. Carbonatite has, in the past, been erupted as lavas from volcanoes elsewhere, but the only active emission known is of thin fluid flows of natrocarbonatite in

Table 2 Volcanic explosivity index

	Non explosive	*Small*	*Moderate*	*Moderate large*	*Large*	*Very large*			
General description	*0*	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*

From Newhall and Self (1992).

the crater of Lengai volcano, Tanzania. The volcanoes Nyamuragira and Nyiragongo in the Western Rift Valley near Lake Kivu erupt potassic lavas rich in leucite.

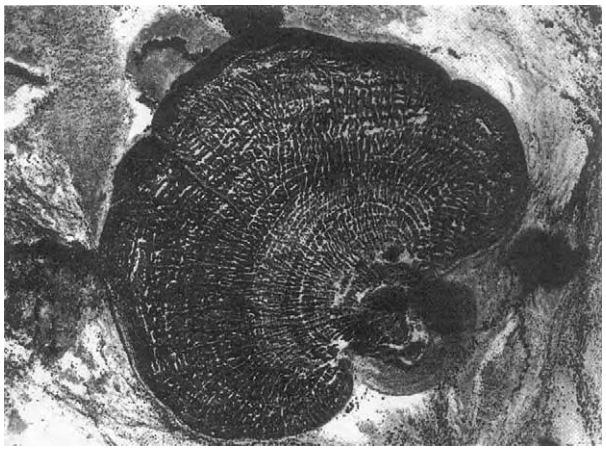

Figure 6 Trachyte flow extending only a few metres from the source vent in an ash cone (Silali volcano, Kenya) (from Green and Short (1971)).

Tephra

All clastic (fragmental) material issued from a volcano is covered by the term 'tephra'. It is classified by size, as in Table 3:

Phreatic Eruptions

Interaction of rising magma and groundwater produces explosive eruptions, commonly with little material emission. Shallow depressions called 'maars' are formed this way and the extreme case is the crater with no material eruptive association except fragmented country rock (e.g., Hole-in-the-Ground, Oregon, Figure 9).

Volcanic Clouds

These may be of steam or ash rising to many kilometres and moving with the wind (Figure 10): the cloud from Stromboli is often carried as far as Greece. Ash clouds may be incandescent. An acid-bearing ash cloud from Klyuchevskaya, Kamchatka, rose to 20 000 m in 1994 and was carried 1000 km to the east by 240 km per hour winds, interfering with air travel.

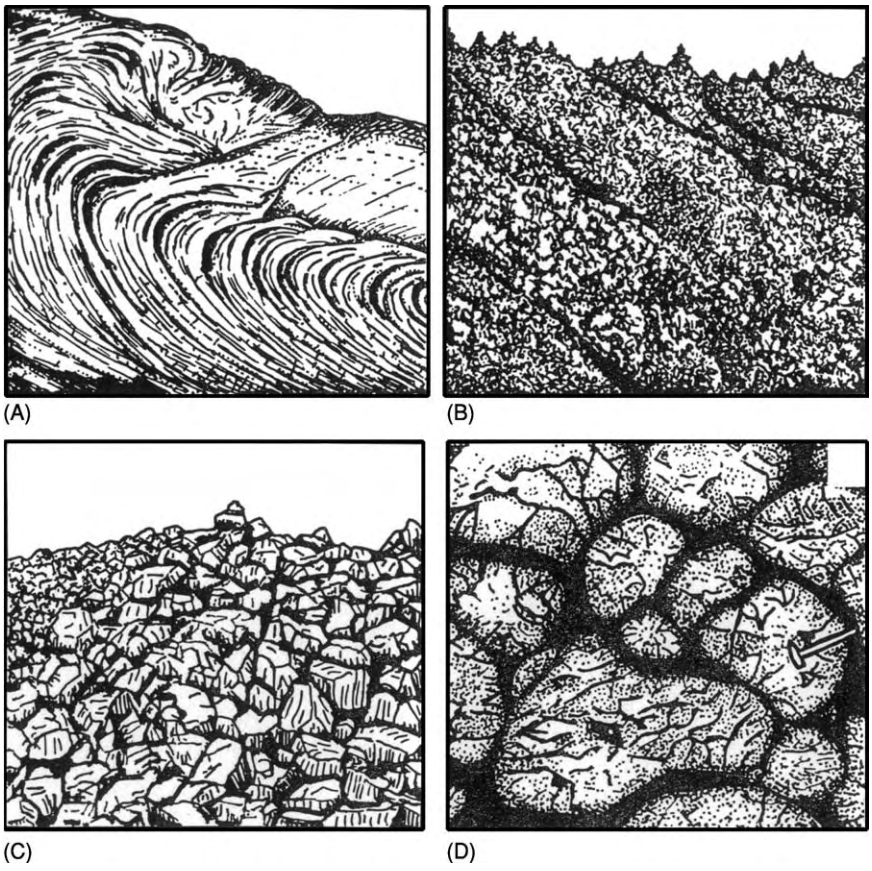

Figure 7 Four types of lava: (A) Pahoehoe; (B) A'a'; (C) Block lava; (D) Pillow lava (from Green and Short (1971)).

Table 3 Tephrà classified by size

Name	*Size range*	*Remarks*
Dust	Less than 0.25 mm diameter	
Ash or sand	0.25 4 mm diameter	When lithified, the finer material is referred to as 'tuff' (**Figure 8**). The terms 'crystal' or 'lithic' are added according to the dominant component. Also the word 'pumice' may be added if pumice is dominant
Lapilli	0 32 mm diameter	
Bombs or blocks	More than 32 mm diameter	When lithified, these coarse deposits are referred to as 'agglomerates' or 'volcanic breccias'. The word 'scoria' is used for clasts with numerous open gas cavities, appearing like a sponge.
Bentonites		Bentonites are montmorillonitic clayey rocks formed by devitrification of volcanic glasses: palagonite is a yellow isotropic material formed by alteration of basaltic glass shards or hydration of them when hot

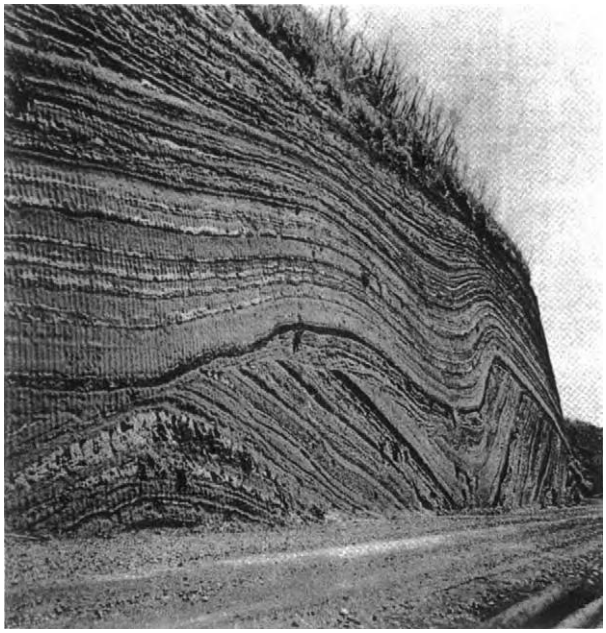

Figure 8 Bedded basaltic tuff of Pleistocene age, O Shima volcano, Japan (from Green and Short (1971)).

Nuées Ardentes

These are glowing avalanches of unsorted tephra or incandscent ash flows. They are characteristic of volcanoes erupting siliceous magma (rhyolite or andesite), and occur when plugs rupture or a sector of the volcanic cone collapses. Another cause is loss of support from below of a lava column. The eruption of Vesuvius in AD 79 killed many by asphyxiation (**Figure 11**).

Lahars

These are volcanic debris flows and may be hot or cold. They may arise from interaction of hot pyroclastic flows and surges with ice and snow covering the volcanic cone summit, as at Nevado del Ruiz, Colombia, in 1985 (**Figure 12**); in this case the duration of the horrific event was small, but in the case of Pinatubo, Philippines, in 1993, pyroclastic flows continued to be reworked by heavy rains, forming lahars which continued for years.

Gases

Volcanic gases are commonly dominate by CO_2, which asphyxiates: such gases are invisible and concentrate in depressions in the land, as in Iceland: these concentrations are called 'mofettes': The Lake Nyos disaster in Cameroon was due to a sudden outburst of these gases from under the lake.

Volcanoes as a Major Natural Hazard

Volcanoes are distributed along plate boundaries and along rifts and fractures within plates, and they are thus fixed features. The hazards they pose are easier to predict and restrict geographically than those of earthquakes, but they pose a great hazard–particularly because the volcanic rocks form rich soils for agriculture and thus populations concentrate around them. Not only active volcanoes pose hazards: in 1943, Paricutin, Mexico, originated as a fissure opened up in a ploughed field and built up to a 2400 m high cone, from which 'a'a' lavas flowed down and buried buildings. Mt Pelée in Martinique was supposed, in 1902, be extinct and a nuée ardentes killed all but one of its 29 000 inhabitants (a prisoner in a gaol).

