Abstract

The Mt. Amiata volcano in central Italy is intimately related to the post-orogenic magmatic activity which started in Pliocene times. Major, trace elements, and isotopic composition of thermal and cold spring waters and gas manifestations indicate the occurrence of three main reservoirs of the thermal and cold waters in the Mt. Amiata region. The deepest one is located in an extensive carbonate reservoir buried by thick sequences of low-permeability allochthonous and neo-autochthonous formations. Thermal spring waters discharging from this aquifer have a neutral Ca-SO₄ composition due to the presence of anhydrite layers at the base of the carbonate series and, possibly, to absorption of deep-derived H₂S with subsequent oxidation to SO₄²⁻ in a system where pH is buffered by the calcite–anhydrite pair (Marini and Chiodini, 1994). Isotopic signature of these springs and N₂-rich composition of associated gas phases suggest a clear local meteoric origin of the feeding waters, and atmospheric O₂ may be responsible for the oxidation of H₂S. The two shallower aquifers have different chemical features. One is Ca-HCO₃ in composition and located in several sedimentary formations above the Mesozoic carbonates. The other one has a Na-Cl composition and is hosted in marine sediments filling many post-orogenic NW–SE-trending basins. Strontium, Ba, F, and Br contents have been used to group waters associated with each aquifer. Although circulating to some extent in the same carbonate reservoir, the deep geothermal fluids at Latera and Mt. Amiata and thermal springs discharging from their outcropping areas have different composition: Na-Cl and Ca-SO₄ type, respectively. Considering the high permeability of the reservoir rock, the meteoric origin of thermal springs and the two different composition of the thermal waters, self-sealed barriers must be present at the boundaries of the geothermal systems. The complex hydrology of the reservoir rocks greatly affects the reliability of geothermometers in liquid phase, which underestimate the real temperatures of the discovered geothermal fields. More reliable temperatures are envisaged by using gas composition-based geothermometers. Bulk composition of the 67 gas samples studied seems to be the result of a continuous mixing between a N₂-rich component of meteoric origin related to the Ca-SO₄ aquifer and a deep CO₂-rich component rising largely along the boundaries of the geothermal systems. Nitrogen-rich gas samples have nearly

atmospheric N_2/Ar ($= 83$) and $^{15}N/^{14}N$ ($\delta = 0\%$) ratios whereas CO_2 -rich samples show anomalously high $\delta^{15}N$ values (up to $+6.13\%$), likely related to N_2 from metamorphic schists lying below the carbonate formations. On the basis of average $^{13}C/^{12}C$ isotopic ratio ($\delta^{13}C$ around 0%), CO_2 seems to originate mainly from thermometamorphic reactions in the carbonate reservoir and/or in carbonate layers embedded in the underlying metamorphic basement. Distribution of $^3He/^4He$ isotopic ratios indicates a radiogenic origin of helium in a tectonic environment that, in spite of the presence of many post-orogenic basins and mantle-derived magmatics, can presently be considered in a compressive phase. © 1997 Elsevier Science B.V.

Keywords: geochemistry; water; gas; stable isotope; geothermics; Mt. Amiata; Central Italy

1. Introduction

Post-orogenic magmatic activity occurred in the northern Apennines (central Italy) during Pliocene to Quaternary times and produced hybrid (crustal anatexis—upper mantle; Poli et al., 1984; Giraud et al., 1986; Peccerillo et al., 1987), anatexis (Barberi et al., 1971) and subcrustal primary K-rich silica-undersaturated magmas in Tuscany and Lazio, respectively (Peccerillo et al., 1987). These magmatic activities are associated with geothermal anomalies which may have persisted for relatively long periods (2–3 Myr; Calore et al., 1981) and been generally more widespread than the volcanic areas on surface. This is particularly evident at Larderello (the most important geothermal field in Italy), where volcanic outcrops are only found 25 km away from the geothermal field itself, and drill holes have encountered only small 3.8 Ma microgranitic dikes at > 3000 m depth (Villa et al., 1987).

Deep geothermal wells in the peri-Tyrrhenian belt show relatively uniform temperatures of 300–400°C at depths of 3–4 km (CEE, 1988). At greater depths, high heat flow is due to deep-seated (6 to 10 km) masses close to their melting point (Puxeddu, 1984). Heat is transferred to shallow depth by conduction and by convection in a regional aquifer hosted in Mesozoic limestone formations ('Tuscan' series), sometimes piled up in accretional prism (Pandeli et al., 1991). This aquifer plays an important role in increasing shallow thermal gradients, so that in those areas, where the aquifer is confined and self-sealed (Travale, Mt. Amiata, Latera and Bolsena, Fig. 1), reservoirs at $> 200^\circ C$ form at < 1 km depth (Carella et al., 1985).

At the margins of such geothermal fields, a large number of $Ca-SO_4$ thermal springs, generally associated with gas emissions, are found, that may indicate

the widespread convective thermal anomaly. Lotti (1910) interpreted these thermal springs as the result of a low-temperature hydrothermal residual activity related to the final stages of the Apenninic post-orogenic magmatism. Trevisan (1951), Tonani (1957) and Bencini et al. (1977) suggested that the thermal $Ca-SO_4$ character of these waters could imply the exothermic hydration process of anhydrite strata ('Burano formation') which occur at the base of the Mesozoic limestones. Deep drill holes, at both Larderello, Travale and Mt. Amiata (Batini et al., 1995) and in some Pb–Cu–Zn mining areas in southern Tuscany (Vighi, 1958, 1966) indicate the occurrence of gypsum where temperature at depth is $< 150^\circ C$.

More recently, Baldi et al. (1973), Ceccarelli et al. (1987a), Minissale and Duchi (1988) suggested that the central Italy geothermal anomaly is mostly related to a deep circulation of meteoric waters in an area of high regional heat-flow (Calamai et al., 1976b). This circulation occurs primarily in a thick (up to 3.5 km; Buonasorte et al., 1991) sequence of carbonate rocks which also host high salinity geothermal systems. However, interaction between the geothermal fluids and the thermal spring waters may be restricted by self-sealing processes (Facca and Tonani, 1967).

Thermal spring waters discharging in the areas of limestone outcrops in central Italy (Duchi et al., 1985, 1987a,b, 1992; Chiodini et al., 1991; Celati et al., 1991) show the following chemical and isotopic features:

- (1) constant flow rate and chemical and isotopic composition;
- (2) $^{18}O/^{16}O$ and D/H isotopic ratios suggesting a meteoric origin;
- (3) low tritium values suggesting a relatively long residence time underground (> 40 years).

As mentioned before, most of the thermal springs have a Ca-SO₄ composition although a limited number of saline Na-Cl springs are also present. The latter have been interpreted as due to either mixing between Ca-SO₄ thermal waters and descending cold fossil seawater trapped in the Neogene sediments (Francalanci, 1959; Duchi et al., 1992) or to water circulation in the Paleozoic basement (Panichi et al., 1974; Panichi, 1982). The latter, although lying below the Mesozoic limestones, may occur adjacent to the limestones in areas of folded terrains. Since occurrence of saline Na-Cl type fluids is closely related to the geothermal systems in central Italy at Larderello (Panichi et al., 1974), Mt. Amiata (Scandiffio, pers. commun.), Latera (Gianelli and Scandiffio, 1989), Torre Alfina (Buonasorte et al., 1988) and Cesano (Calamai et al., 1976a), leakage of these fluids into the regional Ca-SO₄ aquifer cannot be ruled out.

Continental margins are characterised by high CO₂ emissions (Barnes et al., 1978, 1984) and CO₂ vents are very common in central Italy (Duchi and Minissale, 1995). Their origin has been related to either hydrolysis of limestone in the Mesozoic formations (Kissin and Pakhomov, 1967) or to thermometamorphic processes in the Paleozoic basement (Gianelli, 1985; Duchi et al., 1992). Regardless the origin, rising CO₂ may strongly affect the chemical composition of the aquifers through ion exchange processes as well as calcite and/or gypsum precipitation in response to P_{CO_2} variations (Marini and Chiodini, 1994). The precipitation is likely to occur at the margins of the geothermal fields where thermal conditions may change dramatically in short distances (Cavarretta et al., 1985).