The toll on human life is an order less than from earthquakes. Since 1980 there have, however, been more than 30 000 deaths and some 1 million people have been detrimentally affected by eruptions.

In **Table 4**, some selected volcanic disasters, since the eighteenth century, are listed. Fatalities are not a

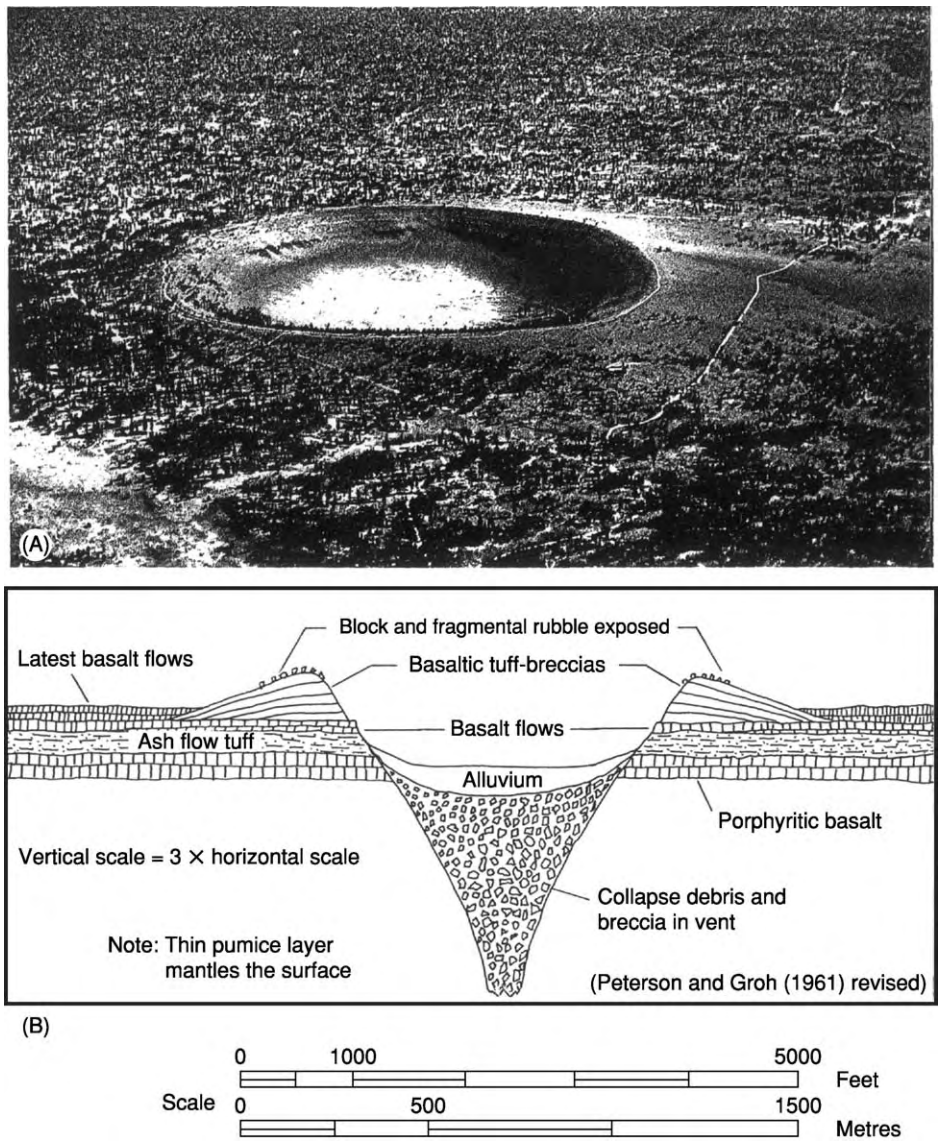

Figure 9 Hole in the Ground, Oregon, a 1.6 km diameter Maar (from Green and Short (1971)).

satisfactory measure of disaster – for example, the 1997 collapse of the old crater wall surrounding the dome complex of Soufriere, Montserrat, cause only 19 fatalities, but the ongoing eruptions over several years caused the capital of the small island and more than half of the island's population to be evacuated indefinitely.

The principal volcanic hazards and effects are listed below:

Hazards

- Lava flows
- Ash falls
- Pyroclastic flows and surges
- Directed blasts and atmospheric shock waves
- Lahars and floods
- Landslides
- Volcanic gases
- Tsunamis
- Climate modification
- Crater lake emptying suddenly
- Ice/snow lava interaction

Effects

- Loss of land and buildings
- Disruption of social and economic infrastructure
- Famine
- Water pollution

- Disease
- Drowning
- Asphyxiation

Lava flows represent the principal hazard of basaltic volcanoes. On Etna, they stream down the flanks and threaten villages and coastal towns. The recent eruptions of Nyiragongo volcano above Goma in the Congo drove a lava flow through the middle of the town, destroying much property. They destroy buildings and usable land. Mitigation by diversion has been tried on Etna but is of limited success.

Pyroclastic flows may attain velocities of tens to hundreds of metres per second and temperatures of 300–800°C. They may generate secondary debris flows. Block and ash flows are slightly less deadly than pumice-rich ignimbrites. The worst of these flows and blasts destroy and kill everything in their path.

Debris avalanches, as at Mt St Helens in 1980 (Figure 4), travel rapidly and are equally lethal and destructive.

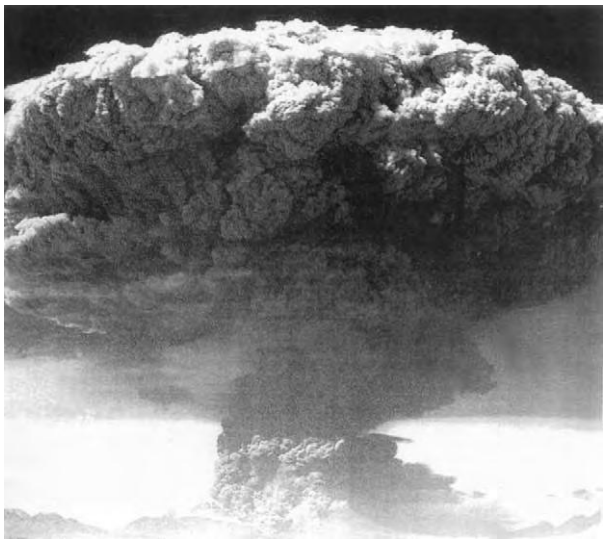

Figure 10 Ash cloud from a devastating eruption of Lascar volcano, Chile (from Pyle (1998)).

Table 4 Selected Volcanic disasters since the eighteenth century

Volcano (country)	*Year*	*Fatalities*	*Cause*
Laki, Iceland	1783	10 500	Famine
Unzen, Japan	1792	15 188	Tsunami
Tambora, Indonesia	1815	92 000	Mainly famine
Krakatau, Indonesia	1883	36 417	Tsunami
Mt Pelée, Martinique	1902	29 000	Pyroclastic flows
Kelut, Indonesia	1919	5110	Debris flows
Lamington, Papua New Guinea	1951	2940	Pyroclastic flows
El Chichon, Mexico	1982	1700	Pyroclastic flows
Nevado del Ruiz, Colombia	1985	25 000	Debris flows
Lake Nyos, Cameroon	1986	1746	Volcanic gases (CO_2) asphyxiation*
Pinatubo, Philippines	1991	500	Various
Soufriere, Montserrat	1997	19	Pyroclastic flows
Goma, Congo	2002	40	Lava flows

*This was not associated with a volcano: the gases came from a lake but were of volcanic origin.
After WJ Maguire.

Table 5 Volumes and non out distances for volcanic debris

Volcano	*Volume (km^3)*	*Run out (km)*
Nevado di Colima	22 33	120
Socompa	17	35
Volcan di Colima	6 12	43
Shasta	26	50
Popocatapetl	28	33
Chimborazo	8.1	35
Mawenzi	7.1	60
Galunggung	2.9	25
Mt St Helens	2.5	24
Fuji	1.8	24
Shiveluch (1964)	1.5	12
Bandai San (1888)	1.5	11
Egmont	0.35	31
Unzen (1792)	0.34	6.5
Asakusa	0.04	6.5

After WJ Maguire.

Lahars can be deadly, as at Nevado del Ruiz in 1985, where a flash flood was generated and spread out 40 km to destroy Armero completely (Figure 12).

A tsunami generated by eruption in the Kurile Is in 1737 swept up a fjord to a height of 65 m.

Tables 5 and 6 list volumes and run-out distances for volcanic debris avalanches and principal mitigating measures for these hazards. An interesting fact, as described by P Delos Reyes, is that animals give indications of forthcoming eruption by their unusual actions.

In Figure 13A and B, the distribution of hazards around a volcano is illustrated and the relative dispersal – the most dispersive fine ash carrying sulphuric acid droplets may extend over the entire circumference of the planet, high in the stratosphere and cause spectacular sunsets for years. In Figure 14, mitigation measures are illustrated.