This paper presents some published data and a large set of unpublished (by courtesy of ENEL Italian Electricity Agency) chemical and isotopic data on thermal and cold waters and associated gases obtained in four prospecting campaigns in central Italy (Ceccarelli et al., 1987b, 1988, 1989, 1991), as well as data for deep fluids from the Travale–Mt. Amiata–Latera geothermal areas. The main goals of this study are:

- (1) to assess the origin of waters which supply both the springs and the deep geothermal fluids;
- (2) to assess the origin of the gas components and discuss their interaction with shallow aquifers;

- (3) to evaluate the trace element distribution in waters and their usefulness in the reconstruction of circulation paths;

- (4) to correlate the chemical and isotopic data of thermal waters and gases with recent neotectonic studies;

- (5) to delineate as yet undiscovered areas of high-enthalpy waters.

2. Geological setting of the Travale, Mt. Amiata and Latera geothermal fields

The area under study is morphologically characterised by the Mt. Cetona ridge (1078 m a.s.l.), the Mt. Amiata (1770 m a.s.l.) linear silicic complex (Ferrari et al., 1996), the Bolsena caldera and the Quaternary K-rich and high-*K* volcanics of Vulsini Mts. and Cimini Mts. (Fig. 1). The Mt. Amiata, Vulsini Mts. and Cimini Mts. volcanic products, characterized by high permeability in the lavas and very low permeability in the pyroclastics, are underlain by sedimentary and metamorphic units with the following sequence from the bottom to the top: (1) low-to-medium permeability Paleozoic metamorphic basement; (2) high-permeability Mesozoic limestone formations ('Tuscanids'); (3) low-permeability allochthonous flysch formations ('Ligurids'); and (4) low-permeability Mio-Quaternary continental and marine post-orogenic sediments (Abbate et al., 1970). The Mesozoic limestones are the main reservoir for the production of the geothermal fluids, whereas the overlying tectonic units act as an impermeable cap-rock. This area has also been affected by NW–SE-oriented tensile tectonics which caused the formation of many Neogene basins (e.g. the Siena and Radicofani basins in Fig. 1) whose sediments have been uplifted to 1000 m a.s.l. in the surrounding areas of Mt. Amiata (Sestini, 1932). Gianelli et al. (1988) interpreted this uprising as the result of the emplacement of a large intrusive granite body at a relatively shallow level in the crust (5–6 km).

The Travale geothermal field is situated at 15 km east of the Larderello field (Fig. 1) and electrical power plants producing a total of 90 MW have been installed there. It is a steam-dominated system with maximum temperature of production of 270°C. The

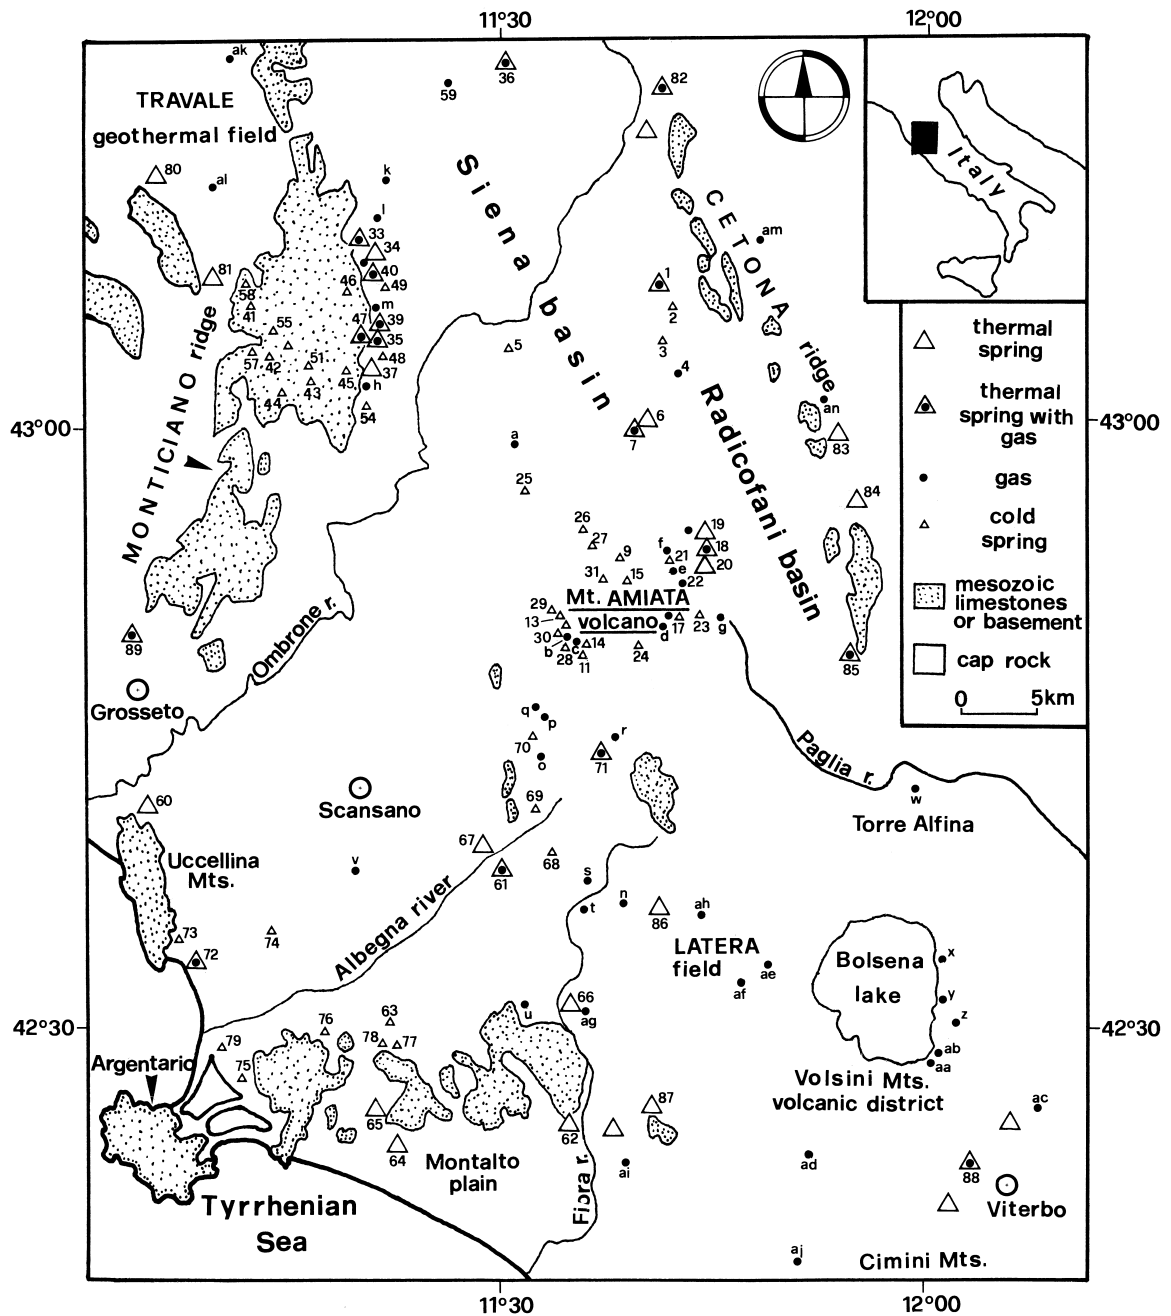

Fig. 1. Sketch map of the study area with locations of the water and gas sampling points. Sites without numbers refer to manifestations not sampled in this study.

geothermal reservoir is located in both the Mesozoic carbonatic horizon and the Paleozoic metamorphic basement at 600–1500 m depth (Barelli et al., 1995).