Volcanoes listed for special study under UN IDNDR are named below (from WJ Maguire):

Decade volcanoes (UN sponsored)

- Colima (Mexico)
- Galeras (Colombia)
- Mauna Loa (USA)
- Merapi (Indonesia)
- Mount Rainier (USA)
- Nyirogongo (Zaire)
- Sakurajima (Japan)
- Santa Maria (Guatemala)
- Ta'al (Philippines)
- Ulawan (Papua New Guinea)
- Unzen (Japan)
- Vesuvius (Italy)

Laboratory volcanoes (EU sponsored)

- Etna (Sicily)
- Furnas (Azores)
- Krafla (Iceland)
- Piton de la Fournaise (Reunion Is)
- Teide (Tenerife)
- Santorini (Greece)

It is noteworthy that none are in Kamchatka, Siberia, often cited as the world's most active volcanic region: 20 volcanoes erupt there, 3–5 times per year.

Volcanoes and Earthquakes

Volcanic earthquakes provide a valuable warning of impending eruption, clusters of small seisms being detected on seismograph arrays. Major tectonic earthquakes are quite distinct from these seisms, but major earthquakes and eruptions can be interrelated:

Table 6 Principal mitigating measures for volcanic hazards

Hazard	*Principal mitigating measures*
Lava flows	Damming or diversion: flow front water cooling
Debris flows (lahars) and floods	Judicious siting of settlements; construction of elevated refuges, sediment dams, and baffles; dredging and levee construction; seismometer and trip wire warning systems
Pyroclastic flows and surges	Judicious siting of settlements; pre evacuation
Tephra	Evacuation of poorly constructed buildings; accumulation of accumulated ash, etc. from roofs; availability of face masks/protective headgear; appropriate medical care for respiratory problems and ingestion of glass microshards; contingency plans for power cut off, communications and transport disruption; availability of uncontaminated water supplies; measures to minimise crop and livestock damage; warnings to air traffic
Landslides and debris avalanches	Identification of collapse prone areas; slope stability monitoring; pre evacuation
Directed blasts and shock waves	Pre evacuation
Volcanic gases	Gas monitoring; resettlement if a permanent problem: pre evacuation if episodic and predictable: public safety guidelines and warning notices; construction of elevated refuges where appropriate
Tsunami ('tidal wave')	Identification of unstable slopes adjacent to water bodies; slope stability monitoring; pre evacuation; establishment of a tsunami warning network both regionally and internationally

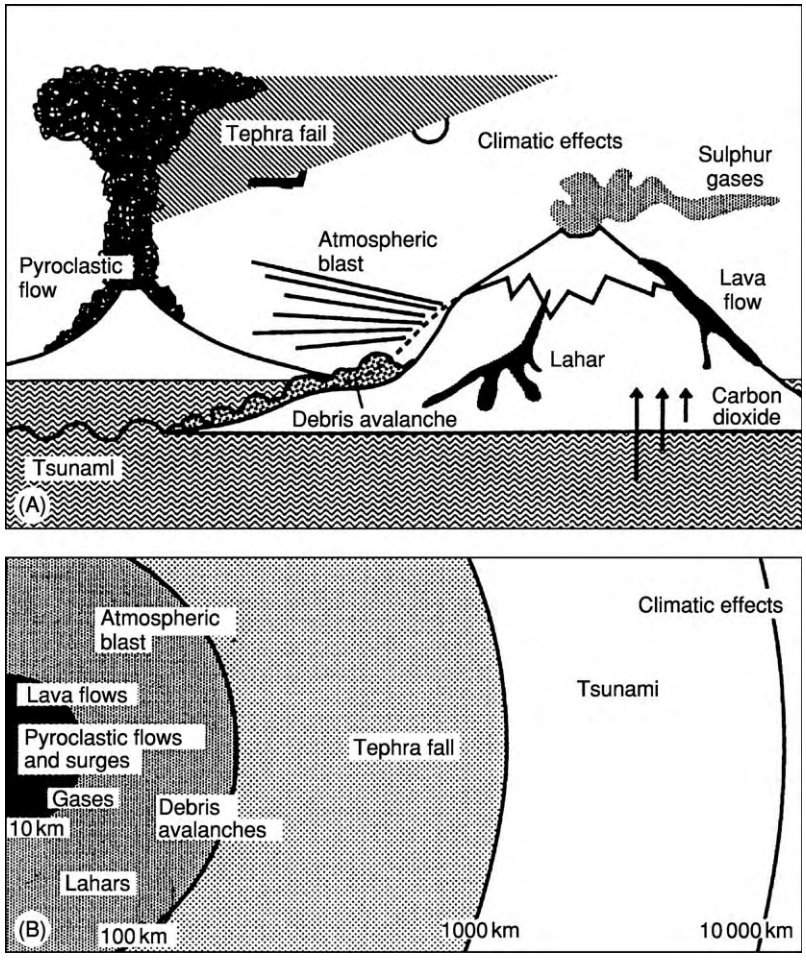

Figure 13 The destructive processes generated by volcanoes: (A) showing those confined to the immediate vicinity. (B) showing those dispersing further, even globally (from Maguire (1998)).

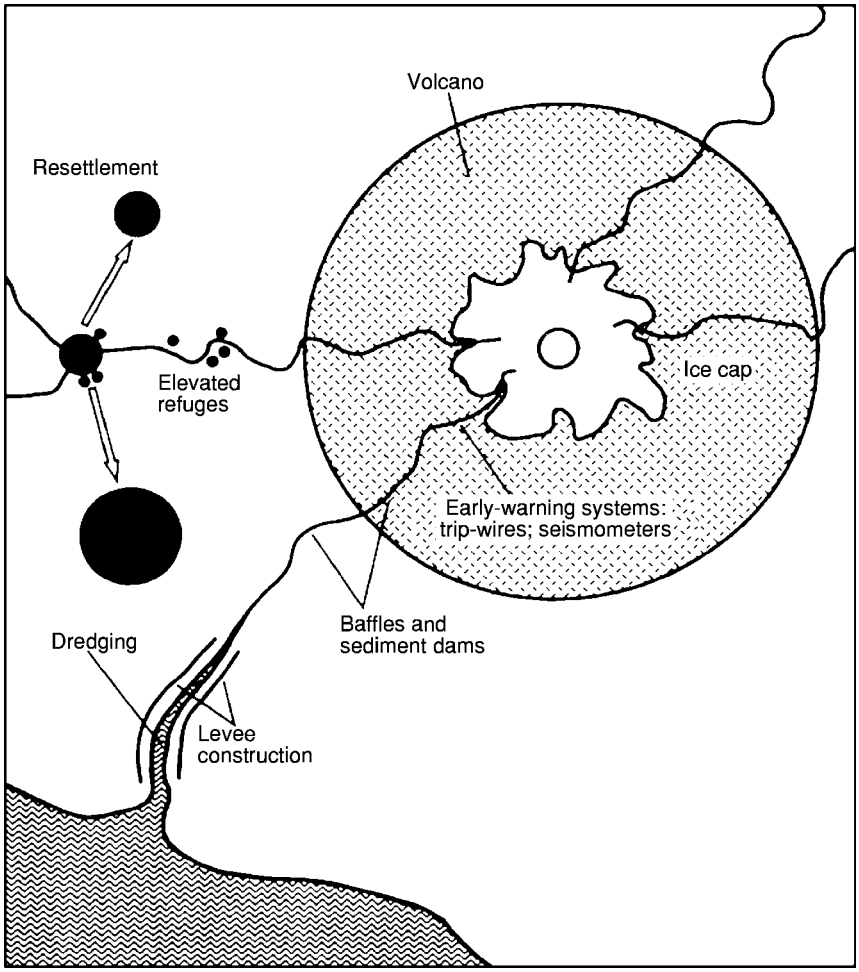

Figure 14 Mitigation measures possible in the case of lahars (from Maguire (1988)).

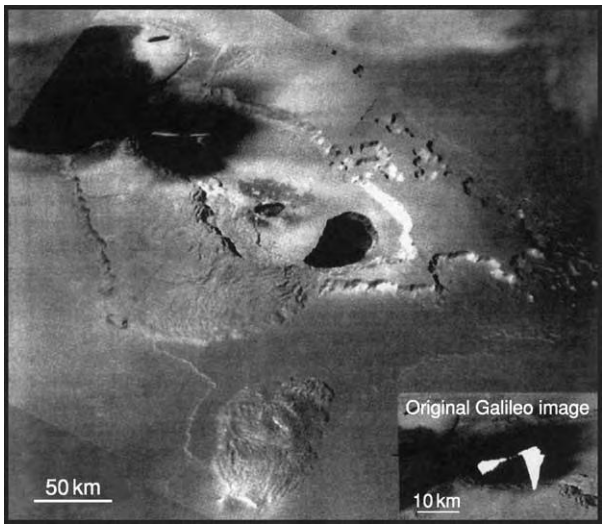

Figure 15 Tvashtar Catena, Io: a 160 km long caldera containing two nested smaller lava filled pits and an adventive volcano at the far end, associated with huge lava fountains and black lava effusion down the flanks of the host volcano. There is also a volcano of more viscous lava with a small summit crater in the foreground. Lighter areas are due to sulphur (NASA Galileo 1999 image).

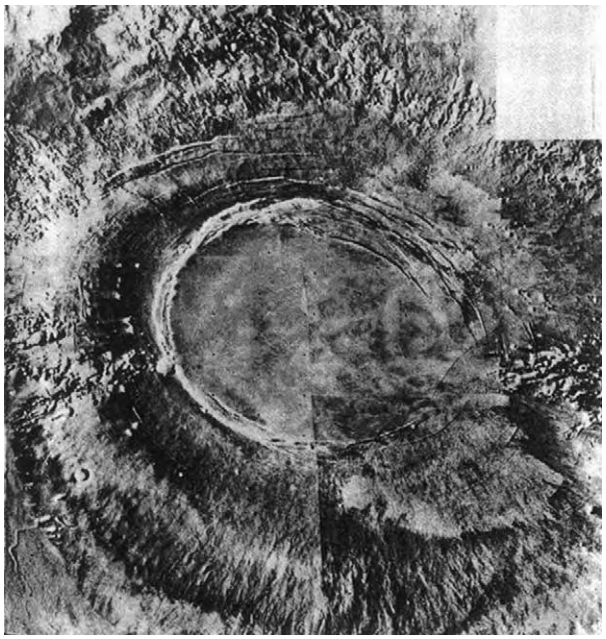

Figure 16 Arsia Mons volcano, Mars, with a 99 km wide caldera (NASA Viking Orbiter 1 image).

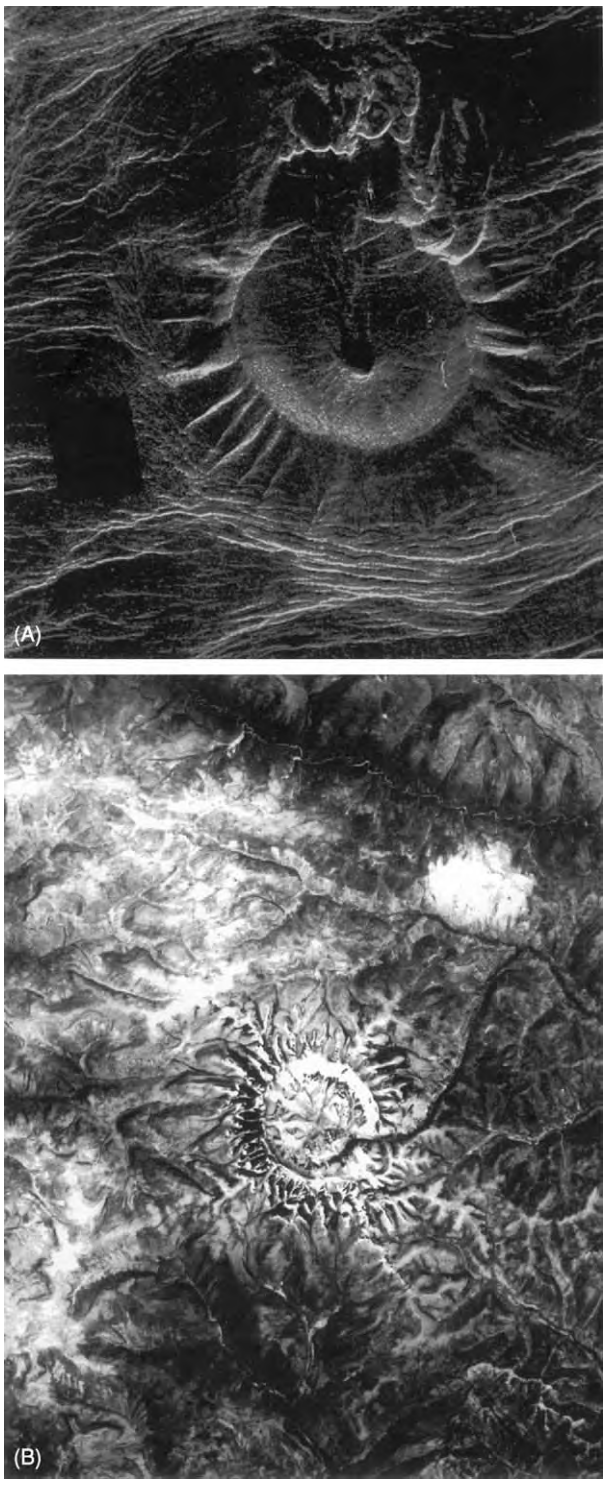

Figure 17 (A) False colour radar image of a volcanic crater on Venus (35 km diameter at summit). Note lava flow which has passed through a breach in the wall at top; also the eroded (?) lateral slope ridges and gullies which suggest Earth like processes operating (NASA image). (B) The Gora Konder crater, diameter 22 km, Siberia: in remote terrain, the origin, volcanic or impact is unknown, illustrating the difficulty of differentiating impact and volcanism on physiography alone: the similarity of the flank ridges and gullies to a) is striking (NASA, Shuttle Discovery image).

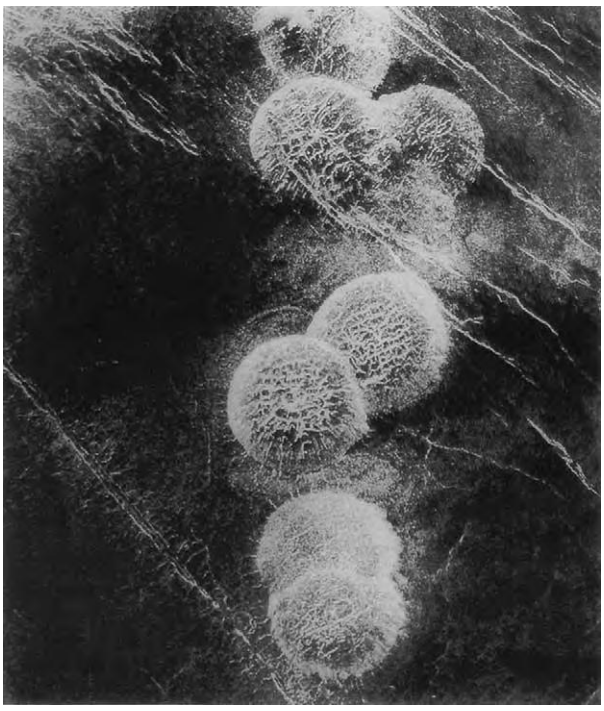

Figure 18 False colour radar image of seven eruptive domes, each 25 km in diameter, overlying one another, on Venus: possibly domes of viscous silicic lava? (NASA image).

a major earthquake in Chile in 1960 is recorded as activating several Andean volcanoes and a major earthquake in Sicily is recorded as having been preceded three days earlier by an eruption of Etna.

Extra-terrestrial volcanoes

Active volcanoes are known on Jupiter's satellite Io (Figure 15), and huge extinct volcanoes occur on Mars and Venus (Figures 16, 17 and 18). Venus's thick CO_2 rich atmosphere is believed to be volcanically sourced.

WEATHERING

W B Whalley and P A Warke, Queen's University Belfast, Belfast, UK

Introduction

Weathering can be defined as the irreversible structural and/or mineralogical breakdown of rock through the cumulative effects of chemical, physical, and biological processes operating at or near the Earth's surface (Table 1). However, this seemingly straightforward definition masks the complexity of rock weathering, in which interactions between the many different components of the weathering system give rise to an element of unpredictability that is characteristic of non-linear systems. The weathering behaviour of rock is a response to subaerial (Earth surface) conditions, where temperatures and pressures differ from those under which the minerals were formed. Consequently, adjustment to surface environments is manifest through rock breakdown, the rate of which is controlled by many factors: characteristics of the rock itself, the availability of weathering agents such as salt and moisture, biological agents such as lichens, and, especially, the microclimatic environment to which the rock is exposed.

Without weathering and, in particular, the breakdown of one mineral type into another, there would be no soils of any significance and little scope for widespread development of flora and fauna on land. Thus, long-term weathering is of paramount importance to the biosphere and is a crucial element of both long-term and short-term landscape development.

Nonequilibrium Conditions and the Lithological Cycle – General Significance

The lithological cycle provides a useful starting point when considering the role of weathering in landscape development. Erosion is generally preceded by a combination of weathering processes, which are usually crucial in the formation of silt, clays, and resultant solutes and in the release of residual components of crustal materials.

As rock approaches the Earth's surface, either through tectonic uplift or through erosion of the overburden, associated changes in pressure and/or temperature mean that it is no longer in a state of equilibrium. In this context, 'surface' should be taken to include the range of locations where the hydrosphere, atmosphere, and biosphere interact with the lithosphere; the maximum extension of these interactions is *ca*. 100 m (e.g. where there is tropical deep weathering), although it is normally much less than this. Differences in pressure and temperature at or near the Earth's surface give rise to important (intrinsic) aspects of rock breakdown that can create or reinforce positive-feedback conditions in weathering systems.

- Thermodynamically and chemically different conditions at the Earth's surface can destabilize minerals, thus increasing their susceptibility to subaerial weathering processes.
- Changing chemical and thermodynamic conditions may be accompanied by volume changes resulting from decreased overburden pressures, which lead to differential stresses that are realized as discontinuities at various scales, from joints and cracks to microcracks. Volume changes can also occur when one mineral is altered to another.