The Mt. Amiata geothermal area locates at 60 km southeast of Travale. The two Bagnore and Pincastagnano fields produce a two-phase fluid origi-

nating from two separate horizons of production. The shallower is at 500–1000 m depth in the carbonates and produces a 200–230°C fluid whereas the deeper one (> 3000 m) is in the Paleozoic basement where temperature ranges from 300 to 350°C (Calamai et al., 1970; Gianelli et al., 1988).

Moving to the south, the Latera geothermal field produces a few megawatts from a liquid-dominated reservoir (800–1000 m deep) containing Na-Cl water at 200–230°C (Bertrami et al., 1984). Wells at Torre Alfina (600–1000 m deep) have encountered a liquid-dominated system with Na-Cl waters at 150°C (Cataldi and Rendina, 1973; Buonasorte et al., 1988). There, the low reservoir temperatures limit the productive extraction of the geothermal energy.

3. Analytical methods

Seventy-nine water samples (24 thermal, 51 cold and 4 stream waters), 8 samples from the Mt. Amiata geothermal wells and 67 surface gas samples have been analysed for major, trace and isotopic composition. Temperature, electrical conductivity, pH, Eh, Rn concentration and flow rate have been measured in the field. Isotopic composition of oxygen and hydrogen in water and $^{13}\text{C}/^{12}\text{C}$ in CO_2 , $^{15}\text{N}/^{14}\text{N}$ in N_2 , $^{40}\text{Ar}/^{36}\text{Ar}$ and $^3\text{He}/^4\text{He}$ ratios have been measured in selected thermal waters and gases.

In order to determine heavy metals, water samples were treated in the field as follows: (1) filtered with 45 μm filter; (2) acidified with HNO_3 ; and (3) diluted (1:10) for silica determination. Analytical methods are as follows; HCO_3 by titration with HCl ; SiO_2 by colorimetry; Ca, Mg, Sr and Fe by atomic absorption spectrophotometry (AAS); Na, K, Li, Rb and Cs by emission spectrophotometry; Cl, SO_4 , I and Br by ion chromatography; B, As, Sb, Ba, Zn and $\text{Al}_{(\text{tot})}$ by graphite furnace AAS; NH_4 and F by potentiometry.

Gas samples were collected in two pre-evacuated 100 cm^3 bottles, one of which contains 50 ml of 4M NaOH to concentrate the non reactive components (Giggenbach, 1975). CO_2 , N_2 , H_2S and $\text{O}_2 + \text{Ar}$ were determined by gaschromatography using a thermal conductivity detector, while H_2 , CO, CH_4 and C_2H_6 were analyzed with a He ioniser detector. He contents were determined with a Du Pont 120-SSA spectrometer; He/Ne and $^{40}\text{Ar}/^{36}\text{Ar}$ ratios were

measured with a quadrupole Spectralab 200 VG-Micro-mass spectrometer; $^3\text{He}/^4\text{He}$ ratio was measured with a magnetic MAP 215-50 mass spectrometer. Some of the $^{13}\text{C}/^{12}\text{C}$ in CO_2 and all the $^{15}\text{N}/^{14}\text{N}$ isotopic ratios (Minissale et al., 1995) were determined with a Finnigan MAT 251 spectrometer.

4. Chemical composition

4.1. Major elements in waters

Results are listed in Tables 1–5 and the classification of water samples according to the Langelier and Ludwig (1942) diagram is shown in Fig. 2.

Most of thermal spring waters are in the Ca- SO_4 field with the exception of four samples in the Siena basin (#33, #35, #36, #47) and sample #72 located along the Tyrrhenian shoreline that plot in the Na-Cl sector. The saline geothermal fluids from the Latera and Mt. Amiata wells also lie in the Na-Cl sector (Fig. 2). Owing to the low solubility of Ca- SO_4 and Mg co-precipitation in clay minerals at high temperature (Ellis, 1971), these geothermal fluid samples fall along the $(\text{Ca} + \text{Mg}) = 0$ axis, but they have a higher HCO_3 content with respect to seawater (sw).

Although plots of cold water samples scatter all over the Langelier–Ludwig diagram, most of them have a groundwater Ca- HCO_3 composition. Low-pH samples are SO_4 -rich waters, which is likely due to the oxidation of H_2S to SO_4 in subaerial environment, and are indicated as ‘acidic waters’ (Fig. 2). These waters plot along the $\text{HCO}_3 = 0$ axis since at $\text{pH} < 4.3$ the bicarbonate ion is completely transformed into CO_2 . A few cold springs have a Na-Cl composition. They emerge in the outcrop areas of the Neogene formations and are likely related to fossil seawater trapped inside the sediments (Duchi et al., 1992).

Most of the samples could be interpreted as a mixture of the following three endmembers: (1) seawater (or fossil seawater); (2) Ca- HCO_3 groundwater; and (3) Ca- SO_4 thermal water. The so-called ‘ CO_2 -interaction’ lines are others possible evolutionary paths for waters with any original composition because CO_2 is extremely ubiquitous at shallow level in the crust in central Italy (Panichi and Tongiorgi, 1976). High CO_2 concentration causes ionic

Elevation (elev.) in m; flow rate (flow) in l/s; temperature (*t*) in °C; conductivity (cond.) in $\mu\text{S}/\text{cm}$; Total dissolved solids (TDS), Ca, Mg, Na, K, HCO₃, Cl, SO₄, B and SiO₂ in mg/kg. s = spring; sg = spring with associated gas; ts = thermal spring; tsg = thermal spring with associated gas; w = well.

nd = not determined.

^aOriginal data in Minissale and Duchi (1988).

exchange of Ca ions in the solutions with Na (K) ions contained in clay mineral lattice. Since clay minerals are abundant in both the ‘Ligurids’ and the post-orogenic clastic formations, addition of CO₂ may modify the chemical compositions of waters in confined aquifers to a Na-HCO₃ chemical composition (Drever, 1982).

4.2. Trace elements in water samples

Abundances of Cs, Rb, As, I, Sb and Zn, in both cold and thermal spring waters (Tables 3 and 4) are low and below their instrumental detection limits in most of samples. Al_(tot) and Fe have shown high concentration (up to 44 and 390 ppm, respectively) only in the relatively low-pH waters, indicating that their content is mainly controlled by dissolution of country rocks with acid fluids formed through H₂S oxidation.

In contrast, Sr proved to be positively correlated with emerging temperatures of springs (Fig. 3), and plots of Sr against F (Fig. 4) can be used to delineate

Fig. 3. Strontium vs. emergence temperature (°C) diagram. Temperatures for geothermal wells are measured at the bottom.

springs whose waters circulate through the regional Ca-SO₄ aquifer. The high Sr contents are easily explained in thermal springs, because this element intimately associates with Ca and hence is enriched in the Ca-SO₄ samples. Fluorine concentration may be controlled by equilibration with secondary anhydrite and fluorite inside the Mesozoic carbonates

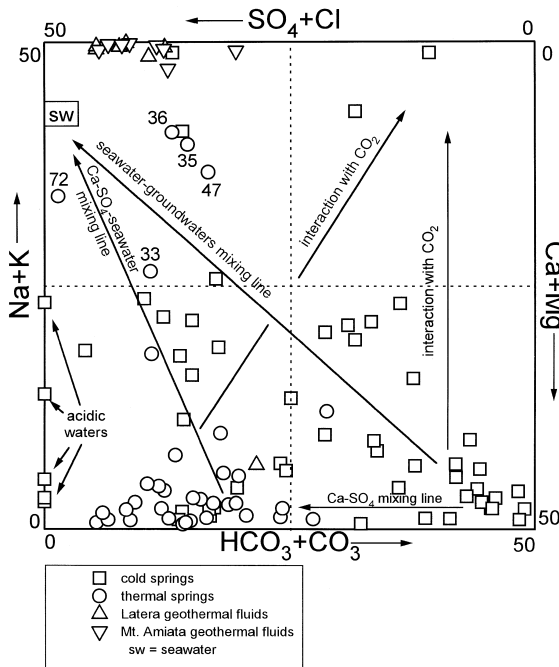

Fig. 2. Langelier and Ludwig (1942) diagram for spring water samples and some geothermal fluids of wells from Latera and Mt. Amiata.