When the rock arrives at the Earth's surface, the interplay of hydrosphere, atmosphere, and biosphere provides more complexity, although, for the most part, we can reduce this to a small number of extrinsic factors, namely water (in all three phases), temperature (usually between -40°C and $+40^{\circ}$C at or near the Earth's surface), and biotic activity (which depends on water and temperature). The interplay of these factors has had important consequences for long-term global climate change as well as landscape development, as discussed below.

Joints, Cracks, and Microcracks

One major result of the uplift of rocks to the Earth's surface is that, as pressure decreases, there is a volumetric expansion. The most significant way in which this manifests is through the creation of crack systems, from joints to microcracks. The intersection of joints, which can be many metres in length and depth, can substantially weaken a mass of rock. This gives rise to the concept of 'rock-mass strength' (as opposed to the 'intact strength' of small blocks). Therefore the 'strength' of the rock on a face in a quarry (rock mass) will differ from the crushing strength of the aggregate (intact strength). At a smaller scale, microcracks are plentiful in many rocks; they are usually a few micrometres wide and perhaps a few centimetres long.

Table 1 Examples of weathering processes and mechanisms

Weathering process	*Weathering mechanisms* (*Main mechanisms outlined, not a full discussion of hypotheses*)
Sometimes referred to as physical or mechanical weathering	
Salt weathering (haloclastis)	**Salt crystallization** In pores and microfractures salt crystallization can result in the creation of expansive stresses in excess of the tensile strength of the rock. Repeated exposure to the stress effects of salt crystallization can result in the disruption of intergranular bonds and a reduction in structural coherence
	Crystalline phase change Changes from dehydrated to hydrated states through the absorption of atmospheric humidity result in volumetric expansion of salt crystals in pores and microfractures. Typically, take up of moisture by an anhydrous salt forms a crystallographically different mineral
	Thermal expansion and contraction Interstitial salt crystals exhibit coefficients of thermal expansion that are often greater than those of the rock minerals that surround them
	Mobilization of silica Under highly alkaline conditions disruption of aluminosilicate minerals can occur together with the dissolution of quartz and silica cement
Frost weathering (macrogelivation)	**Freeze thaw** Repeated freezing results in volumetric expansion of water in pore spaces and fractures. This can also enhance the disruptive hydration effects of swelling clay minerals
	Hydrofracture Moisture freezes in a microfracture sealing off the surface end, and any unfrozen water trapped in the substrate may be forced under pressure, through volumetric expansion of the ice, towards the tip of the microfracture and thus extend it
Thermal weathering (insolation weathering, thermoclastics)	**Thermal fatigue** The effects of insolation weathering arise from differential volumetric expansion of individual mineral grains and/or surface and near surface rock layers in response to repeated (diurnal) heating and cooling
	Thermal shock is a rapid increase in rock surface temperature (typically associated with bush fires). Thermal gradients develop quickly, giving rise to tensile stresses between expanding heated surface rock layers and cooler substrate material
Chemical weathering	**Solution of minerals** occurs as a result of exposure to water, its effectiveness is influenced by contact time, the pH of the water, and the solubility characteristics of the elements of the individual minerals
	Carbonation is the reaction of minerals with 'carbonic acid' (CO_2 dissolved in water) and is a particularly important reaction in limestone weathering
	Hydrolysis is the chemical reaction between hydrogen ions in water and the ions in any mineral structure
	Oxidation is when electrons are lost from an atom and usually describes the reaction with oxygen to form oxides, e.g. the conversion of ferrous to ferric iron (such as the weathering of olivine) with an associated volume increase
	Reduction is when an atom gains an electron, usually under anaerobic conditions (typically, gleys in soils)
	Hydration is an exothermic reaction involving the addition of water to a mineral. It is an important weathering characteristic of many clay minerals, which undergo considerable volumetric expansion when water is incorporated into their crystal lattices, e.g. swelling clay minerals such as bentonite from weathered volcanic ash
Biological weathering	**Chemical dissolution of minerals** through the action of organic and inorganic acids
	Chelation is the removal of metallic ions by chelating agents of organic origin
	Plucking is the dislodgement of rock or mineral fragments through the contraction of lichen thalli and fungal hyphae on drying
	Boring into rock by biota (e.g. snails, sea urchins)
	Fracturing by root penetration and exploitation of joints and cracks.

This table gives only the main mechanisms considered to be involved in rock weathering.

The surface area of rock components (say intact rock blocks) is the area upon which physical and chemical weathering processes act. This surface area is extended substantially by the presence of microcracks, joints, and cracks because, as long as water can reach these surfaces, weathering reactions can act upon them. Such physical and chemical action can further extend microcrack and joint systems by increasing the tensile stresses at crack tips. The interpenetration of discontinuities at any of these scales aids weathering in general.

Minerals and Rates of Weathering

Minerals in rocks can be divided into those that are relatively resistant to weathering (such as quartz), those that are rather vulnerable to weathering (such as olivine), and those that have been produced by weathering. Figure 1 shows the Goldich weathering series (which is the inverse of the Bowen reaction series, in that the minerals that crystallize at the lowest temperatures in the melt are also the most stable in the conditions found at the Earth's surface).

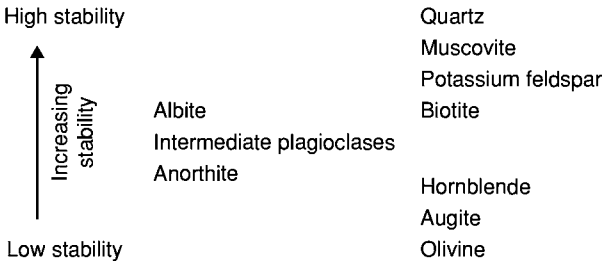

Figure 1 Weathering and the stability of some rock forming minerals. The continuous plagioclase series is given in a separate column.

With the exception of thermoclastis, all Earth-surface weathering (physical, chemical, and biological) involves water, which enables chemical reactions, facilitates the mobilization and ingress of salt into rock fabrics, and, in its solid phase (ice), contributes directly to rock breakdown. Chemical weathering is particularly complex in that the efficacy of reactions depends on moisture availability, temperature, and the nature of the mineral assemblage. Mineral reactions are therefore controlled by the mineralogical nature of the reactants and the acidity (pH) and reduction–oxidation potential (Eh or redox potential) of the water. The dissociation of water into H^+ (protons or hydrogen ions) and OH (hydroxyl radicals) is important in weathering reactions, especially in hydrolysis, where one or other of these ions replaces ions in a mineral structure.

Weathering products are of three main types: layer silicates in the clay minerals, silica in solution (usually given the formula H_4SiO_4 – 'silicic acid'), and alkali-metal ions in solution.

The example of orthoclase weathering to muscovite can be expressed as:

$$3KAlSi_3O_8 + 12H_2O + 2H^+ \rightarrow KAl_3Si_3O_{10}(OH)_2 + 6H_4SiO_4 + 2K^+.$$

Muscovite can then degrade into kaolinite:

$$2KAl_3Si_3O_{10}(OH)_2 + 3H_2O + 2H^+ \rightarrow 3Al_2Si_2O_5(OH)_4 + 2K^+$$

(It should be noted that there are several ways of expressing these reactions and that these two examples are rather generalized because of the complex nature of feldspars and clay minerals.)

The significance of water-soluble products, which may be removed by agents such as groundwater, is clearly seen as the solute loads of rivers. Additionally, the relict nature of weathering products not removed in solution can be seen in saprolites and duricrusts, which may be legacies of previous weathering stages.

In terms of rock weathering, one of the most dramatic examples of the role of chemical weathering in landscape development is provided by 'karst' landforms, where the reactions between rainwater, atmospheric gases, and calcareous rocks (typically limestones) can over time create distinctive and dramatic surface features (Figure 2). Rainwater dissolves atmospheric CO_2 to give bicarbonate ions, HCO_3, in solution as a weak acid, carbonic acid, as a result of a reversible reaction:

$$H_2O(l) + CO_2(g)\{ReversReact\}H^+(aq) + HCO_3(aq)$$

Calcium carbonate is an important constituent of chalks and limestones and is soluble in carbonic acid:

$$CaCO_3 + H_2CO_3\{ReversReact\}Ca^{++} + 2HCO_3$$

These reactions also create subsurface weathering structures, such as cave systems, and features such as stalagmites, which are formed when the reaction is reversed and calcite is deposited.

The rate laws of chemical reactions show how rates depend on the concentrations of the reactants. Although this is significant in reactions that take place over very short periods of time (usually less than a few hours), it can be ignored for our purposes. More significant is the application of Arrehenius' equation to chemical reactions. In particular, increases in temperature speed up reactions. A general rule is that an increase in temperature of 10 K doubles the 'weathering rate'. Clearly, there are direct links with the extrinsic factor of climatic temperature. Assuming a constant (mean annual) temperature at a location, we might reasonably expect, at least over relatively short periods of time such as a few thousand years, the rate of weathering to be constant. When a distinctive weathering product is produced, this can be used as a marker or even as a somewhat primitive chronometer. Rock varnish is a good example of the latter. Weathering horizons in soils buried by subsequent deposition (palaeosols) also provide distinctive marker horizons.

Weathering in Surface Landscape Interpretation

Weathering studies have tended to be somewhat overshadowed by other geomorphological disciplines, and yet weathering is extremely significant because it is the principal means of sediment production for erosion, transport, and deposition by aeolian and fluvial processes. There has been a tendency to investigate more visually prominent weathering features, such as tafoni (shallow rounded cavities in rocks produced by weathering), but it is now widely accepted that such features are exceptional and not truly

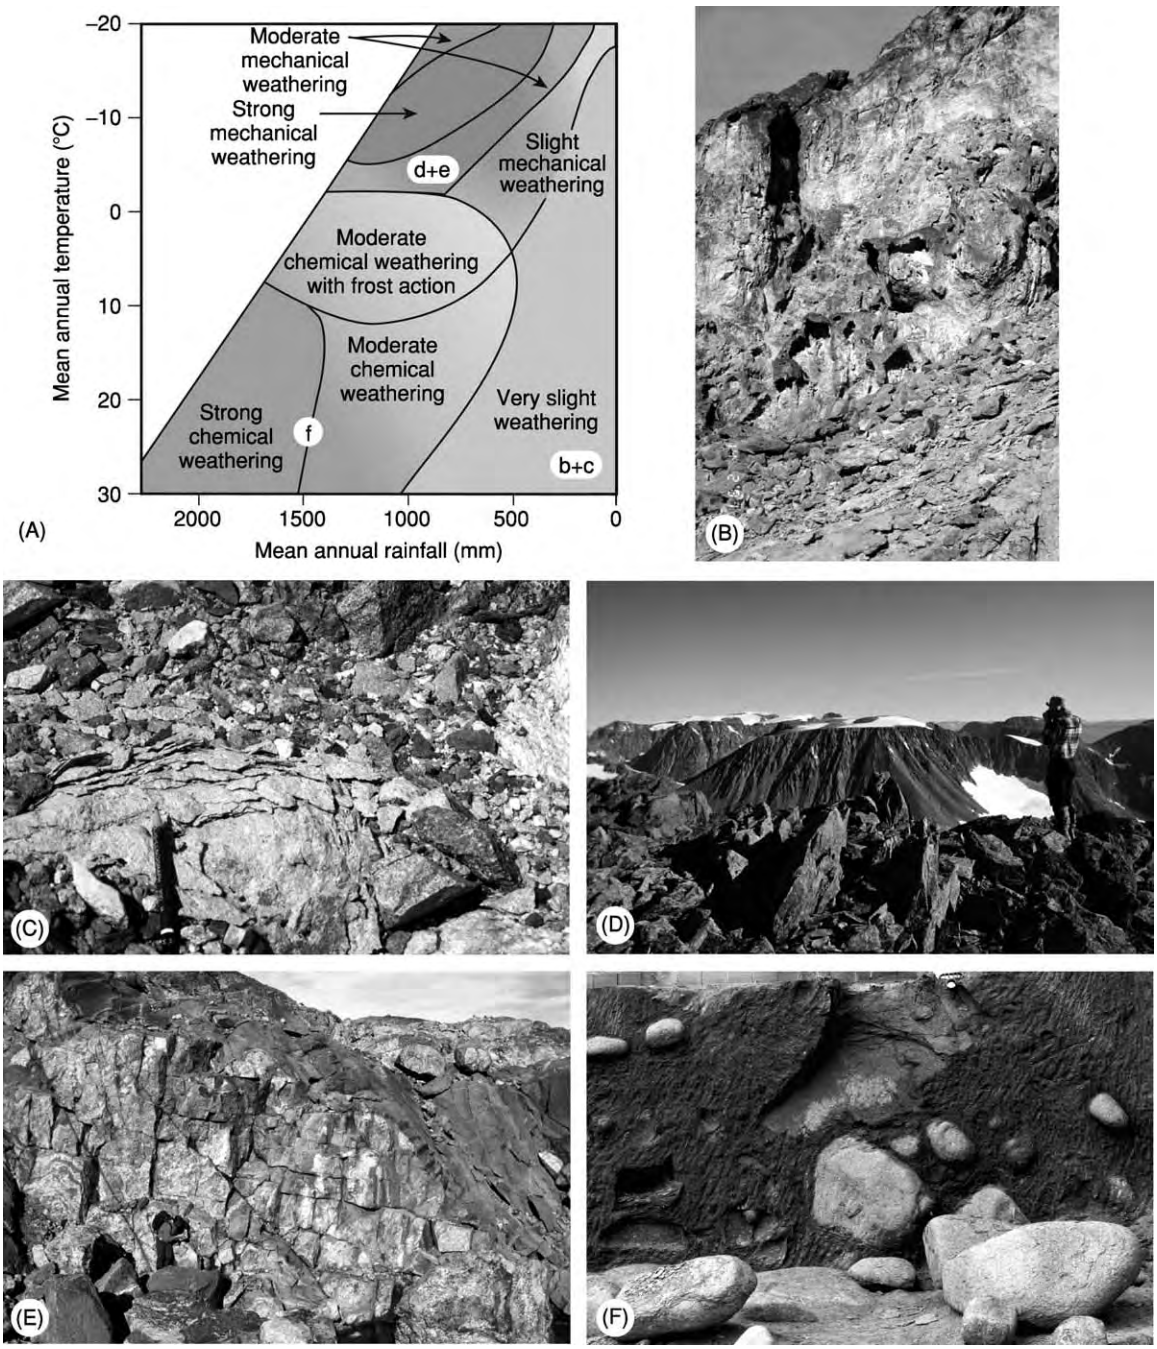

Figure 2 (A) Peltier's zonal classification of weathering, based on average annual temperature and moisture availability. Images shown in parts (B) (F) are marked on the corresponding weathering zones. (B) Present day weathering of a sandstone outcrop in Death Valley, California (a hyperarid hot desert); breaching of the casehardened outer layers of stone and subsequent development of basal tafoni is contributing to undercutting and periodic collapse and retreat of the rock face. Present day weathering processes comprise a complex assemblage of physical, chemical, and biological mechanisms, which are of both spatially and temporally variable effectiveness (cliff height is approximately 4 m). (C) Also in Death Valley, the active disintegration of clasts occurs under present day conditions primarily but not solely because of the effect of groundwater that is rich in a complex assemblage of salts, which facilitates salt weathering mechanisms and the preferential chemical weathering of silicates owing to the strongly alkaline conditions. Owing to the often prolonged absence of surface water, debris disintegrates *in situ*, leading to a local accumulation of sediment, which is periodically transported away from the site during flash flood events. (D) High latitude regions, such as this site in the Lyngen Alps, northern Norway (70°N), tend to be associated with physical weathering by frost action because of the present day climatic conditions, which are dominated by low average annual temperatures. However, this inference is not wholly accurate as the gabbroic rock of the region has been subject to long term chemical weathering (perhaps extending as far back as the Tertiary), leading to an accumulation of clay minerals in a weathering mantle on the plateaux that can be up to 2 m deep. Thus, the present day environment belies the long term activity and changing environmental conditions, especially temperature. This inheritance is also

representative of most landscapes, which are dominated by extensive debris mantles (saprolites) and where weathering phenomena tend to be more mundane. Increasing understanding of the factors controlling weathering phenomena in a wide variety of climatic regions, in the latter half of the twentieth century, has highlighted several major conceptual issues that underpin much of contemporary rock-weathering research – issues that have significant implications for the understanding of landscape development. These issues include: climate, rock weathering, and classification; magnitude and frequency of rock weathering; feedback mechanisms; equifinality (form convergence) – the problem of linking process and form; and inheritance effects.

Climate, Rock Weathering, and Classification

The traditional classification of weathering tends to be climatically zonal, reflecting temperature characteristics and precipitation, with the implication that maximum weathering occurs in the humid tropics and minimum weathering occurs in hot and cold desert regions. However, better understanding of the conditions under which specific weathering processes operate demonstrates that the efficacy of these processes cannot necessarily be clearly associated with specific climatic zones, primarily because of the temporal and spatial variability of conditions at the rock–air interface (Figure 3). For example, chemical weathering is relevant to rock breakdown in arid environments because the spatial variability of microenvironments can create atypical 'pockets' of activity. Many early schemes neglected the temporal aspects of weathering systems, whereby, if sufficient time is allowed, many weathering features hitherto ascribed to specific climatic zones can develop in regions with quite different climatic parameters. For example, the development of karstic (limestone) weathering phenomena associated with moisture availability proceeds slowly in many present-day hot arid environments but rapidly in colder conditions (because of the greater solubility of carbon dioxide in water at low temperatures).

Further complexity is introduced by the temporal variability of conditions at the rock–air interface, whereby long-term (tens to thousands of years) and/or short-term (diurnal and seasonal) environmental changes can alter the nature and extent of rock weathering at a specific location. This is particularly important in hot and cold deserts, where small changes in environmental parameters may have significant effects on weathering activity. Furthermore, viewing weathering as a consequence of the existing climate neglects the effects of inheritance (see below), which are important when considering the landscape as a whole and as a continuum. It is now accepted that, rather than trying to ascribe particular weathering processes to specific climatic zones, it is better to view weathering features as azonal phenomena *per se*.