Fig. 4. Strontium vs. F diagram.

Table 3
 Minor, trace and isotopic composition of cold, shallow and stream samples

All elements in mg/kg.

Al(t) = total aluminium; Al(m) = monomeric aluminium.

 $\delta^{18}\text{O}$ and δD in permil vs. SMOW.

nd = not determined.

(Marini et al., 1986). Although circulating in the same geological formations, most geothermal fluids have a lower Sr content (< 7 mg/kg) with respect to the thermal springs (generally > 10 mg/kg, Fig. 3). This is due to the fact that Sr tends to coprecipitate with Ca during gypsum and calcite precipitation at high temperature in response to variations of CO_2 partial pressure (Marini and Chiodini, 1994).

Barium, which crystallochemically behaves like Sr, has a higher content in the cold shallow springs than in the thermal waters and this can be explained with the precipitation of barite inside the Mesozoic formations, due to the large concentration of SO_4 ions in the thermal waters from the dissolution of anhydrite. This agrees well with the saturation indexes calculated for relevant minerals using WATEQ 4F (Ball and Nordstrom, 1991) program, indicating that most of thermal samples are barite saturated. Moreover, dispersed barite ore deposits occur in the Mesozoic limestone in several areas of southern Tuscany (Tanelli, 1983; Ceccarelli et al., 1989).

Bromine is geochemically correlated with Cl and a Br vs. Cl diagram (Fig. 5) can be used to determine if those Cl-rich thermal samples emerging at the boundaries of the carbonate reservoir formation are genetically related to recent unmodified marine

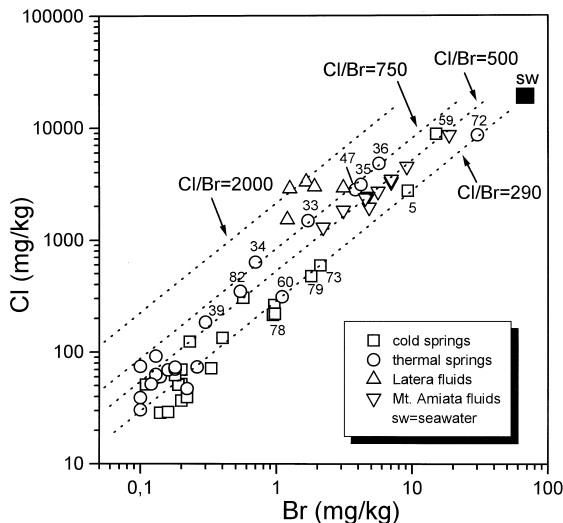

Fig. 5. Bromine vs. Cl diagram. Dilution lines with fresh seawater ($\text{Cl}/\text{Br} = 290$) and springs from the Siena basin ($\text{Cl}/\text{Br} = 750$) and geothermal fluids from Mt. Amiata ($\text{Cl}/\text{Br} = 500$) and Latera ($\text{Cl}/\text{Br} = 2000$) are shown.

Fig. 6. Silica vs. sampling temperature ($^{\circ}\text{C}$) diagram.

($\text{Cl}/\text{Br} = 290$) waters, to modified fossil waters, or to high salinity Cl-rich (magmatic?) fluids. Only sample #72 emerging close to the Tyrrhenian shoreline, a few cold waters close to sample #72 (#73, #78, #79), and sample #5 in the Siena basin have Cl/Br ratio close to that of seawater. In contrast, thermal spring waters #33, #35, #36 and #47 and cold sample #59 (all emerging in the Siena basin, Fig. 1) have the Cl/Br ratio ranging from 500 to 750, suggesting a marine end-member mixed with geothermal fluids. High Cl/Br ratios are measured for the geothermal fluids from deep wells at Mt. Amiata and Latera, having Cl/Br ratios as high as 500 and 2000, respectively (Fig. 5).

The concentration of silica in thermal springs (20–50 mg/kg) and in most cold springs (5–15 mg/kg) suggests that this compound is equilibrated at depth with chalcedony (Fournier, 1973) at temperatures close to those measured at the emergence (Fig. 6). This implies long circulation underground (Duchi et al., 1987a, 1992), that is also confirmed by the absence of radiogenic tritium in these springs (Celati et al., 1991; Battaglia et al., 1992). As observed in other volcanic products, silica content in cold waters circulating within the Mt. Amiata volcanic edifice plot along with the amorphous silica solubility curve (Fournier, 1973), whereas geothermal well waters

Data for Latera and Vulsini are from Gianelli and Scandiffio (1989).

nd = not determined.

from Latera plot along the solubility curve for quartz at bottom hole temperatures.

Ammonium and B have a large variability in both the thermal (0.1–88 and 1–800 mg/kg, respectively) and cold (0.1–46 and 0.1–185 mg/kg, respectively) springs. They are generally correlated with Cl due to the presence of a marine-originated endmember as already observed in other areas of central Italy (Bencini and Duchi, 1986). Ammonium and B show a positive correlation in both the thermal spring waters and geothermal fluids (Fig. 7) suggesting their common origin, and that thermal springs from the Siena basin (#35, #36 and #47) might leak from undiscovered geothermal fluids rich in B and NH_4 .

4.3. Gas compositions

Major and minor components of gases from thermal and cold springs as well as dry vents are reported in Table 6. Carbon dioxide is the main component among the gases in the cold springs and/or dry vents (> 85–90%), while N_2 is generally very abundant (> 50%) in the gas phase associated with the thermal springs (Duchi and Minissale, 1995).

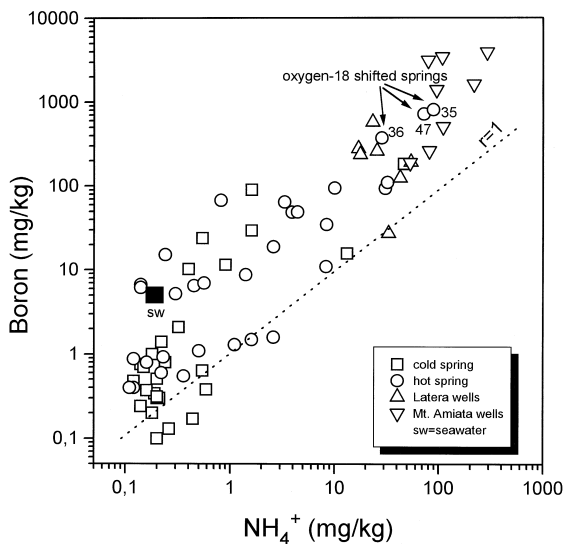

Fig. 7. Boron vs. NH_4^+ diagram. Spring waters emerging in the Siena basin, which have a relevant shift in oxygen-18 (Fig. 9), have similar NH_4 and B concentrations with those of fluids discharging from geothermal wells.

Fig. 8. Hydrogen vs. CO diagram in the sampled gases.

The gases from dry vents, generally emerging from the cap-rock formations, are rich in CH_4 with a maximum of 13% by vol. (sample #h), whereas it is < 2.2% in the gases associated with cold water and generally < 0.6% in the gases associated with the thermal springs emerging at the boundary of the carbonate reservoir rocks. This suggests that CH_4 prevalently forms at shallow level underground above the Mesozoic limestone formations, and/or, if derived from inside or below the reservoir, it solubilizes at a higher $\text{H}_2\text{O}/\text{gas}$ ratio when associated with the regional thermal aquifer.

The maximum H_2S concentration in the gases is 1.2%, but a clear discrimination between those in 'cold' and 'thermal' gases has not been observed. Thus, similar origin of H_2S might be suggested for both the two groups (e.g. alteration of pyrite, sulphate reduction, bacteria activity ..., etc.). However, when considering the high reactivity and solubility of H_2S in shallow aquifers, it is unlikely that the measured concentration at surface would reflect the real H_2S content at depth.