Magnitude and Frequency in Rock Weathering

Sudden high-magnitude increases in the stress burden on rock through the operation of weathering processes may result in rapid or catastrophic breakdown of the rock fabric. Breakdown might not have occurred, or might have occurred less dramatically, if the stress had been applied more gradually. For example, the freezing rate and the number of oscillations across the freezing point of water in rock (which may be several degrees below 0°C) have been shown to be important in determining the efficacy of frost weathering. The rapid freezing of moisture within the rock fabric reduces losses through evaporation and 'cryosuction' (converting liquid water to solid), increasing the energy available for shattering. This in turn is related to the threshold concept, whereby, if the critical threshold of material strength is greater than the stress applied, no apparent change will occur. The absence of obvious visual damage in a rock can, however, be misleading, as it implies that the material is unaltered, even though microscopic external and internal changes may have occurred, the accumulation of which may eventually reduce cohesive strength and lead to 'fatigue' failure. Similarly, the effects of extreme heating and high rates of surface temperature change (thermal shock) are clearly demonstrated in the natural environment during bush fires, where widespread splitting and spalling of natural rock outcrops occurs as critical thresholds of strength are exceeded over very short periods of time (minutes). Depending on the nature of the

seen in the concordance of plateau summits, which are thought to be Mesozoic in age and probably the result of long term *in situ* chemical weathering producing an 'etch plain'. The effects of glacial activity and periglacial weathering in this environment are far less important than would be implied by a superficial view regarding only present day processes. (E) The gabbroic cliffs (Øksfordsjøkel plateau, northern Norway) show clear evidence of jointing and removal by small rockfalls as well as glacial activity, illustrating the importance of weathering and crack or joint frequency in the wider context of erosive agents. Unlike in (D), the deeply weathered plateau blockfield material has been removed, and the weathering seen is mainly 'cryogenic'; nevertheless, chemical weathering continues to act on mafic minerals, producing a weathering rind. (F) Corestones remain in a deeply weathered Brazilian saprolite as a consequence of long term chemical weathering processes. Without a good stratigraphical marker, the age of these deposits and time taken to form such materials is indeterminate (profile section depth is approximately 2 m).

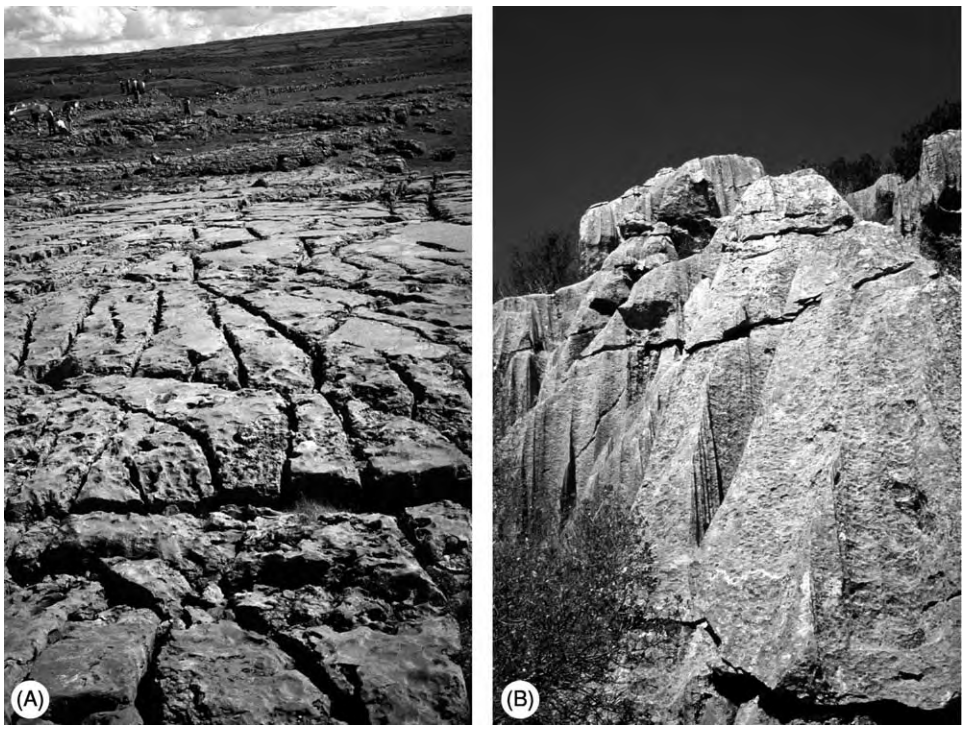

Figure 3 (A) Limestone pavement ('clints' and 'grykes') developed in the horizontally bedded Carboniferous limestone of the Burren, County Clare, Ireland. This limestone has a low porosity, resulting in the chemical dissolution effect of rainwater being concentrated along vertical joints, which form naturally occurring lines of weakness. (B) In contrast, the Jurassic limestone outcrops of the Sierra Norte mountains in Mallorca have been contorted and tilted by orogenesis, with the resultant flow of rainwater over surfaces preferentially weathering joints to create a different limestone landscape of pinnacles and towers on which a hierarchy of smaller solutional weathering features have formed.

environmental stress, prolonged and continuous stressing of rock may be less destructive than – or not so obviously destructive as – repeated high-magnitude short-term events.

Although the magnitudes and frequencies of stress events are important, material characteristics must also be considered. For example, the impermeability of some rock types may leave them relatively unaffected by high-magnitude weathering events, primarily because weathering agents such as moisture and salt cannot penetrate the rock fabric because of a lack of microcracks. Other rock types, exposed to the same environmental conditions, may be more susceptible because their structural and mineralogical characteristics facilitate the ingress of exploitative weathering agents. Consequently, in a landscape where different lithologies are present, it is probable that the nature and extent of the weathering response will vary.

Feedback Mechanisms

The weathering system may be best characterized as a nonlinear system primarily because of the variety of pathways and the unpredictability of outcomes. The unpredictable nature of rock-weathering pathways reflects the operation of positive- and negative-feedback conditions, with the former resulting in an overall change in system state through the acceleration of weathering activity while the latter maintains the system status quo or acts to retard weathering. The trigger for a change in feedback conditions can be seemingly insignificant but may result in considerable system destabilization. For example, a change in groundwater conditions can be sufficient to initiate widespread salt weathering of both natural rocks and manmade building material. Similarly, a change in microenvironmental parameters such as atmospheric humidity may activate salts that have hitherto been present but 'dormant' as regards weathering of rock.

Feedback conditions may help to explain some anomalous rock weathering responses. Part of a rock outcrop, for example, may exhibit well-developed weathering phenomena while an adjacent part of the same outcrop with the same exposure conditions shows no obvious evidence of deterioration. Examples of this are shown in Figure 4. Figure 4A shows a combination of basal tafoni with smaller hollows (alveoli) forming above; in Figure 4B there are no basal hollows but there are well-developed

Figure 4 (A) Sandstone outcrop at Capitol Reef, Utah, showing well developed basal tafoni and alveolar weathering features some 2 3 metres above ground level. (B) Sandstone monolith in Arches National Park, Utah, with well developed alveoli formed some 2 3 m above ground level.

alveoli perched several metres above ground level. In both examples alveoli have formed adjacent to seemingly intact rock that has been exposed to the same environmental conditions and has the same general lithological characteristics. Positive-feedback will have influenced decay pathways initially through the creation of conditions conducive to the initiation of these hollows and subsequently through their progressive development. Initiation of the alveoli may have occurred as a result of structural or compositional anomalies within the sandstone, which were preferentially weathered because they allowed moisture or salt to penetrate. Hollow development may have been slow until increasing size allowed the establishment of microenvironmental conditions that were conducive to the more intense action of various weathering processes not effective on the outcrop surface. The weathering significance of such features lies not only in their development but also in the reasons why the adjacent rock remains relatively unaffected.

Equifinality – The Problem of Linking Process and Form

Another complicating factor affecting rock weathering is the issue of equifinality. This arises when different weathering processes produce similar weathering forms, thus preventing the identification of simple correlations between process, climate, and form. For example, angular shattered debris is common in both hot desert and high-latitude or mountainous regions. In the former, rock typically weathers *in situ* with little or no fluvial abrasion in an environment characterized by large diurnal temperature fluctuations and limited moisture availability. In the latter, moisture is normally more abundant and air temperatures frequently fall below 0°C. In these different climatic environments different groups of weathering processes contrive to produce similar debris forms. The similarity of clasts from these two environments is a consequence of the elongation of crack tips, typically by salt crystals in hot deserts and by ice in cold deserts. However, it should be noted that salt weathering is not exclusive to hot deserts: the sculptured cavernous weathering features (tafoni) observed in the Dry Valleys of Antarctica are attributed to the action of salt weathering rather than freeze–thaw processes.