Concentration of H_2 and CO, whose high values are good indicators of high temperature at depth (Tonani, 1973; Giggenbach, 1980; Bertrami et al., 1985), are low in most of gases including the high-temperature samples from Travale, Mt. Amiata and

O₂ + Ar, N₂, CH₄, CO₂, H₂S in % by vol.; H₂, CO, C₂H₆, He in ppm (vol); Rn in Bq/l; δ¹³C and δ¹⁵N in permil.

³He/⁴He as R/R_A (R/R_A = ³He/⁴He(sample)/³He/⁴He(air)).

¹³C/¹²C isotopic ratios in CO₂ from Pamichi and Tongiorgi (1976).

¹⁵N/¹⁴N ratios in N₂ are from Minissale et al. (1995).

³He/⁴He, ⁴⁰Ar/³⁶Ar and He/Ne ratios are from Minissale et al. (1997).

Latera geothermal fields. They show a positive correlation in both thermal and cold gases (Fig. 8). The only samples which plot off the general trend are some of those in the Mt. Amiata area where H_2 is about 200 mg/kg (samples #16, #d, #r; Table 6). Reservoir temperatures of 200–250°C are calculated for these samples with the H_2 – H_2S – CH_4 – CO_2 (D'Amore and Panichi, 1980) and H_2/Ar (Giggenbach, 1991) geothermometers.

5. Stable isotopic composition

5.1. Thermal waters and geothermal well fluids

Measurements of the oxygen and hydrogen isotopic compositions have mainly been made on the $Ca-SO_4$ thermal samples associated with the Mesozoic carbonates. Delta ^{18}O and δD original data and data from the literature are included in Tables 3 and 4 and Fig. 9. Two samples from the Latera geothermal wells (Battaglia et al., 1992) and the #35 and #47 thermal springs located in the western margin of the Siena basin have heavy $\delta^{18}O$ values (-2.11 and -2.98‰ vs. SMOW, respectively). The remaining cold and thermal waters fall between the global meteoric (Craig, 1963) and the Mediterranean (Gatt and Carmi, 1970) meteoric water lines (Fig. 9). If we

Fig. 9. $\delta^{18}O$ vs. δD diagram for some of the thermal and cold springs analysed. Isotopic values from the two Latera geothermal wells are from Battaglia et al. (1992).

Fig. 10. $\delta^{18}O$ vs. emergence altitude for both thermal and cold springs.

consider that all the thermal spring waters related to the Italian geothermal and/or volcanic areas display a meteoric origin (Minissale, 1991a), the two thermal samples from the Siena basin must be considered a good indication of the presence of a high-enthalpy system at depth. On the basis of sample #35, Panichi (1982) hypothesized a boiling reservoir with temperatures between 150 and 200°C underneath the Siena graben, far from any of the already discovered geothermal fields.

In order to verify that waters recharging aquifers are of local meteoric origin, $\delta^{18}O$ isotopic data are plotted against the emergence altitude of springs in Fig. 10. The figure shows that the altitude of recharge areas is, in general, within the mean altitude of mountains in the investigated area (200–1000 m), which morphologically coincide with the main outcrops of the carbonate formations. The more positive $\delta^{18}O$ values coincide with the topographically lower areas close to the Tyrrhenian sea, where the isotopic fractionation of ^{18}O in rain is minimal. Similarly the most fractionated $\delta^{18}O$ values have been measured in springs emerging near the Cetona ridge in the Apennines.

5.2. Isotope composition of gas samples

A detailed survey of the isotopic composition of carbon in the CO_2 gas vents in central-southern Italy was conducted in the early 70's by Panichi and

Tongiorgi (1976). Data from the previous study as well as those of the present study have been used to draw the $\delta^{13}\text{C}$ isoconcentration map in Fig. 11. Two different zones can be recognised: (1) the central-northern part where $\delta^{13}\text{C}$ values range between -4.0 and -7.0‰ (PBD); and (2) the southern part where $\delta^{13}\text{C}$ values are high with maximum of $+1.92\text{‰}$ (sample #ad). The $\delta^{13}\text{C}$ values from the southern part have recently been reinterpreted by Marini and Chiodini (1994) as the result of strong thermometamorphic processes in the Mesozoic formations with typical values of limestones ranging from -1.0 to $+2.0\text{‰}$ (Faure, 1986). In the central-northern part, the $\delta^{13}\text{C}$ values are close to those for primary carbonatitic magmas (about -5.0‰ ; Kyser, 1986) and they have been related to a high contribution of CO_2 from the upper mantle (Marini and Chiodini, 1994; Minissale et al., 1995). This interpretation is supported by the map of the $^3\text{He}/^4\text{He}$ [as $R/R_A = (^3\text{He}/^4\text{He}_{\text{sample}})/(^3\text{He}/^4\text{He}_{\text{air}})$] distribution in Fig. 12, where a slight enrichment of mantle ^3He in CO_2 -rich samples (where $R/R_A > 0.2$; Marty et al., 1992) in most of the study area is evident, with a

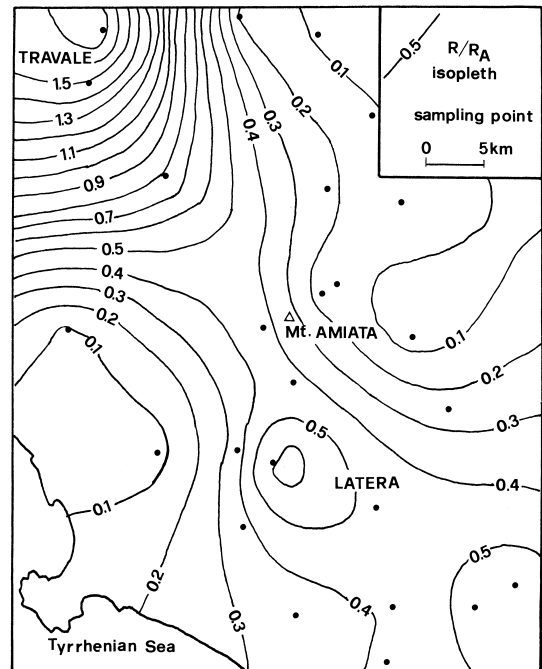

Fig. 12. $^3\text{He}/^4\text{He}$ (as R/R_A) distribution map (same area as in Fig. 1). Two samples in the Travale area show a remarkable contribution of ^3He from the mantle, probably a lateral leakage from the nearby eastern part of the Larderello field (Hooker et al., 1985).

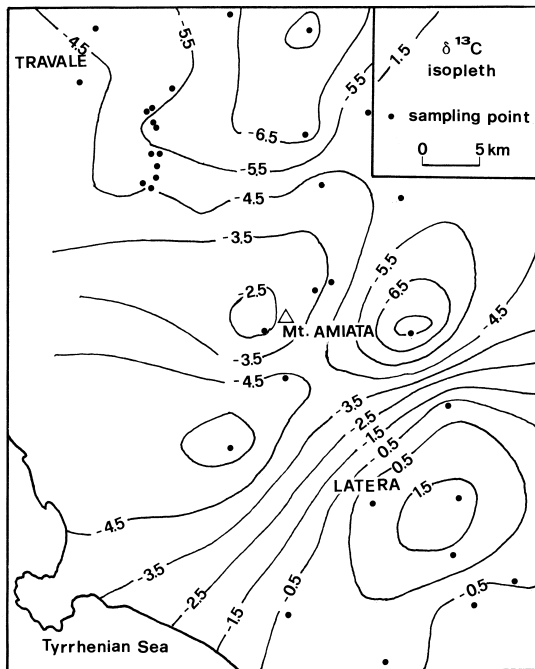

Fig. 11. $\delta^{13}\text{C}$ in CO_2 isoconcentration map (same area as in Fig. 1). See text.

more pronounced enrichment in the Travale field (up to $R/R_A = 1.81$ in sample #ak, Table 7). Similar high values have been interpreted in the nearby Larderello area as due to a 20–30% contribution of He from the mantle to the total He (Hooker et al., 1985).

N_2 -rich ($> 50\%$) samples have a $\delta^{15}\text{N}$ value similar to the air ($\delta^{15}\text{N} = 0$) whereas depleted N_2 samples are strongly enriched in ^{15}N (Table 6). Since such isotopic enrichments are found for samples with $\text{N}_2/(\text{O}_2 + \text{Ar}) > 100$, they are presumably related to contributions of N_2 from the Paleozoic metamorphic basement as reported from other areas of continental margin (Jenden et al., 1988). Generally speaking, occurrence of N_2 indicates a meteoric origin, and N_2 -rich gases are relatively common all over the world (Jenden et al., 1988; Giggenbach et al., 1993). This origin is very likely for the gas phase associated to the thermal springs where the mixing of cold air-saturated rainwaters coming from the reservoir

$t(e)$ = emergence temperature; $t(calc)$ = chalcedony (Fournier, 1973); $t(qtz)$ = quartz (Fournier and Rowe, 1966); $t(K-Mg)$ = K/Mg (Giggenbach et al., 1983); $t(N-K-C)$ = Na–K–Ca (Fournier and Truesdell, 1973); $t(N-L)$ = Na/Li (Fouillac and Michard, 1981); $t(N-L)2$ = Na/Li (Kharaka et al., 1982); $t(N-K)$ = K/Na (Truesdell, 1976; Tonani, 1980; Arnorsson, 1983; Fournier, 1979; Giggenbach et al., 1983; Nieva and Nieva, 1987).

outcrops with thermal waters favours the enrichment in atmospheric nitrogen. Minissale et al. (1995) have pointed that N_2 in central Italy is also generated from the Paleozoic metamorphic formations by the oxidation of NH_4 , which is common both in feldspar and mica (Honma and Itihara, 1981). Thus, two different N_2 source zones can be identified: atmospheric and metamorphic. The $\delta^{15}N$ areal distribution does not show the two different sectors observed for the $\delta^{13}C$ and $^3He/^4He$ data, probably because the high concentration of atmospheric-originated N_2 dilutes possible small contributions of the ^{15}N -enriched deep components.

$^{40}Ar/^{36}Ar$ isotopic ratios are very similar to that of the air ($^{40}Ar/^{36}Ar = 295$). Despite the large variation in the $N_2/(O_2 + Ar)$ ratio, no differences in $^{40}Ar/^{36}Ar$ have been observed for N_2 -rich and N_2 -poor gases. If $^{40}Ar/^{36}Ar$ ratios similar to that of the air are plausible for the N_2 -rich gases, air contamination during sampling may also be invoked for the N_2 -poor gases. Since the Ar content in the air is high (about 0.9%), even a small contamination can mask the actual contribution of radiogenic ^{40}Ar from the

depth if: (1) the residence time of the gas phase underground is short; (2) the concentration of K is low; (3) the rate of water–rock interaction is poor. Moreover, since in central Italy several deep and shallow aquifers occur, a rising gas phase may encounter at least one meteoric-originated aquifer before emerging, and this, similarly to what happen to ^{15}N , would dilute possible radiogenic ^{40}Ar .

6. Discussion

6.1. Relationships among different fluids in the Mesozoic carbonate reservoir

As reported in previous studies, geothermal fields in central Italy produce Na-Cl type fluids with high NH_4 and B contents (Table 5). At Latera, geothermal fluids are produced from fractures in the carbonatic reservoir (Bertrami et al., 1984), whereas those at Mt. Amiata are mainly hosted in the Paleozoic metamorphic basement (Bertini et al., 1995). Salinity and chemical composition at both sites strongly dif-

fer from the mean chemical composition of the springs related to circulation in the same geological formations. As mentioned above, some of the thermal and cold springs (#33, #35, #36, #47), although located far from the discovered geothermal fields, have a Na-Cl composition which may suggest a leakage of the geothermal fluids in their circuits. Thermal spring #72 and a few of the nearby saline cold waters which locate near the coast, lie along the Cl/Br = 290 dilution line of unmodified seawater (Fig. 5). In contrast, thermal waters from the Siena basin fall along the line of Cl/Br = 750 suggesting a different deep saline endmember. Geothermal fluids from Mt. Amiata are along the line of Cl/Br = 500

and differ from those of Latera, since the latter have higher Cl/Br ratios (1000–2000). Setting aside the Latera geothermal samples that are scattered in the diagram, all the other groups have a parallel trend with respect to that of ‘fresh’ seawater in the Cl–Br diagram in Fig. 5. The excess of Cl with respect to the Cl/Br = 290 line can be explained as the result of HCl addition to the solutions after hydrolysis of Na-Cl (Fournier and Thompson, 1993) from brines located in deep portions of the crust characterized by extremely low permeability. Similar HCl enrichments have already been reported for the Larderello geothermal field (Truesdell et al., 1989; Duchi and Minissale, 1993), where residual magmatic brines

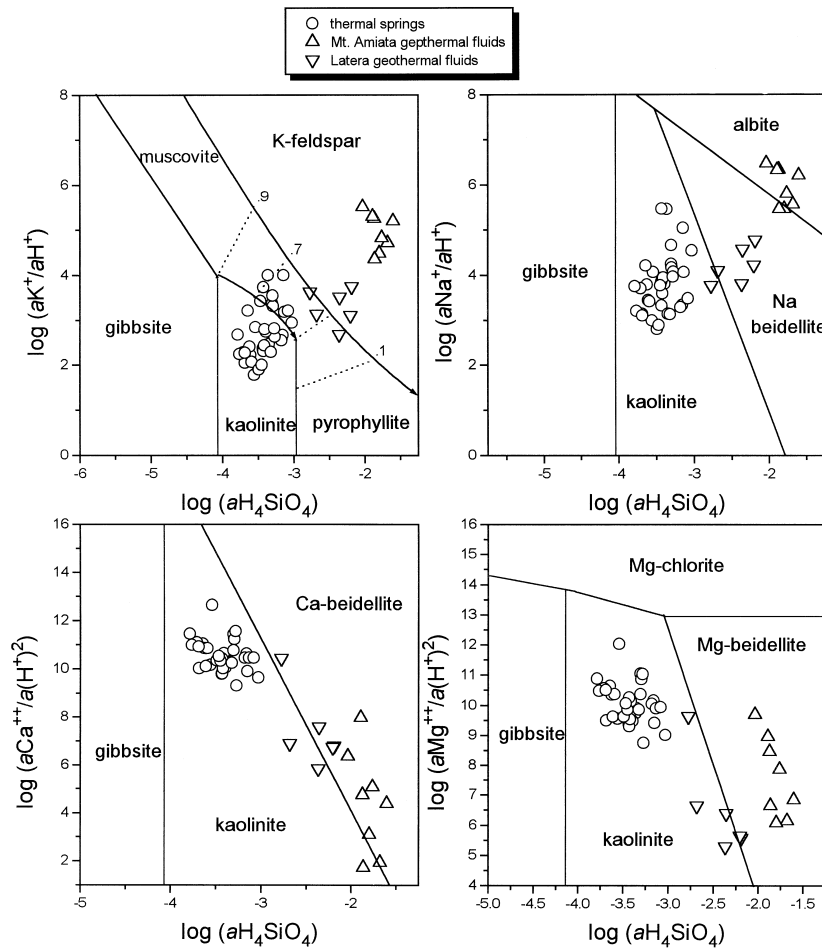

Fig. 13. Activity diagrams for K, Na, Ca, Mg vs. silica on both thermal spring samples and geothermal liquid phases (Nesbitt and Cramer, 1993).

have been suggested to be present under the vapor producing zone (D'Amore and Bolognesi, 1994). Thus, it seems reasonable to hypothesize the presence of residual magmatic brines with high Cl/Br ratio at Latera and Mt. Amiata, and possibly the Siena basin.