At the landform scale, a classic example is that of 'U'-shaped valleys, which were once (and still are by some) viewed as being characteristic of glaciated landscapes. However, these features can also be found in the subtropics, where intense chemical weathering at the water table contributes to 'basal sapping' (weathering plus erosion of products) and

the maintenance of steep-sided valleys. In glaciated regions vertical-sided 'U' shapes can be a consequence of rock sheeting ('exfoliation'; as seen in the granites of Yosemite) and massive block failure. Both can be considered to be large-scale weathering phenomena involving overburden removal by long-term denudation.

Inheritance Effects

Many weathering studies have sought to explain patterns and rates of breakdown in terms of the prevailing environmental conditions and have sometimes relied upon the inference of process from 'form' alone at various scales, from landscape through to individual mineral grains. Too often, weathering processes that are immediately associated with observed rock weathering forms are judged to be solely responsible for their formation. In fact, this 'guilt by association' obscures the role of previous events and conditions – the weathering history of the material.

Exposure to various environmental conditions through either long-term climatic change or the spatial relocation of clasts gives a rock a complex weathering history. Rock outcrops and debris in many present-day landscapes therefore carry within their fabric an inheritance of structural and mineralogical weaknesses incurred under former conditions, which influence their response to present-day processes.

In addition to depending on the prevailing environmental conditions, weathering rates depend on the physical and mineralogical characteristics of the rock, and any factor that alters these characteristics will therefore influence subsequent rates of decay. Such changes may result from present-day weathering processes. However, many changes may be cumulative, each reflecting a set of environmental conditions and/or processes that acted in the past. Indeed, the significance of inheritance effects lies in the fact that they are frequently unrelated to present-day environmental conditions but were incurred under former conditions. For example, in arid environments many weathering features owe their initiation and development to the greater availability of water in the past. In Death Valley, now a hyperarid desert, the influence of water on landscape development is clearly evident, with extensive alluvial fans and, at a smaller scale, corroded cobbles, which can be found along the ancient strandlines that mark lake high stands from the early Holocene. These cobbles exhibit well-developed hollows covered by a manganese- and iron-rich rock varnish, indicating that the processes responsible for their development are no longer active under the present-day hyperarid conditions. Such weathering features created under former conditions are preserved within the present-day landscape and while some may be 'inactive' others may be undergoing some limited modification.

Weathering, Near-Surface Diagenesis and the Geological Record

Weathering of a variety of rocks, and sediments in particular, provides useful evidence of past climatic conditions. The weathering products can be substantial or present just as relict traces. Soils in the geological record (palaeosols) are found in a wide variety of sediments (including loess and river gravels) and in extrusive igneous rocks (typically Tertiary basalts). Substantial deposits related to weathering are exemplified by 'duricrusts'. These are hard durable layers or concretions found exposed (and even actively forming) on the surface of the Earth, typically in semiarid areas. The best known are laterite (Fe and Al rich), calcrete ($CaCO_3$), ferricrete (Fe^{3+}), gypcrete ($CaSO_4$), and silcrete (SiO_2). The main formative process is the upward flow of water with evaporation at the surface. This tends to be a self-limiting process, as the thickening duricrust eventually limits its own development by restricting evaporation.

Silcretes are orthoquartzites formed from fluids containing high concentrations of silica in solution (silicic acid), and silcrete remnants form the triliths at Stonehenge. The deposit from which these were derived (by weathering and removal of the surrounding uncemented sand) has been denuded but *in situ* silcretes have been found in the Paris basin, which forms the southern side of the Tertiary basin of southern England.

Weathering Related to Engineering and Economic Geology

As weathering and weathering-derived products are near-surface phenomena, they have important implications for engineering and economic geology. Frequently these implications are problematical; for example, deep weathering in relation to dams, other containment structures, foundations etc. In tropical areas, deep piling techniques may have to be used for high-rise buildings or substantial thicknesses of deep weathering may have to be removed to reach rockhead. Weathering processes influence many aspects of economic geology, not only by making ores (or traces of ore deposits) visible but also by producing valuable deposits in their own right. Of the former, perhaps the weathering of kimberlite to leave diamonds in alluvial deposits is the most famous.

It is important to remember that the weathering processes that affect rock in the natural environment also operate in urban environments, where their effectiveness can be enhanced by atmospheric pollutants, particularly through the effects of 'acid deposition', which results from increased concentrations of atmospheric SO_2, SO_3, NO_2, and NO (sometimes referred to colloquially as SOx and NOx) dissolved in rainwater. Although carbonates suffer most from such attacks, especially but not uniquely in industrial areas, other rock types used for building facades also suffer. Feldspars in certain granites are susceptible, as are calcareous sandstones. The main reactions are the result of atmospheric CO_2 dissolved in water (carbonic acid) and acid deposition (most commonly as aqueous H_2SO_4) on calcium carbonate, which is a common constituent of many rock types.

$$CaCO_3(s) + H_2SO_4(aq) \rightarrow Ca^{2+}(aq) + SO_4^{2}\ (aq) + H_2O(l) + CO_2(g)$$

In this reaction (which is also believed to occur in some natural karstic systems in addition to the usual CO_2 reaction), rainwater removes the dissolved, although sparingly soluble, calcium sulphate. Where there is no running water, or where there is air containing water droplets of low pH (occult precipitation), hydrated calcium sulphate (gypsum; $CaSO_4 \bullet 2H_2O$) can form. Where 'soot' particles are also scavenged from the local atmosphere and precipitated with the gypsum, 'black crusts' may form. There is still debate as to whether such crusts protect the underlying stone or exacerbate decay.

Biological Influences on Weathering

The traditional view of biological factors in rock weathering relates to tree roots penetrating preexisting cracks in rocks, forcing mechanical breakdown. This is probably insignificant in comparison with the effects of micro-organisms on (and very near) rock surfaces and, in particular, bacterial action and root gas–water exchanges in soils. The metabolism of plants (and bacteria) produces organic acids (e.g. humic acid and fulvic acid), which can lower the pH of soil water and directly attack some minerals such as calcite. In addition, roots can increase gaseous CO_2 thus giving rise to high concentrations of HCO_3 and increased acidity. The earliest soils (which were poor in metabolically important elements) were probably altered by the action of prokaryotic and early eukaryotic organisms, which broke down minerals and enriched soils with iron and phosphorous by chelation mechanisms.

The very presence of root structures and decaying vegetation not only increases CO_2 concentrations but also helps to retain moisture, allowing chemical weathering reactions to take place around soil particles. It has been shown that in modern streams the rate of chemical weathering is about seven times higher in a forested area than in surrounding bare areas.

Long-Term Changes in Weathering – Some Complicating Factors

There are several ways in which changes in weathering rates have had a marked effect on the geological record. The weathering of calcium and magnesium silicate minerals removes CO_2 from the atmosphere. This may be represented by

$$CO_2 + CaSiO_3\{\text{Revers React}\}CaCO_3 + SiO_2$$

The concentration of CO_2, moderated by weathering, may influence climate. A computer simulation by Berner estimated levels of CO_2 in the Phanerozoic and showed a marked drop in the later Palaeozoic. This has been interpreted as the result of an increase in weathering during this period. The following aspects are significant.

In the Devonian land plants became more diverse and colonized previously barren land (especially upland). This extension of forested areas resulted in an increase in weathering. Atmospheric CO_2 continued to fall during the Carboniferous, even after the spread of forests, and this is attributed to burial of those forests in swampy areas (CO_2 sequestration). This total decline in atmospheric CO_2 is assumed to have weakened the effect of greenhouse warming and thus induced, or at least exacerbated, an extension of the southern hemisphere ice-sheets at about this time. An increase in levels of atmospheric CO_2 in the Mesozoic is attributed in part to minimal amounts of orogenesis (which increases weathering and removes CO_2 from the atmosphere) but mainly to increased emission during the metamorphism of calcareous oozes in subduction zones. In the Cenozoic a slow decline in the CO_2 concentration is attributed to orogenesis, in particular that of the Himalaya–Karakorum chains. This is an area of investigation that has been prompted by the work of Ruddiman and Raymo and is still an area of considerable research. A further factor is the position of land masses relative to the tropics: higher temperatures and precipitation increase weathering, and a lack of vegetation in more extreme conditions may reduce weathering (thus decreasing CO_2 sequestration). Clearly, the area of continental masses exposed to

prevailing climatic belts also affects the total amount of weathering and is part of the self-regulating system of global climate. For example, increases in precipitation as a result of maritime influences increase terrestrial vegetation, weathering, and CO_2 capture, reducing the greenhouse effect and leading to decreased temperatures (and evaporation rates). Overall, temperature and precipitation affect the amounts and the extent of weathering. Thus, in moderating atmospheric CO_2, weathering on the Earth's surface exerts substantial negative feedback on global climatic change.

Concluding Comments

Weathering processes rarely, if ever, operate in isolation. Consequently, the weathering forms that we see are probably products of the cumulative and sequential effects of a variety of physical, chemical, and biological processes. Recent investigations focusing on the mechanisms of weathering rather than on the resultant forms have led to a wider and deeper understanding of the importance of weathering in topics ranging from building-stone conservation to long-term controls of climate and evolutionary processes.