The majority of thermal springs are calcite-, aragonite-, dolomite- and quartz-saturated and all these minerals are well represented in veins in the Mesozoic limestone formations (Bertini et al., 1985; Cavarretta et al., 1985). Although these waters have mainly a Ca-SO₄ composition, none of them is anhydrite saturated. This is due to the CO₂ release at their exit, that causes precipitation of travertine subtracting Ca ions from the solution resulting the undersaturation of gypsum or anhydrite.

Those thermal springs where Al_(tot) is > 0.02 mg/kg (i.e. above the instrumental detection limit) are also saturated in several silicate minerals such as kaolinite, illite, smectite, etc. As these minerals are present at very low percentages in the Mesozoic limestone formations, both as primary and hydrothermal minerals, it is possible that they are derived from dissolution of argillitic alteration zones (< 150°C) overlying the reservoir (Cavarretta et al., 1985). In contrast, Gianelli and Scandiffio (1989) have calculated using the EQ3/6 software package (Wolery, 1979) that the geothermal fluids at Latera and the reservoir rock are in a thermodynamic equilibrium with primary feldspars. By plotting values in the activity diagram for the main cations (Na, K, Ca and Mg) vs. SiO₂ (Fig. 13), it is shown that the Mt. Amiata fluids fall effectively in the field of stability of primary minerals (feldspars), while the thermal springs fall in the stability field of kaolinite representing lower temperature supergenic conditions.

6.2. Geothermometry

Temperatures at the top of the carbonate reservoir are relatively well known in the study area (Fig. 14; C.N.R., 1982). Their distribution has been drawn using temperatures measured at the geothermal wells at Travale, Latera and Mt. Amiata and temperatures calculated from shallow holes drilled for thermal gradient prospecting in areas where the carbonate top is known through geophysical surveys. In the reservoir outcropping areas temperatures are those of

Fig. 14. Estimated temperatures (°C) at the top of the Mesozoic carbonate formations (same area as in Fig. 1; redrawn after C.N.R., 1982).

thermal springs (generally < 50°C), whereas in the remaining areas (mainly along the Tyrrhenian coast) they derive from the application of the silica geothermometer to the thermal springs discharging in the area (C.N.R., 1982). Such waters commonly discharge at a high flow rate, thus, it is likely that silica concentrations are not reset during ascent from the reservoir to the land surface and, hence, the silica-based geothermometers provide accurate indications of reservoir temperatures near the top of the carbonate aquifer.

By applying geothermometers to these springs and by considering the hydrogeochemical features of both spring waters, natural gases and geothermal fluids as described so far, some insights can be derived for temperature estimates at depth in those areas affected by the presence of the regional Ca-SO₄ aquifer. Results of geothermometric calculations are reported in Tab. 7. For most samples, two types of temperatures are calculated: (1) a low-temperature (< 100°C) calculated with the chalcedony (Fournier,

1973), quartz (Fournier and Rowe, 1966) and K^2/Mg (Giggenbach et al., 1983) geothermometers; and (2) higher temperature (ranging from 150 to 300°C) calculated with the Na/K, Na–K–Ca (Fournier and Truesdell, 1973) and Na/Li (Fouillac and Michard, 1981; Kharaka et al., 1982) geothermometers. Since thermal water discharge and recharge areas are very close, the springs might locate at the basal level of karstic circulation in a large unconfined aquifer characterized by a deep convective circuit in limestones (Minissale and Duchi, 1988), whose thickness in the area is potentially more than 3 km (Buonasorte et al., 1991). In spite of this, addition of Cl-rich brines to the Ca-SO₄ aquifer is plausible while it is highly likely in the Siena basin. By applying the geothermometric technique proposed by Giggenbach (1986) and reported in the Na–K–Mg ternary diagram in Fig. 15, additions of cations from such brines are partly responsible for the observed trend between the

immature Mg corner and the equilibrium line, the latter being the result of the isochemical re-crystallization of a primary rock into a secondary mineral assemblage (Giggenbach, 1988). Although this is relatively clear for the Siena basin samples, most of the remaining thermal springs are close to the Mg corner, suggesting that their temperatures at depth are < 100°C.

Another estimation of deep reservoir temperatures can be obtained with geothermometers based on the gas composition. Although some gas components may partly solubilize in waters and suffer re-equilibration processes at low temperature, their less reactive components (H₂, CH₄, N₂) are likely to reflect their deep chemical equilibration temperature. Among the many diagrams proposed by Giggenbach (1991, 1993); Giggenbach and Soto, 1992; Giggenbach and Glover, 1992; Giggenbach et al., 1994), we focused our attention to the CH₄/CO₂ vs. CO/CO₂

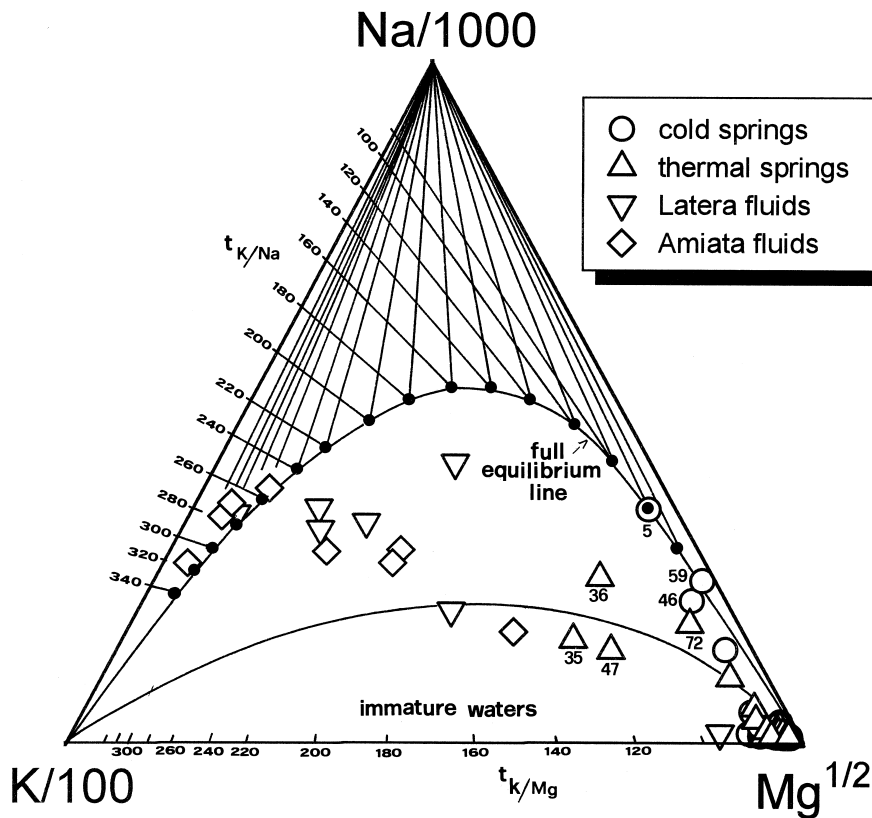

Fig. 15. K/100–Na/1000–Mg^{1/2} ternary diagram (Giggenbach, 1988). See text.

diagram (Fig. 16). This diagram is based on the assumption that the gas phase, equilibrated either in vapor or liquid phases, is constrained by the FeO–FeO_{1.5} pair, which is believed to be the main mineralogical buffer in a relatively wide interval of hydrothermal temperatures (Giggenbach, 1987). Similarly to Fig. 15, where geothermal waters from productive wells in the Mt. Amiata area were close to the full equilibrium line at bottom hole temperatures, geothermal gases in Fig. 16 are in the inner part of the liquid–vapour equilibrium boundaries (two phases) at temperatures comparable with those that occur in the reservoir (250–300°C). On the other hand, most of the natural gases associated with the springs (especially the N₂-rich ‘thermal’ samples), in spite of showing evidence of disequilibrium composition in Fig. 16, indicate high reservoir temperatures. If not referred to deep reservoirs below the carbonate reservoir inside the metamorphic basement (which is likely for those gases emerging at the boundary of limestones), these higher temperatures apply to the confined geothermal zones of the carbonate reservoir, from which the Cl-rich brines leak up into the Ca-SO₄ aquifer.

6.3. Geothermal gradients, hydrogeology and deep circulation

The distribution pattern of deep temperatures in central Italy (CEE, 1988) shows that, in response to an upper-mantle rising at 20–25 km depth (Calcagnile and Panza, 1979) with consequent higher thermal gradients, the isotherms tend to flatten in the upper part of the crust along the peri-tyrrhenian margin. The mean geothermal gradient is about 80–100°C/km leading to temperatures of 250–400°C at 3–4 km depth in those areas where the limestones are relatively thin and not affected by the circulation of meteoric waters. These deep temperatures agree well with those directly observed in the geothermal fields, even where the very shallow thermal gradient is as high as 500°C/km (Larderello, Cataldi et al., 1963). In contrast low gradients (up to 40°C/km) have been measured in those areas where thick Mesozoic limestone formations occur (e.g. Torre Alfina; Buonasorte et al., 1991). The lower gradients can be explained by different Moho depth, however, the contrast in the thickness of Mesozoic limestones

Fig. 16. Log(CH₄/CO₂) vs. log(CO/CO₂) diagram (Giggenbach, 1991). See text.

suggests that the permeability of the limestone is high and cold meteoric water circulation occur in the formation, causing a decrease in the geothermal gradient locally, and dilution of both the deep-seated waters and gases.

Confined thermal Cl-rich brines possibly leaking from the geothermal reservoirs may mix with the Ca-SO₄ waters while the associated gas components, especially the more soluble (CO₂, H₂S), may be absorbed in these waters in the carbonate aquifer. Other possible processes related to this mixing are:

- (1) mobilization and re-deposition of sulphides (Tuscany Metallogenic Province, Tanelli, 1983);
- (2) alteration of primary silicates and re-deposition in hydrothermal veins (Cavarretta et al., 1982, 1985);
- (3) dissolution and/or deposition of anhydrite and/or calcite at the boundaries of the geothermal systems (Marini and Chiodini, 1994);
- (4) modification of the water chemistry to HCO₃–SO₄ chemical compositions through the dissolution of CO₂ and H₂S which are likely components in geothermal fluids;
- (5) changing the composition of gases associated to the springs, from CO₂-rich to N₂-rich, as a function of the meteoric water/deep fluid ratio.

Since these processes are enhanced in areas of large thermal gradients and large permeability, they

are most developed both at the top of the convective circuits at the boundaries of the low-permeability flysch formations and at the bottom of the convective cells which usually coincides with the base of the Mesozoic limestones. In the Paleozoic basement and the lateral margins of the carbonate outcrops close to the geothermal systems, the hydrologic and thermodynamic conditions may change dramatically over short distances, leading to self-sealed low pressure zones typically described for the Larderello–Travale geothermal fields (Facca and Tonani, 1967; Minissale, 1991b). These zones, generally not directly connected with the overlying unconfined aquifer(s), may be underlain by deeper high-enthalpy reservoirs in the Paleozoic metamorphic basement. Such deep reservoirs are found in both the Mt. Amiata (Bertini et al., 1995) and Travale (Barelli et al., 1995) fields, where fluids with different temperature are produced from the main carbonate reservoir at 200–250°C and the basement at temperature ranging from 300 to 350°C.

Geodynamic implications are suggested by the regional $^3\text{He}/^4\text{He}$ isotopic distribution in the gas manifestations (Fig. 12). Central Italy has generally been considered to be in an extensional phase, which would favor the intrusion of crustal and subcrustal magmas as in the Mt. Amiata and Mts. Vulsini volcanic areas (Conticelli and Peccerillo, 1992). However, recent tectonic interpretations of the post-orogenic structures imply that the Northern Apennines might be in a compressive phase, where basins are not the result of structures crossing the crust, but formed by folding and thrusting in a compressive tectonic regime in shallow environment ('piggy-back or pearced type basins'; Boccaletti et al., 1995). The $^3\text{He}/^4\text{He}$ isotopic ratios in the sampled gases reported as R/R_A areal distribution in Fig. 12 suggest significant gas contributions from the mantle only at Travale, which is not far from the already reported ^3He -anomaly area of the Larderello field (Hooker et al., 1985). In the remaining areas, especially in the Siena–Radicondoli basin, the $^3\text{He}/^4\text{He}$ ratio is low, indicating little mantle contribution to the area and/or high production of radiogenic ^4He in the shallow crust, which is consistent with the recent hypothesis suggested by Boccaletti et al. (1995). Since the volcanic activity at Mt. Amiata and Mts. Vulsini is quite recent (< 0.2 Ma; Fornaseri,

1985), the occurrence of the described large thermal anomalies in the study area would have to be considered a residual phase of a regional mantle activity preceding the present compressive regime.

7. Summary and conclusions

The flow systems for both thermal and cold springs in a large sector of central Italy are fed by waters of meteoric origin. Although contributions into the carbonate reservoir of saline waters driven down from aquifers in the Neogene series and/or residual Cl-rich magmatic brines leaking from confined self-sealed geothermal systems are very likely in the Mt. Amiata, Siena basin and Latera, respectively, the regional aquifer maintains a general CaSO_4 character all over the area. This is due to the large convective circulation of meteoric-originated waters in high permeable limestones that buffers the input of fluids of different composition. The convective circulation in the limestone dramatically lowers the thermal gradient where the limestones are tectonically thickened as happens at Torre Alfina, where temperatures < 200°C are measured at 4.5 km depth (Buonasorte et al., 1991).

The behavior of the gas phase is, in some ways, similar to that of thermal waters. The huge amount of CO_2 produced and/or accumulated inside the confined geothermal fields in the carbonates and the basement rises and dissolves in the colder upper parts of the regional aquifer in those zones where it is unconfined. In those areas where the gas flow is higher, or the permeability of the carbonates is reduced (high gas/water ratio), the chemical composition of the gas phase may be only slightly modified by contamination of N_2 driven down in the reservoir by rainwater. By contrast, the higher the amount of the meteoric gas component involved near the recharge areas, the higher the N_2 content. As a consequence, the gas composition present at depth is not always the same as at the surface.

Reservoir temperature estimates based on geothermometric calculations for thermal springs and gases can be considered unreliable in the absence of drill hole measurements or knowledge of the process that affects the chemistry of the surficial features. The application of fast re-equilibrating geothermometers

(such as SiO₂) to the springs discharging in the Mt. Amiata, Latera and Travale areas would have not suggested the presence of the geothermal systems, but only revealed the convective circulation in the unconfined upper parts of the carbonate reservoir. Nevertheless, it can reasonably be hypothesized that the $\delta^{18}\text{O}$ shift observed in the two Na-Cl type thermal waters from the Siena basin (samples #35 and #47) and the high H₂ content in the gas sample from Selvena (sample #r) situated at about 10–15 km southwest of Mt. Amiata, derive from two thermally anomalous areas not yet discovered by drilling.

³He/⁴He isotopic ratios from the 26 gas samples investigated (excluding Travale) suggest little contribution of ³He from upper mantle. This is not consistent with the occurrence of the Neogene post-orogenic basins and the Quaternary primary undersaturated magmas at Mts. Vulsini, where large ³He degassing from active mantle-related structures would be expected. Thus, the existing thermal anomalies in the Mt. Amiata–Vulsini region would have to be related to preceding Pliocene tensive phases.

Acknowledgements

Many thanks are due to ENEL (Italian Electric Agency) for giving us access to a large set of water and gas geochemical data. E. Corazza, M. Pennisi, S. Pieri, U. Rossi and M. Valenti have contributed to the sampling campaigns and the laboratory analyses. Special thanks to G. Scandiffio, A. Ceccarelli and A. Ridolfi (ENEL, Pisa, Italy) for their useful suggestions in the early draft versions of the manuscript. The text greatly improved in clarity after the critical review of M. Sorey and H. Shinohara, who are warmly thanked.
